## Foreword

The fact that this welcome third edition of *New Generation Vaccines* comes so hard on the heels of the second edition is just one sign of the great vigor and momentum of vaccinology, now universally acknowledged as a discipline in its own right. During the first golden age of immunology, the era of Louis Pasteur, Robert Koch, Emil von Behring, and Paul Ehrlich, the nexus between medical microbiology and immunology was very close: vaccines were the practical goal of nearly all investigations of the immune system. But before the end of the 19th century, Ehrlich was to show that one could produce antibodies to the plant toxin ricin, derived from the castor bean, and Bordet discovered antibodies to red blood cells. The observation that nonmicrobial materials could act as antigens was vastly extended by Landsteiner, who showed that specific antibodies could be made against small organic chemicals that had never before existed in nature. Suddenly immunology had burst out of the confines of medical microbiology. Scientists became fascinated with the puzzle of antibody diversity—how one animal could make such a vast array of different antibodies—and the medical side of the discipline soon encountered clinical problems such as autoimmunity, allergy, transplant rejection, and even cancer control. During the second golden age of immunology, around 1955–1975, when nature's broad strategy was revealed, the divorce between immunology and vaccinology was almost complete.

Several forces fostered a remarriage. HIV/AIDS clearly demanded new thinking for an effective vaccine. Also, from the mid-'70s on, the efforts of the World Health Organization and of private foundations such as the Rockefeller Foundation, the Wellcome Trust, and the MacArthur Foundation tempted more academics into vaccinology by a combination of persuasion (publicizing the parlous state of research into vaccines chiefly of interest to developing nations) and substantial grants. Gene cloning was a major catalyst, as in so many other fields, and soon candidate antigens aplenty were produced by recombinant DNA technology. This in turn showed most subunit vaccines to be only weakly immunogenic, and immunologists interested in immune regulation entered the fray, exploring both the nature of adjuvanticity and the possible role of cytokines in enhancing and guiding responses to vaccines. As a result, this third edition carries many contributions from card-carrying immunologists. At the same time, the editors have realized that scientific breakthroughs alone cannot lead to the protection of the 130 million infants born each year worldwide. Therefore, economic, logistic, regulatory, financial, ethical, and political aspects of global vaccinology are also addressed.

The volume begins with a brief historical perspective and then introduces the many high technologies involved in the creation of the new generation of vaccines. These include not only the most advanced platform technologies of the biotechnology revolution but also the equally elaborate methods of assessment: toxicological studies, phased clinical trials, preliminary and definitive evaluation of efficacy, cataloguing of adverse events, and measurement of eventual impact. Some of the major international programs supporting more widespread use of vaccines are also described and the central, not sufficiently appreciated, role of regulatory authorities is outlined.

Eradication of smallpox was a true public health triumph and global eradication of wild poliomyelitis virus is within sight as a fitting encore. It is therefore particularly valuable and timely to get an “insider’s” view of the status of the global polio eradication initiative.

The way that basic immunology can impinge on vaccinology is explored next. Then, a very important series of chapters examines the once arcane but now increasingly scientific field of adjuvants, construing that term in the widest sense to include not only physicochemical immunopotentiation but also novel delivery systems. A special category of the latter is described in depth, namely, live viruses or bacteria as vectors for genetic vaccine constructs, a field that appears promising for the very difficult vaccines such as for HIV/AIDS and malaria. The surprising delivery potential of the mucosal and transcutaneous routes is also reviewed. DNA vaccines and “prime-boost” strategies receive chapters of their own.

Following these chapters, which deal with generic issues, we come to a series of sections dealing with specific diseases. These are grouped in a logical progression. A first set of chapters looks at diseases for which licensed vaccines are in place, exploring issues such as impact, future potential, and, where appropriate, reasons for the need for further improvements, citing relevant examples.

Next come chapters concerning diseases for which licensed vaccines do not yet exist, or, in the case of rotavirus, for which a licensed vaccine was withdrawn. This extraordinary series of examples shows how far the subject has come, even since the second edition. Nevertheless, the chapters do not attempt to hide what a distance there is still to travel. At the same time, it is hard to contain a sense of excitement when contemplating the long-range potential here. Should the next 10 to 20 years prove as successful as they appear from our present perspective, increased attention will have to be given to combinations and alternative delivery systems lest our babies become pincushions! Equally, serious thought will have to be given to financing, even in the industrialized countries. Currently, vaccines account for 2–3% of the sales of the pharmaceutical industry, and public health taken as an ensemble for about 5% of all health expenditures. Surely both figures will have to rise substantially if the full promise of vaccinology is to be realized.

Peering a little further into the future, it is not unreasonable to suggest that vaccines will extend their power into areas of medicine beyond communicable diseases, and multiple chapters explore this issue. Anticancer vaccines have been the subject of research for several decades, although the most clear-cut success area is that of vaccines against infections that can cause cancer. The next probable “cab off the rank” here—a vaccine against human papilloma virus for the prevention of cervical cancer—bids fair to become as important as the prototype, namely, the hepatitis B vaccine. Vaccines against autoimmune diseases, atherosclerosis, Alzheimer’s disease, and drug addiction are more speculative, but the relevant chapters make fascinating reading.

It is saddening to record that vaccines against agents of bioterrorism now constitute a new, but obligate, area of study and concern. It is reassuring to note that the very large budget that has been made available in the United States for such research will also benefit vaccinology more broadly as the National Institutes of Health is looking for bright ideas as well as developmental research.

Can a work be monumental on the one hand and accessible on the other? Can it be both theoretically satisfying and practically useful? Can it contribute meaningfully to the described remarriage of immunology and infectious disease science? The answer is that it can if the editors have an Olympian overview of the field and the authors chosen are authoritative and committed experts in their specialty. This comprehensive third edition of *New Generation Vaccines* is a rare triumph, a vindication of the dedication of all concerned, a “must have” acquisition for any library, institutional or personal, purporting to be serious about supporting vaccine science.

We are living in exciting times in global vaccinology. The Global Alliance for Vaccines and Immunization is spearheading a new global thrust. Individual countries (or groupings like the European Union) are investing more heavily than ever before in research. Vaccine manufacturers in both industrialized and developing countries are raising their game as far as Third World diseases are concerned. Very new initiatives such as the Global Fund to fight HIV/AIDS, tuberculosis, and malaria constitute potential sources for the mass-purchase of vaccines, should effective ones become available. A multitude of public sector-private sector partnerships are springing up as if a post-September 11, 2001, world is at last recognizing that the gross global inequities must be addressed, and that health is not a bad place to begin. As the 21st century unfolds, *New Generation Vaccines* will be a precious guide to many seeking to create a better world.

## Preface to the Third Edition

In the intervening years since the publication of the second edition of *New Generation Vaccines*, extraordinary advances have occurred in the field of vaccines and immunization. These encompass not only breakthroughs in research and development but also advances in assuring vaccine safety, standardizing the way clinical trials are performed (and how data are monitored and validated), manufacture of vaccines, and the public health use of vaccines. The third edition of *New Generation Vaccines* highlights these and many other relevant changes in the field of vaccinology and puts them in a historical perspective.

At the time of publication of the last edition, clinical trials with DNA vaccines were just beginning and there was great expectation that this technology might revolutionize vaccinology. The results of these clinical trials, now available, reveal that DNA vaccines used alone do not meet expectations. On the other hand, fundamental improvements in DNA vaccines and the advent of “heterologous prime-boost” strategies have rekindled interest in their use in focused ways. DNA vaccines appear able to prime subjects so that they can respond to the same antigens when presented in another formulation as a boosting regimen, for example, by means of a viral live vector.

Since the last edition, the Bill and Melinda Gates Foundation has completely revolutionized the funding of research and development and the performance of clinical trials of candidate vaccines against neglected diseases, such as malaria, AIDS, tuberculosis, leishmaniasis, Dengue fever, Group A *Neisseria meningitidis*, and shigellosis.

Another seminal event since the publication of the second edition has been the formation of the Global Alliance for Vaccines and Immunization (GAVI) and its financial instrument, the Vaccine Fund. Working in unison through GAVI, major global partners in immunization (e.g., the World Health Organization, UNICEF, the World Bank, the Gates Foundation, etc.) are raising immunization coverage and introducing new vaccines to infants residing in the world’s 74 poorest countries. A chapter in this edition describes GAVI and the Vaccine Fund, including their research objectives.

Since the last edition, two new conjugate vaccines have been licensed, including a seven-valent pneumococcal conjugate that is now used widely in the United States and a Group C meningococcal conjugate that is used extensively in the United Kingdom. Programmatic use of these vaccines has had a profound impact in diminishing the respective disease burdens.

Since the last edition was published, a major dichotomy has appeared between the industrialized world and developing countries with respect to the vaccines administered to infants and children, their site of manufacture, the formulations and combinations of vaccine antigens, and immunization schedules. A vibrant vaccine industry is emerging in developing countries (e.g., India, Indonesia, Brazil, Cuba) that now supplies most of the vaccine utilized in developing countries; these vaccines are becoming increasingly distinct from those used in industrialized countries. Vaccine safety is increasingly becoming a focus of public concern in industrialized countries, where many pediatric infectious diseases (e.g., diphtheria, measles, pertussis) have largely disappeared and populations do not feel threatened by these infections. In industrialized countries, the switch from live oral polio vaccine to inactivated polio vaccine, the introduction of less reactogenic acellular pertussis vaccine, the discontinuation of use of thimerosal as a preservative in multidose vials, and the withdrawal of a live rotavirus vaccine after it was incriminated as a rare cause of intussusception within one week following immunization of infants are all examples of this trend as regulatory and public health actions are taken to enhance vaccine safety. These topics are all covered in a series of chapters on regulatory issues and vaccine safety. In contrast, in developing countries where infections such as measles, pertussis, and diphtheria still pose notable risks of severe disease and death, and financial resources are constrained, the emphasis is to achieve the highest coverage possible with the most potent vaccines, even at the cost of some reactogenicity.

Another trend in industrialized countries is the search for vaccines to prevent or treat (“vaccine therapy”) various chronic infections that afflict these populations and create an enormous economic burden. Accordingly, chapters that describe strategies

to develop vaccines against Alzheimer's disease, rheumatoid arthritis, insulin-dependent diabetes, multiple sclerosis, and various forms of cancer are included in this edition.

The science of immunology continues to blaze new trails for vaccinology, and multiple chapters in this edition review this work. Practical ways of immunizing without the use of needles are also covered, including mucosal immunization, transcutaneous immunization, and the use of needle-free injection devices.

The tragedy of September 11, 2001, when terrorists hijacked airliners and flew them into the World Trade Center towers in New York City resulting in thousands of deaths, and the bioterrorist dissemination of anthrax spores through the postal system that followed shortly thereafter and resulted in two dozen cases and six deaths (and in major disruption of civil society) had a perceptible impact on vaccinology. Following these events, governments in the United States and many other countries encouraged the development of new or improved vaccines against several potential bioterror agents and diverted resources toward that end. Chapters covering this subject are also found in this edition.

The pace and extent of modern vaccine development make it impossible to include within a single volume all the notable research advances on all vaccines. Accordingly, as before, there are gaps. For example, progress on the development of vaccines to prevent *Pseudomonas aeruginosa* pulmonary disease in cystic fibrosis patients is omitted, as are updates on progress in administering attenuated measles vaccine by aerosol and the development of new measles vaccines that aim to immunize infants in the developing world who are too young to get the current parenteral vaccine.

Assembling the third edition of *New Generation Vaccines* has been a formidable undertaking that required input and help from many individuals. We heartily thank all the authors who contributed the diverse chapters that comprise the fundamental strength of the volume. We also express our indebtedness to Sandra Beberman and Barbara Mathieu of Marcel Dekker, Inc., who provided invaluable assistance and guidance. Special thanks and appreciation go to our families and friends who gave encouragement and showed patience during the many evening and weekend hours consumed in the preparation and editing of the book. Finally, this volume could not have been completed without the organizational prowess, fastidious attention to detail, tenacity, technical competence, and diplomatic skills of Mrs. Dottie Small, Assistant to Myron M. Levine.

## Preface to the Second Edition

The second edition of *New Generation Vaccines* appears at a propitious time, two centuries after Edward Jenner initiated the dawn of vaccination in 1796 by demonstrating that inoculation with material from cowpox lesions induced protection against smallpox. Indeed, as the 20th century comes to an end, vaccines are now recognized as among the most cost-effective preventive measures available in modern medicine's armamentarium. With aggressive use of vaccines, smallpox has been eradicated globally, poliomyelitis regionally, and measles has been brought under control worldwide. Moreover, the tools of modern biotechnology make it within the realm of possibility to prepare candidate vaccines against almost any infectious disease, as long as sufficient resources are committed. In this second edition, we acknowledge the arrival of vaccinology as a discipline that has come of age.

A global picture of public health interventions with vaccines is depicted in two chapters in this second edition, one documenting the triumphs of the Expanded Programme on Immunization and the other describing international disease eradication and disease control efforts. In other chapters, the painstaking stepwise process by which candidate vaccines move progressively from Phase 1 and 2 clinical trials to Phase 3 and 4 trials is discussed.

We have attempted to provide reviews of the fundamental advances in immunology and biotechnology that constitute the underpinnings to vaccine development. Many chapters offer illustrative examples of vaccine candidates representing the application of state-of-the-art biotechnology. However, it is also clear that technologies gain and lose popularity, with some succeeding and others disappearing. For instance, notably absent are examples based on the use of antidiotypic antibodies, and there are few examples of synthetic peptide vaccines, indicating how enthusiasm for these technologies has dissipated since the first edition. In contrast, live-vector vaccine technology has matured, and therefore considerable attention is paid to the use of vaccinia and attenuated *Salmonella* live vectors. Multiple examples of antigen delivery systems such as poly(lactide)/poly(glycolide) microspheres, liposomes, cochleates, and viruslike particles are contained in this edition. A very popular new technology, "DNA vaccines," did not exist in 1990, when the first edition was published; this revolutionary approach has gained extraordinary momentum in the time between the planning of this edition and its publication. Results of clinical trials being carried out with DNA vaccines in the late 1990s should indicate whether this approach will flourish.

In many chapters, considerable attention is paid to mucosal immunization, not only to achieve SIgA responses to protect mucosal surfaces but as a way of eliciting serum antibodies and cell-mediated immune responses. An ultimate form of mucosal immunization might be with "edible vaccines," as explained in the chapter that describes the engineering of transgenic plants expressing vaccine antigens.

With contributions from leaders in their respective fields, we have tried to provide many examples of improved vaccines for diseases against which licensed vaccines already exist and of new vaccines against diseases that were previously unassailable by immunoprophylaxis. Unfortunately, it was impossible to be completely inclusive. Examples of specific material not covered in this edition include the excellent recent progress made by teams in Vienna, Boston, and Berne working on vaccines against *Pseudomonas aeruginosa*, and update on maternal immunization, and progress in vaccines against leprosy, cytomegalovirus, and group B streptococcal infections.

Several new vaccines have become licensed in many countries since the first edition. *Haemophilus influenzae* type b conjugate vaccines, for example, have had an extraordinary impact in industrialized countries where they have been used in a programmatic way. These vaccines have been found to interfere with respiratory tract colonization by *H. influenzae* type b. As a consequence, there has been an interruption of transmission, and a herd immunity effect has been observed. Vaccines against hepatitis A, varicella, typhoid fever (Ty21a and Vi polysaccharide), cholera (CVD 103-HgR live vaccine and B subunit-killed whole-cell combination vaccine) and Japanese B encephalitis, and acellular pertussis vaccines have been licensed in various

countries since the first edition. The development of vaccines against several infectious diseases of importance solely (or mainly) in developing countries, such as malaria, has been lagging, compared to the extraordinary progress made in vaccines considered to be priorities for the industrialized countries (e.g., *H. Influenzae* type b conjugates and acellular pertussis vaccines). Moreover, where new vaccines against infections important in developing countries have become licensed (e.g., Ty21a, Vi polysaccharide, and the live and nonliving oral cholera vaccines), they have not been introduced for routine use; rather, these are largely vaccines used by travelers from industrialized countries who visit developing countries. Finding ways to help developing countries introduce programmatic use of new vaccines poses a challenge that must be addressed by the vaccinology and public health communities.

Even as the technology for vaccine development has burgeoned and clinical vaccine testing has become more sophisticated, so have public perceptions and the views of regulatory agencies changed with time. For this reason, chapters on regulatory issues have been included to further broaden the perspective of the book.

The editors would like to thank the many contributors who have provided outstanding chapters for this edition. Special thanks go to family and friends whose support and patience sustained us during the many evening and weekend hours required to plan and edit this edition. This book could not have been completed without the competent assistance of Dottie Small and Brenda Lown at the Center for Vaccine Development and Henry Boehm at Marcel Dekker, Inc.

### I. INTRODUCTION

The history of immunization, from the earliest attempts to modern, genetically engineered vaccine candidates, represents a long road marked with many milestones. Extensive historical reviews document many of the cardinal achievements [1–4]; however, it is not the purpose of this chapter to recapitulate these events in any depth. Rather, a few of the most pivotal milestones will be mentioned briefly, such as variolation, Jenner's experiments of inoculating subjects with cowpox to prevent smallpox, and the earliest live and inactivated bacterial and viral vaccines and toxoids. This chapter will emphasize the historical accounts of several aspects of vaccinology that heretofore have not generally been well described. These include some early attempts at eliciting local immunity via oral vaccines, attempts over the centuries at grappling with the problem of how to assess the safety and efficacy of candidate vaccines before their widespread use, and the evolution of controlled field trial methodology.

### II. THE DAWN OF IMMUNOPROPHYLAXIS

The first attempts to prevent an infectious disease via immunoprophylaxis involved the process of “variolation,” wherein the contents of smallpox vesicles, pustules, or scabs were used to inoculate individuals who had not previously experienced the disease [4]. Records of this procedure date back to about 1000 A.D. in China [4]. Scabs from mildly affected smallpox patients were stored for approximately 1 month (longer in winter), ground up in a ratio of 4:1 with the plant *Uvularia grandiflora*, and then inoculated intranasally. A slight fever was expected 6 days thereafter, which rose markedly on the seventh day, to be followed by the onset of the rash on the ninth or tenth days following inoculation. Fatalities were reportedly uncommon in comparison with

victims of natural smallpox infection. It was stated that [4] “Not one in 10, not one in 100 does not recover.”

Parenteral variolation was practiced in the Indian subcontinent, southwest Asia, and North Africa in the sixteenth and seventeenth centuries. Reports of variolation reached England as early as 1698–1700, through the letters of Joseph Lister, an Englishman working in China with the East India Company [5]. Over the next 15 years, further reports came from many sources. Many references credit Lady Mary Wortley Montagu with having “introduced” the practice of variolation into Great Britain in 1721. Lady Mary herself suffered from smallpox in 1715, leaving her pockmarked. While living in Constantinople as the wife of the British ambassador, she became aware of variolation as it was practiced every autumn by skilled Turkish women. In 1717, Lady Montagu had her 6-year-old son inoculated with smallpox under the supervision of Charles Maitland, the surgeon to the British Embassy [5,6].

Lady Montagu wrote to a friend in England, Sarah Chiswell, extolling the practice of variolation and vowed to make the procedure fashionable in England upon her return. In 1721, 3 years after she returned to England, an epidemic of smallpox raged in London. Lady Mary contacted Maitland, who was also in Great Britain at that time, and convinced him to variolate her 3-year-old daughter. Maitland agreed, but demanded that there be two witnesses, one of whom was Dr. James Keith [6]. Keith was so impressed with the outcome that he had his 6-year-old son variolated. Because these first inoculations were carried out in the face of considerable attention by the College of Physicians as well as the Royal Court, Lady Mary, whose insistence led to the first inoculation, has been widely credited with having introduced the practice into Great Britain. However, Miller [6] argues that Lady Mary's contribution to variolation becoming an accepted and widespread practice in England was, in fact, quite minimal and that the real driving force for the

introduction of variolation into the British Isles was Hans Sloane, physician to the king of England and president of the Royal Society.

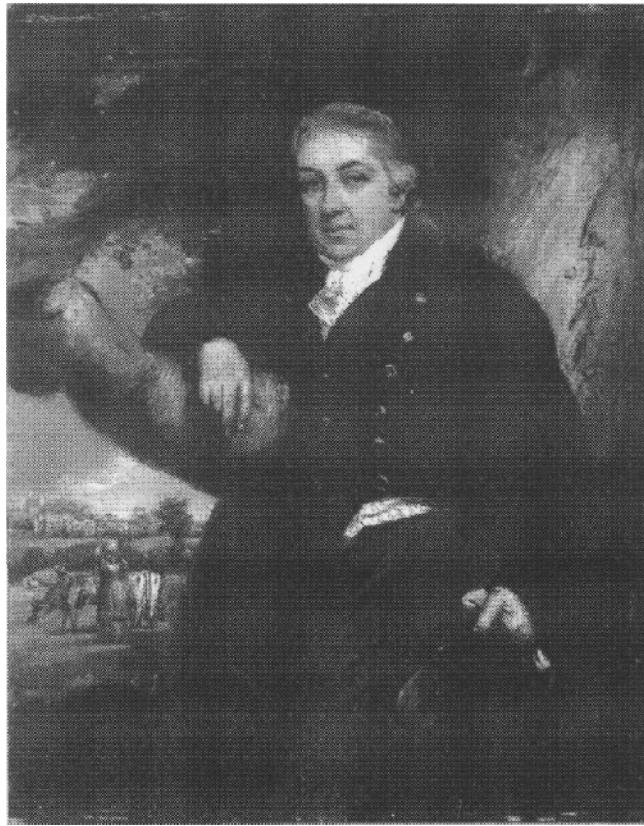

### III. THE ORIGIN OF VACCINATION

During the last decades of the eighteenth century, smallpox was rampant in Europe, despite the increasing use of variolation as a preventive measure. Among rural folk during this period, it was increasingly appreciated that milkmaids were selectively spared the ravages of smallpox and that this was somehow related to the mild pox infection they often acquired from the cows they milked [2,4]. Although several scholars and physicians in the period 1765–1791 acknowledged this association and some, like Benjamin Justy, even inoculated family members with cowpox [2], appropriate credit must be given to Edward Jenner for his pioneering achievements (Fig. 1). In 1796, he undertook to rigorously test the putative protective effect of a prior cowpox infection against smallpox by actively immunizing an 8-year-old boy with cowpox, and later challenging the child with smallpox (i.e., by variolation). Other vaccinations of additional children, followed by challenge, were carried out thereafter.

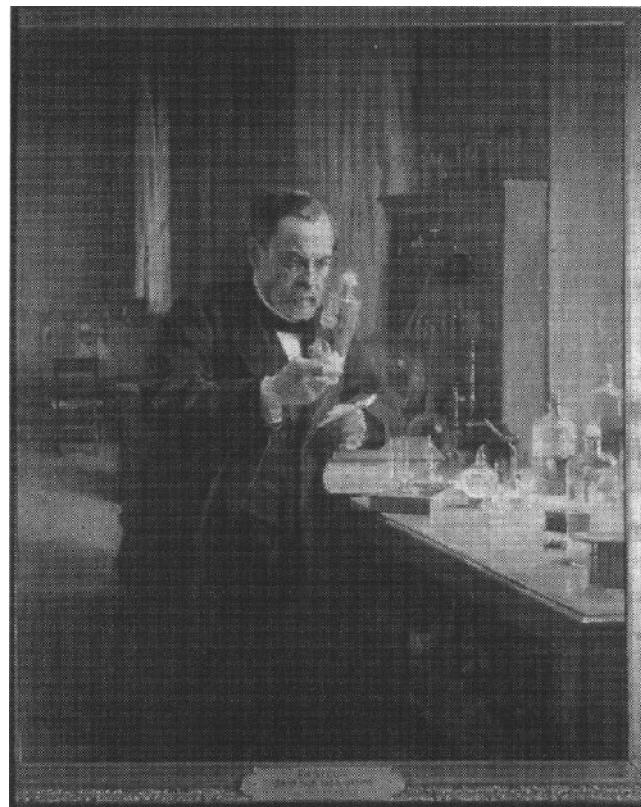

Jenner had the foresight and perseverance to publish his results and, for the rest of his professional life, promulgated the practice of “vaccine inoculation” [7,8].

During the nineteenth century, smallpox vaccination became increasingly popular and accepted in other areas, including Europe and North America [4]. It is fitting that smallpox became the first (and so far, the only) communicable disease to be actively eradicated, an accomplishment achieved in the decade 1967–1977. An enigma that remains unresolved after the eradication of smallpox concerns the origin of vaccinia, the smallpox vaccine virus. Whatever its origin, vaccinia is a separate species within *Orthopoxvirus*, genetically distinct from both cowpox and variola viruses. Hypotheses that have been promulgated include the theory that it represents a hybrid between cowpox and variola virus, that it derives from cowpox virus, or that it is a descendant of a virus (perhaps of equine hosts) that no longer exists in nature.

As Jenner demonstrated with cowpox and smallpox, there are instances among viruses where, because of the host specificity of virulence, an animal virus gives aborted and attenuated infection in the human host, sometimes leading to an acceptable level of protection. Examples include influenza viruses, rotaviruses and parainfluenza viruses. Remarkable

**Figure 1** Edward Jenner (1749–1823), father of vaccinology. (An 1800 pastel portrait of Edward Jenner by J. R. Smith, courtesy of The Wellcome Institute Library, London, UK.)

**Figure 2** Louis Pasteur (1822–1895), a nineteenth century pioneer of vaccinology. (Print courtesy of Institut Pasteur, Paris, France.)

is the fact that the Jennerian approach to immunoprophylaxis remains valid in modern vaccine development, as the reader will see in the chapter “Live Vaccines Strategies to Prevent Rotavirus Disease.” Finally, it is worth noting that Louis Pasteur, himself one of the most influential pioneers of vaccinology, coined the term *vaccine*, in honor of Jenner, to refer generically to immunizing agents (Fig. 2).

#### IV. THE FIRST USES OF ATTENUATED BACTERIA AS PARENTERAL AND ORAL IMMUNIZING AGENTS

In the last quarter of the nineteenth century, bacteriology became a burgeoning science. One after another, bacteria came to be revealed as etiological agents of important human and veterinary diseases such as cholera, typhoid fever, anthrax, plague, diphtheria, and tuberculosis. The ability to obtain pure cultures of the causative bacteria paved the way for the development of vaccines.

Pasteur observed that cultures of *Pasteurella septica*, which causes the lethal disease fowl cholera in chickens, lost their virulence when the cultures were allowed to sit for 2 weeks [9]. He found that chickens inoculated with the old cultures did not develop illness and, furthermore, were protected when subsequently inoculated with highly virulent fresh cultures. Pasteur concluded that in old cultures the bacteria undergo certain changes that result in attenuation but not in loss of immunogenicity.

Pasteur applied his theory in an attempt to attenuate *Bacillus anthracis*, the cause of anthrax, an infection of cows, sheep, and goats (and occasionally humans) that is often fatal. Pasteur found that maintaining shallow cultures of *B. anthracis* at a temperature of 42–43°C for 2 weeks resulted in a loss of virulence (furthermore, spores did not form at this temperature). In these early experiments, Pasteur established an approach that was followed in multiple later attempts at immunoprophylaxis: the first inoculations given in the immunization schedule were highly attenuated in order to maximize safety, whereas subsequent inoculations were somewhat less attenuated to increase antigenicity.

On May 5, 1881, Pasteur and his colleagues Emile Roux and Charles Chamberland carried out a historic public experiment in Pouilly-le-Fort, France [10]. They inoculated one set of farm animals (24 sheep, 1 goat, and 6 cows) with an initial highly attenuated vaccine; a second inoculation with a less-attenuated vaccine preparation was given on May 17, 1881. On May 31, these immunized animals and a set of uninoculated controls (24 sheep, 1 goat, 4 cows) were challenged with virulent *B. anthracis*. Over the next 4 days, spectacular results documented the efficacy of the vaccine: in the control group, the 24 sheep and the goat died and the 4 cows became overtly ill, whereas there was only one death (a sheep) among the vaccinated animals. Within a short time, the anthrax vaccine became widely used in France. As early as 1882, Pasteur was able to report excellent results from the use of the vaccine in more than 79,000 sheep in France [11].

The first bacterial vaccine used in humans was administered in 1884, barely 1 year after the initial isolation of

*Vibrio cholerae* by Robert Koch [12], when Jaime Ferran inoculated live, putatively weakened *V. cholerae* parenterally [13]. Ferran’s vaccine, which consisted of broth cultures containing “attenuated” vibrios, was administered to about 30,000 individuals who eagerly sought protection during the 1884 epidemic of cholera in Spain. This experience generated much interest internationally, and commissions from several countries came to inspect and evaluate Ferran’s work. The most influential committee, sponsored by the Pasteur Institute, Paris, criticized Ferran’s vaccine and argued that no convincing proof was provided to support claims for a prophylactic effect [41]. Furthermore, it was reported that Ferran’s live vaccine was heavily contaminated with other microorganisms and that only a small proportion of the bacteria were *V. cholerae* [14]; contamination may have accounted for the severe adverse reactions associated with this vaccine and its apparent lack of efficacy [14].

In 1891, only 1 year after Waldermar Haffkine had joined the Pasteur Institute in Paris, Pasteur asked him to carry out research to develop an immunizing agent against cholera [15]. Following Pasteur’s general principle that live vaccines confer protection superior to vaccines consisting of killed microorganisms, Haffkine prepared two modified *V. cholerae* strains for use as live vaccines. The first strain was attenuated by culture at 39°C with continuous aeration, whereas the second strain underwent multiple intraperitoneal passages in guinea pigs in an attempt to increase its virulence. Haffkine utilized these strains sequentially as parenteral immunizing agents; the attenuated strain was inoculated first, followed 6 days later by the strain of supposedly enhanced virulence [16]. Typical side reactions following vaccination included fever, malaise, and headache, as well as pain and swelling at the injection site. In later evaluations of the vaccine, Haffkine abandoned the initial inoculation with the attenuated vibrio and administered to humans only the pathogenic strain without an increase in adverse reactions. Statistical analysis of several clinical trials of Haffkine’s live cholera vaccine in India suggested that it was efficacious [17]. Nevertheless, further use of the vaccine was abandoned because of difficulty in standardizing it and producing it in large quantities.

The other early success in attenuated bacterial vaccines was the bacille Calmette–Guérin (BCG) vaccine against tuberculosis. Camille Calmette and Alphonse Guérin obtained a stable, attenuated strain incapable of causing tuberculosis in the highly susceptible guinea pig [18]. It was achieved by repeatedly subculturing (213 times over 13 years), in the presence of ox bile, a tubercle bacillus originally isolated from a cow by Edmond Nocard in 1902 [18]. The first administration of BCG vaccine to a human occurred in 1921, when a newborn infant, whose mother had died of tuberculosis, was given an oral dose without adverse effects. Calmette initially advised that the vaccine be administered orally to young infants; accordingly, by the late 1920s, approximately 50,000 French infants had received the apparently well-tolerated BCG vaccine [19]. By the late 1920s, the intradermal route of inoculation rapidly began to replace the oral route of vaccination. It was not until the 1950s that controlled field trials confirmed the efficacy of at least one strain of BCG [20].

## V. EARLY INACTIVATED WHOLE-CELL BACTERIAL VACCINES

Three parenteral inactivated whole-cell bacterial vaccines to protect humans against cholera, typhoid fever, and plague, originally developed at the end of the nineteenth century, were used with little modification for three-quarters of a century thereafter. In each instance, the isolation of the causative agent in pure culture was followed shortly thereafter by vaccine candidates.

### A. Cholera Vaccines

In 1896, Wilhelm Kolle [21] recommended the use of agar-grown, heat-inactivated whole *V. cholerae* organisms as a parenteral immunizing agent. This nonliving vaccine was markedly simpler to prepare and to standardize than Haffkine's live parenteral vaccine. By 1911, Haffkine was also utilizing inactivated vibrios as a vaccine with 0.5% phenol as a preservative [22]. Kolle-type vaccines were first used on a large scale during the 1902 cholera epidemic in Japan [23]. In the 1960s and early 1970s, randomized, controlled field trials carried out in Bangladesh [24–26], the Philippines [27], Indonesia [28], and India [29] documented that killed whole-cell cholera vaccines can confer significant short-term protection in older children and adults.

### B. Typhoid Vaccines

In 1896, Richard Pfeiffer [30] and Almoth Wright [31] independently reported that a vaccine against typhoid fever could be prepared by inactivating cultures of typhoid bacilli with heat and preserving them in phenol [32]. By 1915, killed whole-cell parenteral typhoid vaccines had become widely used by the military in Europe and in the United States. Systematic use of the vaccine in the U.S. Army, in 1912, was followed by a diminution of approximately 90% in the incidence of typhoid fever [33]. Thus epidemiological data suggested that the vaccine was protective [34], although rigorous controlled field trials of efficacy of the parenteral heat-phenol typhoid vaccine were not carried out until the 1950s [35]. Controlled field trials sponsored by the World Health Organization (WHO) in the 1950s and 1960s demonstrated that the heat-phenolized vaccine conferred about 50–75% protection against typhoid fever [34,36–38].

## VI. LIVE VIRUS VACCINES

Following their success with the development of a vaccine against anthrax, Pasteur and coworkers turned their attention toward the problem of rabies [39,40]. Although unable to cultivate the virus as they could a bacterium, they nevertheless established that the infectious agent resided within the spinal cord and brain of infected animals. Pasteur and his team inoculated nerve tissue from a rabid animal submeningeally into rabbits and removed the spinal cord after the rabbits died; they were able to pass the infection from rabbit to rabbit in this manner. Roux discovered that if the spinal cords were desiccated for 15 days, they lost their ability to induce rabies. Spinal cords dried for less than 2

weeks were less attenuated, whereas minimally dried spinal cord clearly contained virulent virus. Pasteur's group prepared a vaccine that consisted of dried spinal cord suspended in saline. Their immunization schedule involved daily inoculations for 14 days, commencing with material from spinal cord that had been dried for 14 days and progressing on the successive days to the use of cord dried for less and less time. This was continued until, after 2 weeks, the final inoculation was carried out with minimally dried cord, which contained virulent virus. Needless to say, this vaccination procedure was quite controversial, even among the members of Pasteur's group. What is extraordinary is how Pasteur and colleagues identified the tissues where the rabies virus resides and how they managed to achieve attenuation yet retain immunogenicity.

In the late 1920s and early 1930s [41,42], Max Theiler and colleagues developed an attenuated strain of yellow fever virus by repeated passage of the wild-type Asibi strain in minced chick embryo tissue, from which the head and spinal cord had been selectively removed to minimize the amount of nerve tissue. Somewhere between the 89th and 114th passages, the virus lost its neurotoxicity. Theiler adapted this attenuated virus, strain 17D, to grow in chick embryos. In the 1930s and 1940s, this attenuated virus vaccine set a standard for safety, immunogenicity, and efficacy that continues to draw admiration even today. Strain 17D remains one of the best all-around vaccines ever developed. It has been safely given to hundreds of millions of adults and children and provides long-term protection. This is an amazing feat, but particularly so when one considers that the vaccine was developed in an era before modern tissue culture techniques and concepts of viral genetics had evolved.

## VII. “SUBUNIT” AND “EXTRACT” VACCINES

The early diphtheria and tetanus toxoids should be regarded as the pioneer subunit vaccines. In each instance, their development followed a similar course. Discovery of the etiological agents of diphtheria by Edwin Klebs [43] and Frederick Loeffler [44], and of tetanus by Shibusaburo Kitasato [45] was followed by the demonstration that *Corynebacterium diphtheriae* and *Clostridium tetani* were elaborate potent exotoxins. Inoculation of broth cultures of these bacteria through porcelain filters resulted in sterile filtrates that were toxic for animals, leading to syndromes characteristic of human disease [46]. The production of specific antitoxins for passive protection came next, and this was followed by the use of toxin/antitoxin mixtures to achieve active immunization [47]. As will be reviewed later, mistakes in the preparation of such mixtures sometimes led to disastrous consequences. Ultimately, it was found that through treatment with formalin, diphtheria and tetanus toxins could be rendered biologically innocuous and yet retain their ability to stimulate neutralizing antitoxin [48,49]. Alexander Glenny [49] claims to have prepared formalinized diphtheria toxoid as early as 1904. In a personal communication to Henry Parish [1], Glenny related that his first toxoid was prepared by accident! He observed that a batch of diphtheria

toxin lacked toxic activity yet elicited antitoxin in animals as efficiently as fully active toxin. The *C. diphtheriae* cultures used to produce the toxin had been grown in large earthenware containers which could not be readily sterilized. One of the steps in sterilizing the containers for the next batch involved washing them with formalin. Glenny hypothesized that residual formalin had apparently inactivated the toxin. He subsequently proved that formalin could, indeed, alter diphtheria toxin to toxoid, rendering it innocuous yet preserving its antigenicity.

### VIII. STIMULATION OF LOCAL IMMUNITY

Many infectious agents interact with the mucosa of the gastrointestinal tract, the respiratory tract, or the urinary tract, as a site of colonization or as a preliminary step before invasion. Recognition of the mucosal immune system as a unique component of the overall immune system of the mammalian host underlies extensive current research to develop oral or intranasal vaccines to prevent enteric infections such as cholera, typhoid fever, rotavirus diarrhea and shigellosis, and respiratory infections such as influenza and respiratory syncytial virus (RSV) bronchiolitis. The leading pioneer in the concept of local immunization was Alexandre Besredka [50], who was generations ahead of his time in his approach and his concepts. However, Besredka did not believe that antibodies were involved in mediating the local immunity that he stimulated. Albert B. Sabin's pioneering work, which resulted in a practical and effective live oral vaccine against poliomyelitis, set a paradigm for other oral and nasal vaccines (Fig. 3).

The parts of this book describing vaccines against cholera show that the modern approach to prevent this disease involves oral immunization with either inactivated antigens or attenuated bacteria. However, these modern oral cholera vaccines are descendants of a long tradition. For example, the first report of nonliving whole *V. cholerae* used as an oral vaccine in humans was published in 1893 [51]; it related the lack of adverse reactions following the ingestion of multiple doses containing billions of inactivated vibrios.

In the 1920s and 1930s, field trials of Besredka's killed oral *V. cholerae* vaccine, combined with bile (the so-called bilivaccine), were carried out in India [52–54] and Indochina [55]. Significant protection was apparently achieved. In the Indian trials, the oral vaccine was also compared with a killed parenteral whole-cell vaccine. However, it is not certain if the vaccine and control (nonvaccinated) groups were fairly randomized, such that the risk of infection was equal. Nevertheless, the oral bilivaccine provided 82% protection and the parenteral vaccine 80% protection during the period of surveillance [52–54]. The bilivaccine was administered in a total of three doses on consecutive days; the subject to be vaccinated first ingested a bile tablet, followed 15 min thereafter by a bilivaccine tablet containing 70 billion dried vibrios. Because of the bile component, the bilivaccine commonly caused adverse reactions, including nausea, vomiting, and acute diarrhea; it appears that, in large part as a consequence of these reactions, further work with the bili-vaccine was abandoned.

**Figure 3** Albert B. Sabin (1906–1993), a twentieth century pioneer of vaccinology, administering oral polio vaccine—1959. (Print courtesy of Heloisa Sabin.)

Early investigators who pursued the concept of copro-antibodies in the gut and local antibodies on other mucosal surfaces include Arthur Davies in the 1920s [56]; R. Torikata and M. Imaizuma [57] and Theodore Walsh and Paul Cannon in the 1930s [58], and William Burrows [59] in the 1940s.

### IX. CLINICAL EVALUATION OF THE SAFETY AND EFFICACY OF VACCINE CANDIDATES

When a vaccine candidate appears, its safety must first be demonstrated in a series of small clinical trials before the large-scale use of the vaccine can be considered. The need for such studies was recognized as early as the introduction of variolation into England in 1722, when royal permission was given to variolate six condemned prisoners in an effort to determine the safety of that procedure [5,6]. The prisoners were offered pardon in exchange for their participation—if they survived. In November 1721, it was announced in the London newspapers that some orphan children of St. James parish, Westminster, would be inoculated as an experiment to assess the effect of variolation in children [5,6]. The use of prisoners and institutionalized children for vaccine safety studies in the 1720s established a precedent that continued

until the mid-1970s. For example, in the United States in the 1950s, the attenuated poliovirus vaccine was initially tested for safety and immunogenicity in adult prison volunteers [60], whereas the inactivated poliomyelitis vaccine was evaluated early on in institutionalized children [61]. In the early 1970s, the ethics of experimentation in such populations, particularly prisoners, underwent reevaluation [62]. There emerged a new consensus that considered prisons to be inherently coercive environments in which it was difficult to guarantee informed consent [63]. As a consequence, by the mid-1970s, the use of prison volunteers for Phase I studies to assess the safety and immunogenicity of vaccines had virtually disappeared.

There also exists a long history of evaluating the efficacy of candidate vaccines in experimental challenge studies. In the first of Jenner's famous experiments, James Phipps, an 8-year-old boy was inoculated on the arm with cowpox. Jenner wrote [8]:

Notwithstanding the resemblance which the pustule, thus excited on the boy's arm, bore to variolous inoculation, yet as the indisposition attending it was barely perceptible, I could scarcely persuade myself the patient was secure from the Small Pox. However, on his being inoculated some months afterwards, it proved that he was secure. This case inspired me with confidence; and as soon as I could again furnish myself with Virus from the Cow, I made an arrangement for a series of inoculations. A number of children were inoculated in succession, one from the other; and after several months had elapsed, they were exposed to the infection of the Small Pox; some by Inoculation, others by variolous effluvia, and some in both ways; but they all resisted it.

To put Jenner's challenge of cowpox-vaccinated children with smallpox virus into proper perspective, one must appreciate that variolation was a widespread practice in England in the last quarter of the eighteenth century.

In Berlin, Germany, during the Great Depression, Wolfgang Casper, a physician who worked in the gonococcal wards of the Rudolf Virchow Hospital, developed a gonococcal vaccine consisting of a polysaccharide extract of gonococci [64]. In 1930, he carried out an unusual clinical experiment to test its efficacy. Casper recruited 10 destitute individuals whom he had previously seen with gonorrhea and who had recovered [3]. These 10 volunteers were moved into a ward at the hospital and provided with room and board. Five received his gonococcal vaccine and five were injected with a placebo. At a later point, a female volunteer, a prostitute, was brought onto the ward to spend one night with the 10 male volunteers, all of whom had sexual intercourse with the prostitute. Within 1 week, 4 of the 5 placebo recipients had developed gonorrhea vs. none of the 5 recipients of Casper's vaccine [3].

Preliminary, small-scale clinical studies to assess the safety and immunogenicity of new candidate vaccines (Phase I studies) constitute a critical first step in the evaluation of any vaccine, as is discussed in the chapter in this book by Carol O. Tacket, Karen Kotloff, and Margaret Rennels. Similarly, experimental challenge studies to assess vaccine efficacy represent an important step in the development of

vaccines for those infectious agents that readily respond to antimicrobial therapy or those that cause self-limited illness and for which well-established models of experimental infection exist. Data from these safety, immunogenicity, and challenge studies serve to identify vaccine candidates worthy of further evaluation in large-scale field trials. In recent years, this evaluation process has been applied to vaccines against cholera [65,66], shigellosis [67], malaria [68], and influenza [69]. In the modern era, there exist strict ethical guidelines to recruit the volunteers who participate in such clinical trials and to obtain their informed consent, assuring that they understand the potential risks involved and the procedures to which they will be exposed. Under the sponsorship of the World Health Organization, the Vaccine Trial Centre was established at the Faculty of Tropical Medicine of Mahidol University in Bangkok, Thailand, in the mid-1980s. This represents the first unit in a developing country where challenge studies with various pathogenic organisms could be undertaken to assess vaccine efficacy following rigorous ethical and technical local review of protocols according to international standards [70].

The relative importance of experimental challenge studies that assess vaccine efficacy in volunteers increased in 1993, when the Vaccines and Related Biologic Products Advisory Committee to the Center for Biologics Evaluation and Research of the Food and Drug Administration (FDA) voted that the results of such studies should constitute sufficient evidence of the vaccine's efficacy for submission of a Product Licensure Application. The case in point considered by the committee was the efficacy of a new live oral cholera vaccine for use in adult U.S. travelers [71]. The conclusion was that the challenge studies provided a better measure of the efficacy of the vaccine for U.S. adults than would the results of a field trial in an endemic area involving a population repeatedly exposed to cholera antigens. Previously, the efficacy of live oral cholera vaccine CVD 103-HgR, as demonstrated in volunteer challenge studies, was sufficient to allow the licensure of that vaccine in Switzerland and Canada.

## X. LARGE-SCALE FIELD TRIALS TO ASSESS VACCINE EFFICACY

In modern times, the prospective randomized, double-blind, controlled field trial under conditions of natural challenge is the definitive "gold standard" test of the efficacy of a vaccine. In general, the result of at least one such trial is required for the licensure of a vaccine in most countries. One exception to this general rule is cited above.

Historically, the development of epidemiological methods for conducting field trials to evaluate the efficacy of vaccines represented an obvious and necessary offspring of the development of new vaccines themselves. According to Cvjetanovic [17], the first attempts to determine vaccine efficacy by controlled field trials were the tests of Haffkine's live cholera vaccine in India. Initially, uncontrolled trials were carried out by Haffkine throughout India, in 1893 and 1894, involving 42,197 individuals, and, from 1895 through 1896, involving an additional 30,000 persons [72–74]. How-

ever, the historic testing of his vaccine, from an epidemiological perspective, involved relatively small groups of individuals residing in prisons and on tea plantations [72–74]. As reviewed by Cvjetanovic [17], Haffkine concluded that to properly assess the efficacy of his cholera vaccine, equal-sized groups of individuals should be compared, who were randomly allocated to receive vaccine or to serve as unimmunized controls, and who faced essentially identical risk of exposure to natural infection.

Many consider that the first large-scale vaccine field trial that was rigorously designed and executed according to modern standards was the trial initiated by Macleod et al. [75] of a multivalent pneumococcal vaccine, which was carried out among recruits at a training base during World War II. In this double-blind study in a high-risk population, 7730 persons were allocated to receive vaccine or saline placebo, and surveillance was maintained for pneumococcal disease with bacteriological confirmation of clinical cases. In this book, the chapter authored by John Clemens, Abdollah Naficy, Malla Rao, and Hye-won Koo (“Long-term Evaluation of Vaccine Protection: Methodological Issues for Phase II and IV Studies”) shows how much field trial methodology has evolved since Macleod and coworkers carried out their trial in the early 1940s.

A decade after Macleod’s field trial on pneumococcal vaccine, the famous Francis field trial of inactivated Salk poliovirus vaccine was undertaken in the United States, involving the inoculation of more than 650,000 children [76].

## XI. VACCINE CALAMITIES

An occasional byproduct of the development of new vaccines has been the inadvertent occurrence of severe adverse reactions or fatalities because of contamination, incomplete attenuation, inadequate detoxification, or idiosyncrasy. Such untoward events were obviously more common with the early vaccines. They led to an awareness of the importance of maintaining strict procedures for manufacture, testing of safety, potency, purity, and (where relevant) sterility. These events also gave rise to the formation of regulatory agencies to oversee the control of biological products. Sir Graham Wilson devoted an entire book, *The Hazards of Immunization*, to this topic [77]; it contains information on relevant materials up to the mid-1960s. Some of the more prominent disasters and incidents related to vaccines, culled from various sources, are briefly summarized below.

### A. The Mulkowal Disaster

In October 1902, in Mulkowal, India, 19 persons died from tetanus after being inoculated with Haffkine’s inactivated parenteral whole-cell plague vaccine drawn from the same bottle. An investigative commission concluded that contamination had occurred during the manufacture of the vaccine in Haffkine’s laboratory in Bombay, India [15]. Initially, Haffkine was held personally responsible and was suspended as director of the government laboratory at Bombay. Sir Ronald Ross was instrumental in releasing the report of a

board of inquiry, showing that Haffkine and his laboratory were blameless [15]. Under further pressure from Sir Ronald Ross, Haffkine was officially exonerated and offered the directorship of a laboratory in a government hospital in Calcutta. In a final vindication, in 1925, the Plague Research Laboratory of Bombay was renamed the Haffkine Institute.

### B. The Lubeck Disaster

During its initial introduction, the BCG vaccine was administered via the oral route and was given primarily to young infants. In Lubeck, Germany, approximately 250 infants were inadvertently fed virulent *Mycobacterium tuberculosis* instead of attenuated BCG [78,79]; 72 of these infants died of tuberculosis, all but 1 within 12 months. The virulent strain of human tubercle bacillus had been kept in the same laboratory as the stock for the BCG vaccine and had inadvertently been used instead of the vaccine strain. Investigation of the incident vindicated the safety of the BCG vaccine and initiated regulatory measures to assure proper laboratory conditions, training of personnel, and procedures in laboratories where vaccines are manufactured.

### C. Disasters Following Diphtheria Immunization

As noted above, the earliest active immunization against diphtheria consisted of the concomitant administration of mixtures of diphtheria toxin and antitoxin. Tragedies caused by efforts in the manufacture stage were recorded in Dallas, TX; Concord and Bridgewater, MA; Baden, Austria [77,80]; Russia [81]; and China [82]. In another instance, in Bundoora, Australia, a diphtheria toxin–antitoxin mixture became contaminated with *Staphylococcus aureus* during the manufacture of a product that contained no preservative [77,83]. Of 21 children inoculated from the same bottle, 12 died of sepsis, 6 became seriously ill but survived, while only 3 children remained healthy. *S. aureus* was isolated from abscesses in the ill but surviving children.

### D. Typhoid Fever Following Immunization with a Heat-Treated Oral Typhoid Vaccine

In 1904, U.S. Army bacteriologists proposed to administer killed typhoid bacilli as an oral vaccine against typhoid fever. The bacterial culture was intended to be inactivated by heating at 56°C for 1 hr. Initial cultures of the heated vaccine were sterile. Of 13 men who ingested the vaccine, 7 developed clinical typhoid fever and 3 others suffered “febrile illness,” with onset at 6–16 days after ingestion of the first dose of vaccine [84]. Repeat bacteriological examination of the vaccine demonstrated that a few viable typhoid bacilli were recoverable (2–3 organisms/mL).

### E. Hepatitis Following Vaccination Against Yellow Fever

The attenuated yellow fever virus vaccine strain 17D developed by Theiler remains as one of the safest and most

effective vaccines ever developed. However, during World War II, it was administered to U.S. servicemen along with human immune serum. Among approximately 2.5 million troops vaccinated, 28,600 cases of icteric hepatitis occurred, leading to 62 deaths [85]. Through careful epidemiological investigations and volunteer studies, it was discovered that some lots of immune serum used were contaminated with a hepatitis virus [86]. When human serum ceased to be given along with the yellow fever vaccine, the problem disappeared.

#### F. The Cutter Incident

Shortly after the favorable results of the Francis field trial of Salk inactivated poliovirus vaccine were publicized in April 1955, the FDA licensed Salk-type vaccine prepared by several manufacturers. During a 10-day period in April 1955, a total of 120,000 children were immunized with two lots of inactivated vaccine manufactured by Cutter Laboratories of Berkeley, CA [87–89]. Cases of poliomyelitis occurred among 60 recipients of these vaccine lots and 89 of their family members. The median incubation period for vaccinees was 8 days, whereas the median incubation was 24 days for the family contacts. During faulty production, wild poliovirus did not have sufficient contact with formalin to inactivate all the virus present.

#### G. Swine Influenza Vaccine and Guillain–Barré Syndrome

In the United States in the spring of 1976, fatal influenza occurred in two individuals (one of whom was a healthy young adult) from whom a “swine” influenza virus (Hsw1N1) was cultured. Through serological studies, it was determined that the virus antigenically resembled that of the great influenza epidemic of 1918–1919, which was characterized by high case fatality even in young adults. Accordingly, the Public Health Service, fearing a possible large-scale outbreak of Hsw1N1 disease in the coming winter, undertook a national program to prepare a swine flu vaccine and to initiate a nationwide immunization campaign. The intention was to have the vaccine prepared and safety-tested and mass vaccination under way before the onset of the winter influenza season. Between October 1 and mid-December 1976, approximately 45 million doses of swine flu vaccine were administered. However, beginning in late November and early December, reports began to appear about the occurrence of Guillain–Barré polyneuritis syndrome among recent recipients of vaccine. By December 16, the findings of a preliminary investigation corroborating this association led to a discontinuation of further immunizations with the vaccine. An extensive and detailed investigation carried out by prominent epidemiologists led by Alexander Langmuir [90] concluded that the administration of the swine flu vaccine during the national campaign resulted in a 3.96- to 7.75-fold increase in risk of developing Guillain–Barré syndrome during the first 6 weeks postvaccination compared with the normal, expected, endemic incidence.

#### XII. SUMMARY COMMENT

We find ourselves entering a particularly promising era in the history of vaccinology, spurred on by the application of tools of modern biotechnology, resulting in a new generation of novel vaccines. And yet, even as we look ahead with great anticipation at this unfolding “golden era” of vaccinology, we glance back with admiration at the legacy of pioneering achievements left by our scientific forefathers, who developed the first vaccines, provided our initial understanding of immune mechanisms, and forged the early methods to assess the safety, immunogenicity, and efficacy of vaccines in clinical and field trials.

# An Overview of Biotechnology in Vaccine Development

**James B. Kaper**

*University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.*

**Rino Rappuoli**

*Chiron S.r.l., Siena, Italy*

The current era of vaccine development is unprecedented in terms of the broad range of technologies that are being applied in this area. The technological revolution consisting of recombinant DNA, genomics, proteomics, and progress in understanding the immune system has removed most of the technical barriers that formerly limited vaccine developers and has presented amazing new opportunities to use vaccination approaches to prevent and treat not only infectious diseases but also cancer, allergies, and many chronic diseases. As surely as Jenner's use of cowpox pustules more than 200 years or Pasteur's use of cultured microorganisms more than 100 years ago mark revolutions in the history of vaccine development, the use of biotechnology in the current era of vaccine development has enabled totally unprecedented advancements in the development of vaccines.

This chapter will present a broad overview of the use of biotechnology in vaccine development organized into four broad areas. The first area, initially applied more than 20 years ago in the development of the recombinant hepatitis B vaccine, is the use of recombinant DNA technology to produce antigens for subunit vaccines and to create defined mutations for attenuated vaccines. The second area is the development of novel antigen delivery systems including vector vaccines, transgenic plants, and DNA vaccines. The third area includes the use of genomics to discover novel antigens for vaccine development. The most revolutionary approach in this area is "reverse vaccinology," but techniques that characterize *in vivo* gene expression also utilize genomic approaches for antigen discovery. The final area is the application of biotechnology to understand the immune system and enhance antigen presentation and processing. The range of techniques in this area include the development of transgenic animals to study fundamental issues of immune response and the use of recombinant cytokines, chemokines, and novel adjuvants to stimulate the appropriate immune response. Selected aspects of these four areas will be

briefly reviewed in this chapter with an emphasis on genomic techniques for antigen discovery, as this topic is not specifically covered elsewhere in this volume. For most of the topics, primary references will not be given but can be found in other chapters that deal specifically and extensively with the topics.

## I. ANTIGEN PRODUCTION

### A. Subunit Vaccines

The first human vaccine developed using recombinant DNA technology was the hepatitis B vaccine, which was licensed in the United States in 1987. The recombinant vaccine replaced a vaccine consisting of 22-nm particles of the S antigen that were obtained from the plasma of hepatitis B carriers. Although the plasma-derived vaccine was safe and effective, the extensive viral inactivation procedures involved in producing it required up to 65 weeks for production of a lot, thus making it a very expensive vaccine. The S antigen was cloned in yeast cells and the resulting 22 nm-particulate antigens were much easier, quicker, and cheaper to produce than those derived from plasma. Since this initial success, production of protein antigens using recombinant DNA techniques has become standard practice for subunit vaccine development.

A noteworthy variation of the cloned antigen subunit vaccine can be found in a recombinant acellular pertussis vaccine. After the initial cloning and sequencing of the *ptx* genes encoding pertussis toxin (PT), detailed structure-function analysis identified amino acid residues in the S1 subunit that were critical for the ADP-ribosyl transferase activity of the holotoxin. A double mutation of two key residues produced a toxin that lacked toxicity yet maintained an unaltered antigenic conformation. This genetically detoxified toxin was combined with purified filamentous

hemagglutinin and pertactin to make an acellular vaccine that was safer and more immunogenic than the traditional killed whole cell vaccine [1]. This vaccine, which is now licensed and widely used in many countries, illustrates that not only can naturally occurring antigens be cloned and efficiently purified by recombinant techniques, but also antigens that do not exist in nature can be engineered and produced for use in subunit vaccines. An extension of this approach can be seen with epitope-based vaccines (see “Epitope-Based Vaccine”), which combine multiple epitopes from different antigens from the same pathogen or even from different pathogens into a single protein using synthesized genes.

### B. Live Attenuated Vaccines

The inverse of using recombinant DNA techniques to produce subunit vaccines by cloning or more antigens is using these techniques to develop live attenuated vaccines by deleting genes encoding one or more virulence or metabolic factors from wild-type pathogens. Whereas traditional live attenuated bacterial or viral vaccines were derived by serial *in vitro* passage or random chemical mutagenesis, with unknown secondary effects and the risk of reversion, recombinant attenuated vaccines are specifically engineered to inactivate targeted functions with nonreverting mutations.

Two broad categories of mutations are used to construct live attenuated vaccine strains. The first category includes mutations in genes encoding a critical virulence factor, for example, deleting the *ctx* genes encoding cholera toxin in *Vibrio cholerae* (see Chapter 44). The second category includes mutations in genes encoding critical metabolic factors, such as the *aro* genes encoding the metabolic pathway responsible for synthesis of aromatic amino acids in *Salmonella* and other intracellular pathogens (see Chapter 41). The large deletions constructed in these genes eliminate the possibility of reversion to virulence, which was the most serious disadvantage of the live Salk polio vaccine. (New attenuated polio vaccine strains with nonreverting mutations have been developed but the impending global eradication of polio using the Salk vaccine means that these newer vaccines will not be tested for efficacy.) Although the construction of mutations in pathogenic bacteria and viruses is relatively straightforward, the earliest versions of the attenuated *V. cholerae* and *Salmonella* strains proved to be unacceptably reactogenic in human subjects and so additional mutations were required (see Chapters 44 and 41). The unexpected reactogenicity seen with the first recombinant live attenuated vaccines illustrates a common problem in the molecular vaccine era in that technical issues are rarely the limiting factor in vaccine development but instead the limiting factors are deficiencies in our understanding of the disease pathogenesis or protective immune response.

## II. ANTIGEN DELIVERY

There are numerous antigen delivery systems currently being investigated such as liposomes, proteosomes, immunostimulatory complexes (ISCOMS), immunostimulating reconstituted influenza virosomes (IRIVs), virus-like particles

(VLPs), microencapsulation, and other technologies. These systems, which are reviewed in Chapters 22 through 25 in this volume, largely do not utilize recombinant DNA technology. In this section, we will briefly highlight novel antigen delivery systems that could not have existed in the pre-recombinant DNA era.

### A. Vector Vaccines

Vector vaccines employ live attenuated bacterial or viral strains to carry protective antigens of foreign, unrelated antigens and deliver these heterologous antigens to the immune system. One of the most successful vector vaccines yet developed is a vaccinia virus vector that expresses rabies glycoprotein. This vaccine, administered orally to animals via live recombinant vaccine-impregnated bait scattered in rabies-endemic areas, has already been credited with substantial reductions in rabies in wildlife populations in various countries (see Chapter 27). Numerous foreign antigens have been expressed in a wide variety of bacterial and viral vectors, leading to hundreds if not thousands of possible antigen/vector combinations. Fusion of antigen genes to different targeting sequences can direct the antigens to different bacterial/viral compartments, e.g., surface vs. internal locations and/or to different host cell compartments, e.g., endoplasmic-reticulum or lysosome. Vector vaccines can also be engineered to express cytokines or other mediators to increase immune response or to shift the balance between Th1 or Th2 responses. Bacterial species that have been employed as vector vaccines include attenuated strains of *Salmonella enterica* serovar Typhi and serovar Typhimurium, *Shigella*, *Vibrio cholerae*, *Listeria monocytogenes*, *Mycobacterium bovis* (BCG), and *Yersinia enterocolitica* (reviewed in Chapter 30). Other bacterial vectors have included nonpathogenic strains derived from normal flora such as *Streptococcus gordonii* (reviewed in Chapter 57), *Lactobacillus casei*, and *Lactobacillus lactis*. Some of the intracellular pathogens, particularly attenuated *Salmonella* and *Shigella*, have been further exploited to deliver DNA vaccine plasmids to host cells, particularly antigen presenting cells such as dendritic cells, macrophages, etc., whereby the foreign antigen is expressed via a promoter active in eukaryotic cells (see Chapter 30). These bacterial DNA vector strains offer the additional advantage of being delivered by the oral route rather than the parenteral route. A variety of attenuated viruses have also been employed as vectors including vaccinia and other poxviruses (see Chapter 27), adenovirus (see Chapter 28), and single-stranded RNA virus replicon vectors such as alphaviruses, coronaviruses, picornaviruses, flaviviruses, influenza viruses, rhabdoviruses, and paramyxoviruses (see Chapter 29). Depending on the virus, the route of administration of these vectors could be parenteral, oral, or intranasal, and engineered changes in viral tropism offer the potential to target these vectors to specific cell types such as dendritic cells (see Chapter 28).

### B. Transgenic Plants

Transgenic plants expressing antigens of infectious agents offer tremendous potential for the expression of protein

antigens. Such antigens can be delivered orally to the mucosal immune system, giving rise to the term “edible vaccines” to describe these transgenic plants (see Chapter 26). A variety of plants have been exploited for this purpose including tobacco, potatoes, tomatoes, and corn. The amount of foreign antigen produced varies according to the plant species and the integration site of the gene encoding the antigen. For insertion into the nucleus, antigen levels of 0.01–2% of total soluble plant protein have been reported (Chapter 26). One recent report utilized a chloroplast insertion site, which resulted in foreign protein expression levels of up to 45% of total soluble plant protein [2]. Thus, transgenic plants can potentially produce large amounts of protein antigens very efficiently on an industrial agricultural scale. Numerous antigens have been expressed in plants including proteins from rabies, respiratory syncytial virus (RSV), measles, norovirus, rotavirus, hepatitis B and C, HIV, *V. cholerae*, enterotoxigenic *E. coli*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and protective immunity against challenge has been shown in animals for several of these vaccines. Initial clinical trials have studied transgenic plants expressing antigens from enterotoxigenic *E. coli*, norovirus, and hepatitis B, and all have been found to be safe and immunogenic, although no protection data have yet been gathered in humans. Although important questions remain to be completely addressed, e.g., protective efficacy, potential for oral tolerance, public acceptance of genetically modified plants, etc., transgenic plants expressing vaccine antigens offer the potential for efficient and inexpensive production of vaccines that could be produced in developing countries.

### C. DNA Vaccines/Genetic Immunization

An antigen delivery system first described a decade ago does not actually deliver antigens per se. Instead, this system delivers the gene encoding a specific antigen under the control of a strong eukaryotic or viral promoter (e.g., a CMV promoter) into mammalian cells where the antigen is transcribed, translated, and expressed. This technology, called DNA vaccines (Chapter 31) or genetic immunization [3], has been utilized in more than 1000 publications since it was first described [3]. The DNA is delivered on coated gold particles administered via a gene gun or by i.m. injection and the expressed protein is processed and presented to the immune system by the MHC class I-restricted pathway, resulting in cytotoxic T lymphocyte (CTL) induction, the MHC class-II restricted pathway resulting in helper T cell responses, and to B cells resulting in the induction of antibodies. Numerous viral, bacterial, and parasite antigens have been delivered by DNA vaccines and striking humoral and cellular responses and protective immunity from challenge have been reported for many of these systems (see Chapter 31). In addition to infectious diseases, this technology has also been utilized in animal models of allergy, asthma, and cancer. Most applications of DNA vaccines/genetic immunization have delivered one or two antigens that were chosen on the basis of immunogenicity data obtained with other systems. However, this approach can also be used on a genomic scale to inoculate expression libraries of entire bacterial or viral genomes into animals

that are subsequently challenged to determine what pools of clones confer protection (see Section III.D).

The spectacular results obtained in mice with DNA vaccines have not been readily extended to trials involving primates and humans, where limited effectiveness has been shown (reviewed in Chapter 31). A variety of genetic constructs, delivery methods, and adjuvants are being studied to improve responses in humans. One of the most promising approaches is a prime-boost strategy where a DNA vaccine is used to prime and another technology, e.g., vaccinia expressing the same antigen, is used to boost (see Chapters 31, 32, and 71). The prime-boost strategy is being used not only for DNA vaccines but also with the entire spectrum of immunization approaches resulting from the application of biotechnology to vaccine development.

## III. ANTIGEN DISCOVERY THROUGH GENOMICS

The science of genomics is revolutionizing all areas of biomedical research and vaccine development is no exception. Conventional subunit vaccine development focused on one or more protective antigens discovered by growing the pathogen in laboratory conditions and dissecting it into individual components. Each candidate component is then tested for its ability to induce immunity. Limitations of this approach include the fact that only those antigens that can be purified in quantities suitable for vaccine testing can be studied, the fact that critical protective antigens may only be expressed in vivo and not in vitro, and the time-consuming nature of identifying, purifying, and testing the individual components of the pathogen. While obviously successful in many cases, this approach took a long time to yield vaccines against those pathogens for which the solution was easy and failed to produce vaccines for those bacteria and parasites that did not have obvious immunodominant protective antigens. And when dealing with non-cultivable microorganisms, the limitations of this approach are obvious.

The ability to examine potential antigens on a genome-wide scale is significantly changing the field of antigen discovery. Advances in DNA sequencing technology now allow the determination of the complete genome sequence of a bacterium in a few months at a relatively low cost. Complete genome sequences are available for more than 80 bacteria, most of which are pathogens, with an additional 100 bacterial genomes in progress. The availability of the genome of large parasites such as *Plasmodium falciparum*, together with that of the vector *Anopheles gambiae*, and the human host, provides for the first time the entire genomic information of the three living organisms whose interaction is responsible for malaria, the disease which affects one third of the human population. The availability of complete genome sequences and recent advances in recombinant DNA technology mean that every possible antigen of a pathogen can be tested for its ability to induce a protective immune response. Furthermore, these approaches allow the examination of potential protective antigens without the bias that can result from focusing on antigens that are highly expressed under *in vitro* laboratory growth conditions.

### A. Reverse Vaccinology

Rather than starting with the pathogenic organism grown in vitro and fractionated into individual components that are then tested for immunogenicity, the technology known as reverse vaccinology starts with the genome sequence of a pathogen [4]. In silico (computer) analysis is applied to the predicted protein products of every potential open reading frame in the genome to predict those antigens that are most likely to be vaccine candidates. Potential vaccine candidates are chosen using a variety of criteria including predicted localization on the bacterial surface, outer membrane or secreted proteins, lipoproteins, inner membrane proteins, periplasmic proteins, and proteins with homology to known virulence factors of other microorganisms. The selected proteins are then expressed as recombinant proteins by using PCR primers containing appropriate restriction sites to amplify and clone the gene into expression vectors. The expression vectors contain sequences encoding a 6xHis tag or glutathione-S-transferase, thereby allowing rapid purification of the recombinant protein by simple column chromatography. The use of robotics greatly enhances the high throughput cloning and purification steps.

The purified recombinant proteins are then tested for their potential to engender a protective immune response. The tests employed differ according to the pathogen, but a rapid test that can give some indication of protective immunity potential is most preferable when screening a large number of recombinant proteins. At one end of the spectrum of tests is the use of the recombinant proteins to raise immune serum in mice, which is then employed in ELISA or flow cytometry techniques to demonstrate the ability of the immune serum to recognize the native antigen on the surface of the bacteria. At the other end of the spectrum, animal challenge models may be the only screening method for protective immunity. In between these two extremes are other assays such as complement-mediated lysis of Gram-negative bacteria in the presence of specific antibody or an opsonophagocytosis assay measuring antibody and complement-dependent bacterial killing in the presence of neutrophils isolated from fresh blood. Usually, a series of tests are performed involving simple, rapid tests for the initial screen to decrease the number of candidates and animal challenge studies for those proteins that successfully complete the initial screen.

Reverse vaccinology was first applied to the identification of vaccine candidates against serogroup B meningococcus [5]. Of the 2158 putative open reading frames (ORFs) annotated for this pathogen, 600 ORFs were selected as candidate antigens and cloned into *E. coli* for expression as a fusion protein. Three hundred fifty of the 600 ORFs were successfully expressed, purified, and used to immunize mice and screened for potential protective immune response. Ninety-one proteins were found to be surface-exposed and antisera raised against 29 of these included bactericidal antibodies. The genetic diversity of the most promising antigens was examined by sequencing the genes for these proteins from 31 meningococcal strains isolated in different parts of the world; candidates showing substantial sequence variation were discarded from further consideration. These

studies, discussed in further detail in Chapter 36, have resulted in 15 very promising antigens that are being further developed as vaccine candidates [1].

Reverse vaccinology identifies novel antigens not previously identified by conventional approaches and has a number of advantages. The hazards of growing large volumes of pathogenic organisms are avoided and the process can be readily applied to nonculturable organisms. Candidate antigens can be examined without the need to first establish the abundance of the antigen, determine whether it is expressed in vivo or not, develop the optimal cultural conditions for expression of the antigen, etc. The rate-limiting step is the availability and convenience of good correlates of protection, a limitation that also applies to conventional vaccine development efforts. The other limitation of reverse vaccinology is the inability to identify nonprotein antigens such as polysaccharides and the identification of CD1-restricted antigens such as glycolipids. Since the initial application of this technique to group B meningococcus, reverse vaccinology has also been successfully applied to other pathogens such as *Streptococcus pneumoniae*, *Chlamydia pneumoniae*, and *Staphylococcus aureus* (reviewed in Ref. 4). The application of reverse vaccinology to viruses could lead to the discovery of novel viral antigens other than structural proteins that are typically the target of conventional vaccine development. For example, two decades have been spent expressing every possible form of the HIV envelope protein (gp120, gp140, or gp160, etc.) or sub-domains of this protein. A genomic approach would identify potential antigens that are either not part of the final viral particle or present in such low quantities that they could not be purified and used in a conventional vaccine approach. Recent promising results using Tat, Nef, Rev, and Pol antigens in HIV vaccines suggest that development of vaccines against viruses such as HIV or HCV using a reverse vaccinology approach would be a productive approach to pursue (reviewed in Ref. 4).

### B. Epitope-Based Vaccines

Another example of in silico vaccine design on a genomic scale is a new generation of immunogens based on predictions of T-cell epitopes. The concept of using epitopes for the design of immunogens is not novel, having been the basis of vaccine candidates since the 1980s. But what is novel today is the availability in public databases of the genome sequence of most human pathogens and of the sequence of the human genome itself. This unprecedented amount of information makes possible the computational design of new immunogens based on the combination of epitopes deriving from different antigens from the same pathogen or even from different pathogens. The epitopes can be selected by a number of available algorithms that form the basis of modern computational immunology. (See Chapter 15 for a discussion of these algorithms and applications of epitope-based vaccines.) The selection not only allows the inclusion of epitopes that are predicted to be most immunogenic and to bind to most HLA haplotypes, but also allows the exclusion of those epitopes that may have some common

sequence with human sequences and that may be potential causes of autoimmunity and side effects. This powerful bioinformatics approach has been used to predict and prioritize epitopes within the genomes of several viruses, including HIV, HCV, and HBV, and even an entire bacterial genome, *Mycobacterium tuberculosis* (see Chapter 15). In those cases when helper or cytotoxic cellular immunity mediates protection (for instance, in many viral infections and cancer), epitope vaccines, delivered via synthetic peptides, recombinant proteins, or by DNA vaccination, may find practical application.

### C. In Vivo Gene Analysis

Several genomic approaches have been developed to identify genes and proteins that are expressed *in vivo* during the course of infection. The mere fact that a gene is expressed *in vivo* does not guarantee that the gene product will engender protective immunity. But the identification of *in vivo*-expressed genes, particularly those that are not expressed under *in vitro* conditions, provides novel candidate proteins that could form the basis of new vaccines or therapeutic interventions. A number of techniques have been developed to detect *in vivo* gene expression including STM, IVET, and others (reviewed in Ref. 6).

Signature-tagged mutagenesis (STM) was developed to overcome the burden of screening single transposon mutants of a bacterial pathogen individually in an animal model. In STM, a collection of transposons, each tagged with a unique 40-bp nucleotide sequence, are generated and used to mutagenize a bacterial pathogen. The transposon-tagged mutants can be distinguished from one another using DNA probes based on the unique 40-bp sequences. The mutants are then pooled and inoculated into animals. Those mutants with insertions in genes critical for *in vivo* growth or for withstanding host defenses will not be recovered from the animal after the course of infection. The output pool of mutants is hybridized to the unique 40-bp tags present in the input pool to identify those mutants that did not survive the infection. In an application of STM to *N. meningitidis*, a library of 2850 insertional mutants was tested in an infant rat model and 73 genes that are essential for bacteremic disease were identified [7]. Eight insertions were in genes encoding known virulence factors but the remaining 65 genes had not been previously implicated in the pathogenesis of disease because of this organism. Several of the gene products identified in this way are now being developed as vaccine candidates for *N. meningitidis*.

The *in vivo* expression technology (IVET) approach utilizes a library of gene fusions containing pathogen promoters fused to a reporter gene. The library is inoculated into animals, and activation of the reporter gene indicates activation of the promoter to which it is fused (reviewed in Ref. 6). The original description of IVET involved creating transcriptional fusions of random fragments of the *S. typhimurium* chromosome with a promoterless *purA* gene, a gene essential for the synthesis of purines. The library was introduced into a *S. typhimurium* *purA* mutant, which cannot survive in mice, and pools of the fusion strains are inoculated

into mice. Those strains that contain the *purA* reporter gene fused to a promoter that is active *in vivo* will survive mouse passage. After 3 days, the surviving strains were recovered and screened on laboratory media for clones with low promoter activity *in vitro*. The sequences of the *in vivo*-activated promoters were compared to the genomic sequence, and structural genes transcribed by these promoters were further characterized for their role in pathogenesis and as a potential immunogens. A further derivative of IVET, called RIVET or resolvase IVET, utilizes a promoterless *tnpR* gene encoding a site-specific recombinase (resolvase) as a reporter gene. Activation of a promoter fused to the *tnpR* gene results in excision of a fragment of DNA located between two copies of the *res* sequence, the site on which the TnpR resolvase acts. By testing for loss of a selective or differential marker encoded on the excisable fragment, *in vivo*-activated genes can be identified, even if the genes are only active early in the course of infection and repressed later during the course of infection.

Additional technologies to detect *in vivo*-expressed genes are available that do not require any genetic manipulation of strains. Microarray technology involves the extraction of mRNA from pathogens grown *in vivo* or under other specific conditions and the hybridization of the resulting cDNA to an array containing all predicted open reading frames of an organism. Those genes that are specifically expressed *in vivo* can be readily identified and further investigated as potential immunogens. Proteomics involves the separation of proteins expressed under specific *in vivo* or *in vitro* conditions using 2-D gel electrophoresis. The precise molecular mass of an isolated protein of interest is determined using mass spectroscopy (MALDI-TOF), a technology suitable for rapidly analyzing large numbers of proteins. By comparing the experimentally determined mass to the predicted masses of proteins potentially encoded on a pathogen's genome, the isolated protein can be identified. Microarrays and proteomics are powerful technologies that can rapidly examine thousands of genes and proteins for *in vivo* expression or expression within a certain cell type, e.g., macrophages. However, limitations of these techniques include the difficulty of isolating sufficient quantities of mRNA or proteins in a form free from contaminating mRNA or proteins of host cells or other organisms.

### D. Expression Library Immunization

A genomic approach to the identification of protective antigens is called "expression library immunization" (ELI) (reviewed in Ref. 3). An expression library of a pathogen's genomic DNA is constructed under control of a promoter active in eukaryotic cells in a plasmid vector capable of replication within host cells. Portions of the DNA library containing  $10^3$ – $10^4$  clones ("sibs") are used to immunize animals via gene gun or other methods used for DNA immunization, and the immunized animals are challenged with a virulent strain of the pathogenic organism. Those library portions that confer partial or complete protection from challenge are then retested with smaller numbers of clones, e.g., 500 sibs, to see which pool of clones confers

protection. By reducing the complexity of the expression library and testing for protective efficacy in a step-wise fashion, individual clones are eventually isolated that can confer immunity. Expression library immunization allows the entire genome to be tested for vaccine potential by using the animal to select the immunogenic clones. This approach allows all of the proteins encoded in a genome to be tested for protective efficacy in a systematic fashion without pre-existing bias as to which genes may encode protective antigens.

#### IV. ADVANCES IN IMMUNOLOGY

The application of biotechnology and molecular techniques has resulted in dramatic advances in our understanding of the immune system and in our ability to manipulate this system to enhance antigen presentation and processing, thereby enhancing the efficacy of vaccines. One of the most striking advances has been the development of transgenic animals with single and multiple knockout mutations in genes encoding important immune system components. A genomic approach that is producing important insights into the immune system is gene expression profiling using DNA microarrays, which allows the simultaneous determination of the expression of thousands of individual genes in response to infectious agents and vaccines. Biotechnology companies now produce a plethora of recombinant cytokines, chemokines, monoclonal and polyclonal antibodies, and other reagents that are essential components of modern immunology research. Many of these recombinant proteins and/or the genes encoding them are being exploited to enhance and direct the immune responses to antigens. Only a few major advances in this area will be discussed here, but additional details will be found in Chapter 14 and other chapters in this volume.

##### A. The Linkage of Innate to Acquired Immunity

The past few years have seen an explosion of research in the field of innate immunity. It is now widely recognized that innate immunity and the resulting inflammatory process play a key role in initiating the adaptive immune response and determining the nature of this response (see Chapter 14 [Sztein]). An adaptive immune response is initiated after cells considered to be part of the innate immune response, e.g., dendritic cells (DC) and other antigen presenting cells (APC), take up, process, and present antigens to naïve recirculating lymphocytes in secondary lymphoid tissue (e.g., regional lymph nodes). The findings on innate immunity are turning out to be instrumental in the understanding of the mechanisms of action of several adjuvants, mainly those derived from bacterial components. Cells of the innate immune system recognize a wide range of microorganisms through surface receptors (pattern recognition receptors or PRRs) that recognize invariant molecules present in diverse microbes (pathogen-associated molecular patterns or PAMPs), but not in the host. An important family of PRRs is the Toll-like receptors (TLR), which are emerging as key players in the delivery of initial signals to the immune system. Several PAMPs have been useful as vaccine adjuvants, for

example, bacterial lipopolysaccharide (LPS) interacts with TLR4 on APCs, thereby initiating the expression of inflammatory cytokines and costimulatory molecules. In addition to LPS, TLR4 is also implicated in the recognition of the heat shock protein of 60 kDa (hsp60) and of lipoteichoic acid, which have long been known for their adjuvant activity. Nucleic acids containing unmethylated CpG dinucleotides commonly found in bacteria interact with TLR9 and stimulate the innate and ultimately the adaptive immune system in a variety of ways. TLR2 recognizes several microbial components, such as peptidoglycan, bacterial lipoproteins, and zymosan. It is likely that the strong adjuvant activity of complete Freund's adjuvant, which contains mycobacteria, and of monophosphoryl lipid A (MPL), derived from the bacterial cell wall, may be at least partly explained by the interaction with TLR2.

It is now recognized that activation of PRRs profoundly affects the behavior of many cell types, modulates the type of adaptive immune response induced, and recruits macrophages, neutrophils, lymphocytes, and other cells to the inflammatory site (see Chapter 14).

TLR-PAMP interactions on the surface of DCs play a critical role in the induction of adaptive immunity by upregulating the expression of costimulatory molecules required for the activation of naïve T cells specific for antigenic peptides expressed on the same DCs in conjunction with MHC molecules. The new information resulting from research in this area plus the numerous recombinant cytokines and other reagents now available allows a more "tailor-made" approach to generating immune responses to vaccines.

##### B. Lymphokines and Other Immunomodulators

Numerous cytokines, chemokines, and other immunomodulatory factors have been produced in large amounts using recombinant DNA techniques and co-administered with antigens to improve or modulate the immune response at various points in the generation and maintenance of the immune response. A complementary approach is to couple or otherwise co-administer genes encoding these proteins with genes encoding the desired antigens to modulate the response (see Chapter 20). These genes can be introduced via DNA immunization or incorporated into bacterial or viral vector vaccines. For example, a key branch point in the immune response is the Th1 vs. Th2 response. Co-administration of IFN- $\gamma$ , IL-12, or IL-18-encoding plasmids has been shown to enhance the induction of Th1 responses while co-administration of IL-4, IL-5, IL-10, and IL-13 enhances a Th2 response. When cytotoxic T lymphocyte (CTL) responses are desirable, administration of a broad array of cytokines, including IL-2, IL-12, IL-15, IL-18, and GM-CSF, has been shown to enhance this outcome. A number of costimulatory and adhesion molecules, including CD80 (B7-1), CD86 (B7-2), CD40 ligand, ICMA-1 (CD54), and LFA-3, have also been shown to increase CTL responses. Co-immunization with a variety of CCR7 ligands such as IL-8, IP-10, MIP-2, RANTES, MCP-1, MIP-1 $\alpha$ , MIP-1 $\beta$ , and others can yield a variety of results including increased antibody production, enhanced T-cell-mediated immunity,

and increased numbers of DC in secondary lymphoid tissues. Further discussion of the ability of these and other factors to modulate the immune response is presented in Chapter 20.

Numerous adjuvants are now under study to enhance immune responses (see Chapters 18, 19, 20, and 21). The currently licensed adjuvants and the vast majority of those under investigation are used for parenteral administration. Because of intrinsic anatomical characteristics and by serving as the portal of entry of most pathogens, mucosal surfaces represent ideal sites for vaccine delivery. Several live-attenuated vaccines (e.g. polio, *Salmonella* and *V. cholerae* vaccines) are given orally. However, nonreplicating, purified antigens are poorly immunogenic when delivered mucosally and may even induce a state of tolerance. The best mucosal immunogens are those with an inherent ability to attach to epithelial cells, e.g., *Escherichia coli* heat-labile enterotoxin (LT), cholera toxin (CT), bacterial fimbriae, etc. Heat-labile enterotoxin and cholera toxin have been shown to be potent mucosal adjuvants but are unsafe to use as oral adjuvants. Mutants of LT and CT have been engineered to “genetically detoxify” the A subunit, which is responsible for the ADP-ribosylation activity of the holotoxin ultimately leading to diarrhea, while retaining the intact B subunit, which is responsible for binding of the holotoxin. Mutant toxins such as LTK63, LTR72, and R192G retain adjuvant activity and are currently being evaluated with a variety of antigens (see Chapter 21). Interestingly, wild-type CT and LT toxins have potent adjuvant activity when administered by transcutaneous immunization and are currently being clinically evaluated (see Chapter 34).

### C. Improved Responses to T-Independent Antigens Via Conjugate Vaccines

Production of antibodies to most nonprotein antigens, such as glycolipids, nucleic acids, and polymeric polysaccharides, does not require help by cognate T cells and are therefore referred to as thymus-independent (TI) antigens (reviewed in Chapter 14). Bacterial capsular polysaccharides are important TI antigens and for several invasive pathogens, such as *Haemophilus influenzae*, *N. meningitidis*, *Streptococcus pneumoniae*, the surface polysaccharides are crucial protective antigens. Initial vaccines containing the polysaccharide from *H. influenzae* b (Hib) were effective in older children but were poorly immunogenic in infants, a critical target population for vaccines against. Research into this discrepancy revealed that TI antigens could be subdivided depending on whether they are able (TI-1) or not able (TI-2) to induce immune response in neonates. It was further determined that by coupling polysaccharides, which are TI-2 antigens, to T-cell-dependent protein antigens such as diphtheria toxoid or tetanus toxoid, strong anti-polysaccharide antibodies could

be elicited in infants. This realization led to the development of polysaccharide-protein conjugate vaccines that have resulted in dramatic decreases in Hib disease, as reviewed in Chapter 37. Conjugate vaccines have also been developed and are now licensed for *N. meningitidis* (see Chapters 36 and 37), *S. pneumoniae* (see Chapter 38), and *Salmonella* Typhi (see Chapter 40). The breakthrough in understanding how TI-2 antigens can be manipulated to improve immunogenicity is one of the most important advances in recent bacterial vaccine development.

## V. CONCLUSION

There have been tremendous technical advances in vaccine development over the last two decades, particularly in molecular aspects. Indeed, current limitations and problems in vaccine development are rarely due to technical constraints but are usually due to an incomplete understanding of the biological system, including aspects of both the host and the pathogen. The major limitations in the development of many vaccines are the lack of suitable animal models and immune correlates that accurately predict protection in humans, limitations that have plagued us for decades. Indeed, vaccines have been developed that can protect mice against nearly any infectious disease but translation of the successes in mice into human protection has been problematic for many vaccines. Here, too, technology will play an important role in the development of transgenic animals that may more accurately predict efficacy in humans. With continued improvements in our understanding of the immune system and the pathogenesis of disease due to infectious agents, the current “golden era” of vaccine development will continue for the foreseeable future.

## Initial Clinical Evaluation of New Vaccine Candidates: Investigators' Perspective of Phase I and Phase II Clinical Trials of Safety, Immunogenicity, and Preliminary Efficacy

**Carol O. Tacket, Karen L. Kotloff, and Margaret B. Rennels**

*University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.*

### I. INTRODUCTION

Among the tools available to control infectious diseases, vaccines rank high in effectiveness and economic feasibility. Vaccines once consisted of either live whole virus analogs or killed virus preparations. Now new viral, bacterial, and parasitic vaccines are frequently defined by gene sequences or amino acid epitopes. Likewise, vaccine testing has progressed to become a discipline of its own, which includes scientific, epidemiological, ethical, and feasibility aspects. This chapter deals with some of these issues related to Phases I and II vaccine testing.

### II. SELECTION OF VACCINE CANDIDATES

Creative and innovative vaccine candidates emerge from research laboratories in academic institutions, government agencies, and private pharmaceutical and biotechnological companies all over the world. The decision to begin human testing of a candidate vaccine depends on a number of criteria.

First, the vaccine candidate must address a public health need and be a logical means of control for the disease of interest. For example, in the United States, outbreaks of *Cryptosporidium parvum* may be best prevented by improved water treatment rather than by vaccination. Similarly, infections with Shiga toxin producing *Escherichia coli* can be best prevented by improved meat inspection and consumer education about cooking practices, rather than by mass vaccination of children.

Second, the vaccine candidate must have been designed with a sound scientific rationale. There are two mirror-image principles commonly used to develop vaccines. On the one hand, the vaccine may consist of a known or suspected protective antigen, for example, purified hepatitis B surface antigen or *Hemophilus influenzae* type b polysac-

charide. Alternatively, the vaccine may be a live strain of a pathogen attenuated by genetic deletion of known virulence factors, for example, live oral cholera vaccine CVD 103-HgR.

Third, there must be an expectation of safety. The risk/benefit ratio for vaccines against most infectious diseases must be very low since such vaccines are designed for use in healthy individuals who may be at low risk of disease. In contrast, in the development of therapeutic agents, a larger risk may be acceptable since there is the opportunity for therapeutic benefit. Safety of the vaccine candidate, therefore, must be formally demonstrated in an appropriate animal model using a dose and route of administration which is proposed for clinical studies.

Fourth, there must be animal studies demonstrating the immunogenicity of the product when given in the appropriate dose and by the appropriate route and, if possible, a demonstration of efficacy against challenge with the wild-type pathogen in animals. Animal models to demonstrate immunogenicity and efficacy against challenge have been developed for a number of vaccines, e.g., cotton rats for respiratory syncytial virus and mice for *Salmonella*.

Fifth, it is desirable that the vaccine be prepared in a practical formulation at the onset of Phase I studies. This is not an absolute requirement since it is often necessary to first establish the safety and immunogenicity of a prototype vaccine in a preliminary formulation. However, changes in responses to vaccine can be observed when scale-up manufacturing is done or practical formulations are produced [1,2].

Finally, the last consideration is one of commercial development. In a free market, public health need and scientific rationale supporting the likelihood of success of a candidate vaccine will increase the chances that a new vaccine will attract the financial resources needed for its development to licensure and use as a public health tool.

### III. GENERAL DESCRIPTION: PHASES OF CLINICAL TRIALS

The clinical investigation of a new candidate vaccine progresses in three phases. Although these phases are usually conducted sequentially, they may overlap. A Phase I trial is the first human use of the vaccine candidate in healthy volunteers. Participants in Phase I studies are typically closely monitored. These studies are designed to determine the frequently occurring, short-term side effects and the dose response to a candidate vaccine. In a Phase I vaccine study, the immune response to the vaccine is measured; the analogous information in a similar study of a drug would be its pharmacological characteristics in a small number of subjects. The information generated in Phase I about the vaccine's safety profile and immunogenicity should be sufficient to design expanded studies of safety and immunogenicity in Phase II.

Phase II studies are controlled, closely monitored studies of safety and immune response in an expanded number of subjects, perhaps several hundred. Some individuals who participate in Phase II studies may represent the target population for which the test vaccine is intended. For example, infants or elderly subjects may be enrolled if the vaccine candidate is intended for ultimate use in these populations. Multiple Phase II studies are often conducted to develop a database to direct the design of Phase III studies.

The development of a vaccine candidate can be accelerated if there is a human challenge model for the disease against which the vaccine is directed. This allows a preliminary assessment of vaccine efficacy (so-called Phase IIb) by comparing disease attack rates in vaccinees and unvaccinated control volunteers. These challenge studies can be ethically justified if they are conducted by qualified investigators with rigorous adherence to a scientifically valid protocol with clear safeguards for the volunteers [3,4]. It should be recognized that such challenge studies represent experimental models and may not exactly reproduce the disease as it occurs in an endemic area. For example, the inoculum used for challenge for diarrheal illnesses such as cholera and enterotoxigenic *E. coli* is probably higher than what occurs commonly in nature. This is to ensure that the attack rate among challenged volunteers is high enough to achieve statistical differences when comparing small numbers of vaccinated and unvaccinated individuals. However, the experimental challenge model is designed so that the challenge is not so rigorous as to overcome immunity; often the model has been tested by establishing that immunity induced by primary challenge-induced infection is not overwhelmed by a second challenge with the same pathogen [5]. This level of immunity, i.e., immunity after primary infection, is often the gold standard for immunity induced by vaccination. At the Center for Vaccine Development, University of Maryland, challenge models have been applied to testing vaccines against cholera, diarrheagenic *E. coli*, *Shigella*, Rocky Mountain spotted fever, malaria, influenza, and typhoid fever.

If acceptable safety and immunogenicity are observed during Phase II, Phase III studies are planned to evaluate

efficacy. Generally, a Phase III study is a double-blind, controlled study of the new vaccine in a more heterogeneous population, under conditions more closely resembling those under which the vaccine may eventually be used. The study may include as a control group either a true placebo, a licensed vaccine against another disease, or another licensed or experimental vaccine against the same disease. In a Phase III study, the rate of occurrence of side effects that occur infrequently may be measured more accurately. Defined endpoints must be chosen and a hypothesis must be stated. A sample size should be chosen based on assumptions of the expected incidence of disease and the reduction in disease incidence that is anticipated in vaccinees. A pivotal study is a Phase III study which provides the most convincing data supporting the licensure of the vaccine. The pivotal protocol must be rigorously designed and analyzed with impeccable statistical considerations.

After Phase III studies demonstrating the safety and efficacy of the vaccine candidate, the sponsor of the vaccine who will market the product in the United States submits a Biologic Licensing Application (BLA) to the Food and Drug Administration (FDA). Approval requires that the safety and efficacy be demonstrated in well-designed, controlled studies. Once the application is approved, the vaccine may be sold commercially for the specific indication. After the BLA is approved, FDA requires that the holder of the BLA conduct postmarketing surveillance and submit periodic reports including incidence of adverse reactions and follow-up of ongoing Phase III studies. These data are generally descriptive in nature. After marketing approval, additional formal studies may also be designed to continue to measure efficacy and side effects. These studies, termed Phase IV studies, may detect previously unknown, rare adverse reactions among recipients of the marketed vaccine.

### IV. FACILITIES

In general, facilities for vaccine testing include clinical office space for interviews for screening, obtaining consent, and conducting follow-up procedures, facilities for specimen collection and storage, and emergency equipment for treating anaphylactic reactions. The majority of studies can be conducted in an outpatient facility. In Phases I and II studies of vaccines, unlike drug studies, participants usually take only one to three doses of the experimental agent. Many early studies of new vaccines require that signs and symptoms be recorded for a relatively short period after vaccination and that a limited number of blood tests be obtained to measure immune response over a period of weeks to months.

The intensity of surveillance depends on the type of vaccine and the anticipated nature and incidence of side effects. Phase I studies of live vaccines in adults are usually conducted in an inpatient facility to collect preliminary safety data and to determine the excretion of vaccine and potential for person-to-person transmission. For example, the degree of attenuation of some live enteric vaccines is unknown; these must be given under close inpatient supervision [6,7]. Live vaccine studies may require frequent col-

lection of stool samples or respiratory secretions for culture. In addition, for studies requiring very intense surveillance or frequent collection of specimens, inpatient studies may be required to ensure that every event (e.g., fever) is detected and recorded and to ensure compliance with collection of every specimen. For example, live oral *Salmonella enterica* serovar Typhi vaccine strain CVD 906 was found to be insufficiently attenuated and to cause symptoms of typhoid fever in some inpatient volunteers [8]. Concerns about the release of genetically engineered organisms into the environment before their preliminary safety and potential for person-to-person transmission have been established require that some studies be conducted on a closed isolation ward with strict contact isolation measures.

In the United States, the National Institute of Allergy and Infectious Diseases supports several Vaccine Treatment and Evaluation Units at academic institutions. Some of these centers have access to inpatient units where volunteers can be housed for intensive surveillance and specimen collection.

In studies of experimental vaccines in children and infants, surveillance for adverse effects and collection of specimens is carried out in an outpatient setting. Telephone interviews with parents or guardians, collection of questionnaires filled out by parents, and review of medical records are means utilized to collect safety information. Children return to the clinic or physician's office for blood drawing or collection of respiratory secretions. Collection of stools can be accomplished either by instructing the caretaker to bring in soiled diapers or by sending a messenger to the home. Day-care settings can be arranged for studies in which it is necessary to collect extensive clinical data or multiple specimens. The children are observed during the day by nursing staff, and they return home in the evening where the parents continue surveillance. This arrangement is sometimes optimal for Phase I studies of live, attenuated vaccines.

## V. REGULATORY ISSUES

### A. History of the Regulation of Vaccine Development

The ancient Egyptians and Hebrews had strict meat handling laws, and later, ancient Greeks and Romans had regulations prohibiting the addition of water to wine. In the Middle Ages, grocers and druggists had trade guilds which prohibited adulteration of drugs and spices. In the United States, there have been laws governing the size of a loaf of bread and prohibiting the adulteration of bread; in 1785, the first comprehensive food adulteration law was enacted in the United States.

In 1938, the Federal Food, Drug, and Cosmetic (FD&C) Act was enacted in response to a number of deaths caused by the use of diethylene glycol (antifreeze) as the vehicle for an elixir of sulfanilamide. This act required sponsors of Investigational New Drugs (IND) to submit safety data about the candidate product before premarket approval. The turning point for modern regulatory affairs was the passage in 1962 of the Kefauver–Harris Amend-

ments to the FD&C Act. The 1962 amendments required that efficacy data, as well as safety data, be submitted to support IND applications. These amendments followed shortly after the discovery that thalidomide caused birth defects. Although thalidomide was never approved in the United States, it was being used extensively in research. Before the 1962 amendments, there was no requirement that FDA be notified of the use of investigational drugs or regulate their use. Today, sponsors of new vaccines must submit both safety and effectiveness data to support the application. Since these data are gathered through clinical investigations, all sponsors must prepare an IND application and follow a set of principles known as Good Clinical Practice (GCP).

In the United States, when Congress passes a law, the regulatory agency involved writes the regulation and is responsible for enforcing the law. The Code of Federal Regulations (CFR) contains these regulations. Title 21 of the CFR deals with food and drugs, and Title 45 Part 46 deals with protection of human subjects. These regulations give specific directions for all individuals—sponsors, monitors, and investigators—involved in a vaccine trial. The following parts of Title 21 are relevant to clinical investigations of vaccines:

- Part 50 (informed consent).
- Part 56 [Institutional Review Boards (IRBs)].
- Part 312 (Investigational New Drug applications).
- Part 601 (licensing).
- Part 814 (premarket approvals).

### B. Good Clinical Practice

Good Clinical Practice is the set of federal regulations and guidelines for clinical trials which will support an eventual application for licensure of a new vaccine or drug. Good Clinical Practice is designed to ensure the quality and integrity of clinical data and to protect the rights and safety of volunteers. Good Clinical Practice guidelines are described in detail in numerous internet sites from various agencies, including the U.S. Department of Health and Human Services Office for Human Research Protection (OHRP), U.S. Food and Drug Administration (FDA), U.S. Army, U.S. Centers for Disease Control and Prevention, the International Conference on Harmonization (IHC), and others. These websites are listed in Table 1. These regulations are comprehensive, including protocol design and development, informed consent guidelines, record keeping, data reporting, adverse event reporting, etc.

### C. Elements of an Investigational New Drug Application

The components of an IND application are described in 21 CFR Part 312. An IND is filed for a vaccine that has never been approved in the United States, for a new dose, route, or schedule of administration of an approved vaccine, or for a new indication of an approved vaccine. The application includes a completed and signed form FDA 1571, which is

a master administrative document with a table of contents that serves as a check list for the elements of the application. The signature of the sponsor indicates that that sponsor agrees to conduct the investigation in accordance with all applicable regulatory requirements, specifically, to wait 30 days after the FDA receives the IND before beginning the study, not to conduct the study if the study is placed on clinical hold, and that an Institutional Review Board (IRB) will review and approve the study.

After the form 1571, there is an introductory statement about the vaccine's characteristics, a general investigational

plan, an investigator's brochure, and the clinical protocol. Form FDA 1572 and the curricula vitae of the investigators are included. The form 1572 is a contract between the clinical investigator and the federal government to assure one's compliance with 21 CFR 312, involving adherence to protocol, use of informed consent, record keeping, reporting, etc. Next are sections on chemistry, manufacturing and control information, pharmacology and toxicology information, and previous human experience. As the development of the vaccine progresses, the IND application is supplemented with protocol amendments, new protocols,

new investigators, safety reports, information about microbiology or toxicology, and annual reports.

#### D. Obligations of Sponsors

The sponsor of a clinical investigation is the person who has assumed responsibility for compliance with the FD&C Act and FDA regulations and guidelines. The sponsor submits and maintains the IND application. Not until the IND has been prepared can the investigational product be shipped for the purpose of conducting clinical trials. A sponsor who both initiates and conducts a clinical investigation is called a "sponsor-investigator." The specific legal responsibilities of the sponsor, contained in 21 CFR, include selecting investigators, providing adequate information to investigators, monitoring investigations, ensuring compliance with proper IND procedures, and informing FDA and the investigators of any adverse effects or risks of the product being studied. Sponsors may transfer all or part of their obligations to a contract research organization.

#### E. Obligations of Monitors

The monitor of a clinical investigation confirms that the study is conducted according to the protocol developed by the investigator and sponsor and according to the FDA regulations. This is accomplished by meeting with the investigator and the research staff before a study begins and confirming the adequacy of the investigator's facilities. The monitor makes periodic reviews of the investigator's source documents, case report forms, and required reports. Problems with the study must be documented and corrective actions must be taken.

#### F. Obligations of Investigators

Similarly, an investigator's responsibilities are contained in the FDA regulations. An investigator's agreement to conduct an investigation in accordance with regulations and with the clinical protocol is documented when the investigator signs a form FDA 1572 which is filed with the IND application. In summary, the investigator must obtain IRB approval for the protocol, the consent document, and recruiting materials used to identify volunteers. The investigator must obtain approval for study amendments and file regular reports with the IRB. The investigator must keep immaculate records and must report serious and unexpected adverse events to the sponsor and the IRB. The investigator must administer the vaccine and maintain records accounting for the product disposition. The investigator is responsible for educating the volunteers and obtaining written informed consent before volunteers become involved in the study. The investigator is obligated to store records and allow FDA representatives to inspect the study records.

In 2000, the U.S. National Institutes of Health (NIH) issued a directive requiring that federally funded clinical researchers provide evidence of training on the protection of human research participants and on Good Clinical Practice. An online tutorial for NIH intramural investigators was offered as an example (<http://ohsr.od.nih.gov>).

#### G. Institutional Review Boards

An Institutional Review Board is a group designated by an institution to review and approve biomedical research involving humans. IRBs are responsible for the well being of subjects involved in clinical trials. The board includes at least five members, at least one who is not a scientist and one who is not affiliated with the institution. The IRB reviews protocols, investigator's brochures, consent forms, recruiting materials, and additional safety information. The membership of an IRB, standard operating procedures, review of research, voting, and quorums are defined in Part 56 of 21 CFR.

#### H. Record Keeping and Product Accountability for Clinical Trials

Compulsive record keeping is an important component of Good Clinical Practice. Recently, the need for privacy and protection of medical records has led to new regulations under the Health Insurance Portability and Accountability Act of 1996. Under these new complex regulations, restraints on the use of medical information for research were imposed in 2003. The new privacy rules are under debate as regulators attempt to balance the public interest in research with the public interest in privacy [9,10].

Both investigators and sponsors should retain the same records. Case report forms are uniform at all the sites conducting the study and allow the sponsor to look at the same information in the same format from different sites. The case report forms may be used for data entry and analysis and should be designed to efficiently capture the data points that precisely correspond to the aims and endpoints of the protocol. "Source documents," those records on which the information about a participant is first recorded, may be used for some studies. The type of information to be collected may vary with the protocol, but, in general, it would include subject identification, protocol name and number, sponsor's name, date of participant's visit, procedures and tests completed, concomitant medications, occurrence of adverse experiences, and the name of the person entering the information and the date. Corrections to the study records must be initialed and dated.

In 1997, the U.S. FDA established regulations about the use of electronic records in clinical trials (21 CFR Part 11). The regulations permit use of electronic signatures. Investigators now have the option of maintaining records as paper or electronic files. The electronic record must provide an audit trail, i.e., a record of who enters or changes data and when [11]. Teleforms for electronic database entry and on-line case report forms are likely to replace paper forms in the future. The FDA guidelines can be found at [http://www.fda.gov/ora/compliance\\_ref/part11/](http://www.fda.gov/ora/compliance_ref/part11/).

Investigators usually develop a protocol-specific quality management plan to ensure the correctness of the data collected. A sponsor should have a policy about monitoring case report forms which indicates how frequently forms are to be monitored and how intensively. Monitors compare source documents with case report forms, looking for inconsistencies, errors, and appropriate signatures.

In addition to maintaining clinical records, investigators are required to maintain records for the receipt and disposition of all the experimental product. The records should include the name of the material, its IND number, its condition, the lot number, date, and source. Records should show the name of persons who received the study vaccine and what was done with extra doses. Each dose must be accounted for. To assure that the experimental product is not tampered with, vaccine materials should be stored in a secure refrigerator, freezer, or cabinet.

### I. Reporting Adverse Experiences

The NIH has recently developed policies for safety monitoring of all studies that evaluate investigational drugs and biologics. This policy on Data and Safety Monitoring can be found at <http://grants.nih.gov/grants/guide/notice-files/not98-084.html> released in 1998 and Further Guidance on Data and Safety Monitoring for Phase I and Phase II Trials issued in 2000 at <http://grants.nih.gov/grants/guide/notice-files/NOT-OD-00-038.html>. These policies require that there is a system for oversight and monitoring of clinical trials. The mechanism of oversight depends on the risk and complexity of the trial and may be a full Data and Safety Monitoring Board, a safety committee, or an individual independent safety monitor.

Food and Drug Administration regulations require investigators to report all adverse experiences to the sponsor of a study. If the experience is serious or unexpected, the event must be reported promptly to both the sponsor and responsible IRB. A serious adverse experience is “any experience that is fatal or life-threatening, is permanently disabling, requires or extends inpatient hospitalization, or is a congenital anomaly, cancer, or overdose.” An unexpected adverse experience is “any adverse experience that is not identified in nature, severity, or frequency in the current investigator brochure; or, if an investigator brochure is not required, that is not identified in nature, severity, or frequency in the risk information described in the general investigational plan or elsewhere in the current application” (21 CFR 312.32). As a general rule, many sponsors require investigators to report all adverse experiences even if the event is not apparently related to the vaccine. The investigator must keep a record to indicate the treatment and outcome of the adverse experience.

### J. Regulatory Considerations in International Trials

International trials are of particular significance in vaccine development, in which the ultimate target population may be individuals in a country other than that in which the vaccine was manufactured. Such trials may reveal differences in safety, immunogenicity, and efficacy when the vaccine is studied in a new population. For example, a live oral cholera vaccine was less immunogenic when given to Thai adults than to U.S. adults [1], and oral polio vaccine was less immunogenic in children in a developing country [12]. The experimental vaccine may or may not be studied under U.S. IND. If not, the vaccine must be manufactured outside the

United States. Several provisions must be met for the U.S. FDA to accept data from an international trial. These include the following: (i) the data must be applicable to U.S. populations; (ii) international investigators must be competent; (iii) the protocol must be reviewed for ethical considerations; and (iv) the site must be available for FDA inspection.

In studies in foreign countries, the same standards that apply to studies in the United States should be used [13]. The research should be developed in close collaboration with local investigators and other authorities in the country in which it will be performed [14]. The FDA does not require that case report forms or source documents be completed in English, but a translator may be required if the site or records are inspected. Local customs may affect several aspects of the trial, such as the means of obtaining and documenting informed consent and the recognition and reporting of the types of experiences that are considered adverse events.

## VI. PROTOCOL DEVELOPMENT

### A. General Considerations

The success of a vaccine trial in Phase I or Phase II is largely predicted by the quality of the protocol. According to the CFR, a protocol must contain the following components: (i) a statement of the purpose and objectives of the study; (ii) the name and address of the investigator, the name and address of the research facilities, and the name and address of the reviewing IRB; (iii) a statement of the number of participants and the inclusion and exclusion criteria for participating; (iv) the study design, including the type of control group, if any; (v) the dose to be given and the method for determining the dose; (vi) a description of the outcomes to be measured; (vii) a description of the measures to be taken to monitor the participants and to reduce risks.

In addition, many protocols contain a discussion of the scientific background and rationale to place the study in context. It is important to include information about the disease, its clinical nature and epidemiological importance, and whatever is known about the elements of protective immunity. This is useful in justifying the need for the study and risk to volunteers.

The type of study, e.g., controlled, double- or single-blinded, and the method of randomization, if any, should be included. Outcomes to be observed need to be clearly described; objective definitions of outcomes are highly desirable. Definitions of safety (e.g., degree of temperature that defines fever) and immunogenicity (e.g., definition of seroconversion) need to be clearly decided and documented during protocol development. A justification for the dosage should be provided. The means of monitoring patients and contingencies for handling side effects should be described.

Protocols include a section describing the statistical tests to be used to analyze the results and a section to justify the sample size chosen. In Phase I studies, however, it is not always possible to detect statistically significant differences between groups because of the small numbers of participants.

## B. Considerations for Studies Involving Children and Infants

In designing a protocol to be carried out in children, additional considerations are required. In 1998, NIH issued a Policy and Guidelines on the Inclusion of Children as Participants in Research Involving Human Subjects, providing guidance on inclusion of children and justification for exclusion of children in research funded by NIH. In considering the inclusion of children in vaccine studies, the first decision to be addressed is the age group to be vaccinated. The answer depends upon the age at which children are at risk for the infection the vaccine is designed to prevent. For most pathogens, it is optimal to provide protection as early in life as possible. However, the presence of small amounts of maternal neutralizing antibody may inactivate some live viral vaccines, such as measles vaccine, requiring that immunization be postponed to a later age. Usually, pediatric vaccine development proceeds in older children and progresses stepwise to younger children until the target age group is reached.

Early infancy is a time when children receive multiple routine vaccinations. An important issue is whether or not to give an experimental vaccine at the same visit with licensed vaccines. Frequently, Phase I studies will dictate a 4-week separation between the study vaccine and any other vaccinations to avoid either confounding the safety data or inducing immune interference with simultaneously administered vaccines. To be logically practical and economically feasible, new vaccines should eventually be incorporated into the routine vaccination schedule of infancy. Therefore the effects on safety and immunogenicity of concurrent immunization should be evaluated in Phase II studies. The number of doses of vaccine to be administered must also be determined. Two or more doses are often necessary to overcome maternal antibody or to induce priming. This issue is most commonly addressed by giving two or three doses and measuring antibody levels before and after each immunization. The necessity, practicality, and ethics of including a placebo group should also be carefully weighed.

In designing a protocol for pediatric studies, one must carefully balance the need to be minimally invasive but to collect all necessary data. This sometimes requires compromises. The most difficult aspect of carrying out a successful pediatric vaccine trial is the recruitment of sufficient numbers of children. Parents are protective of their children and will refuse to enroll their child or continue to participate in a study that they perceive is too invasive or requires undue discomfort for their child. The number of times that specimens are sampled, therefore, should be kept to a minimum.

## C. Considerations for Vaccines Prepared by Recombinant DNA Technology or Containing Recombinant DNA

The development of attenuated viral and bacterial strains for use as vaccines was one of the obvious applications of the techniques for recombining DNA discovered in the 1970s. Before this time, live viral [15] and bacterial [16] vaccine strains were developed by repeated *in vitro* passage or by

chemical mutagenesis, techniques that resulted in undefined mutations. Nevertheless, live vaccines against diseases such as measles, mumps, rubella, and typhoid fever were developed and licensed. Recombinant DNA technology offered the means to develop attenuated vaccines in which the precise molecular mechanism of attenuation could be known.

Despite the precision of molecular DNA techniques, vaccines developed using recombinant DNA were thought by some to be threatening to the natural environment. To document the potential for environmental consequences of vaccinating humans with such vaccines, sponsors are required to include an environmental analysis (21 CFR 312.23) which includes justification for a claim for categorical exclusion or an environmental assessment. Such justification might include data showing the survivability of the vaccine strain in various natural environments such as local water, soil, and food, especially in comparison with the wild-type pathogen [17]. Phase I protocols to study the safety of recombinant vaccines generally contain provisions for studying the potential for person-to-person transmission of these strains.

## D. Considerations for Vaccines that Can Be Transmitted Person-to-Person

Many of the currently used live bacterial and viral vaccines are shed in respiratory secretions (e.g., live attenuated influenza vaccine) or stool (e.g., polio vaccine) and are potentially transmitted person to person [18]. Transmission of oral polio vaccine was considered desirable in the early years of its use since such transmission led to herd immunity [19]. Transmission to pregnant women or immunocompromised individuals is now recognized as a risk of the use of live vaccines which can be spread from person to person, e.g., transmission of vaccinia virus or its recombinant virus to an individual with eczema can result in severe vaccinia infection [20].

As a result of this concern, many Phase I and Phase II clinical protocols include preliminary measurements of the potential for person-to-person spread of live vaccine candidates. Initially, this may require that the vaccine strain be studied in isolation until a gross assessment of its transmissibility is established, for example, among unvaccinated adults residing with vaccinees on a research isolation ward. Examples of such studies to assess person-to-person transmission include studies of *Salmonella typhi* vaccine strain CVD 908-htrA [21] and of a recombinant vaccinia virus expressing gp160 of HIV [22]. In Phase II, volunteers who reside with infants, pregnant women, or immunocompromised individuals may be excluded because of the possibility of transmission of a vaccine strain whose safety is not completely established. Phase II studies of transmissibility might include cultures of the stool or respiratory secretions of household contacts of vaccinees and, in later phases, attempts at vaccine isolation from environmental reservoirs such as sewage.

The testing of live oral cholera vaccine strain CVD 103-HgR (Mutacol®, Orochol®, Berna Biotech) is a good example of how such testing is executed. This *V. cholerae*

O1 strain is deleted in 94% of the toxic A subunit of cholera toxin [23]. In Phase II clinical studies, the possibility of transmission of this strain to contacts of vaccinees and to the environment around the households of vaccinees was investigated [24,25]. In brief, this strain was shed for a short period by only a small proportion of vaccinees, was minimally transmitted to contacts of vaccinees, and was not recovered from the natural environment near vaccinees.

## VII. SELECTION OF VOLUNTEERS

### A. General Considerations

Initial Phase I studies of candidate vaccines generally involve healthy adult volunteers, i.e., those who have no abnormality that would confound the interpretation of the safety of the product or increase the likelihood of their having an adverse event. Healthy volunteers may be recruited from the community at large or from interested students or employees at research institutions. Students and employees can be a vulnerable population, however, and care must be taken to ensure that there is no element of pressure or coercion to participate. In addition, some protocols may have a seroeligibility requirement, usually the absence of serum antibody to a particular antigen. Rarely, a protocol may specify that only individuals of a certain HLA type may participate, when preclinical data indicate that immune responses will be restricted to a certain genotype [26]. The protocol generally indicates what tests must be performed to establish the volunteers' health. For example, some or all of the following may be done: medical history, physical examination, complete blood count, serum chemistries, urinalysis, HIV serology, and pregnancy test. Formerly, women of childbearing potential were sometimes precluded from participation. However, in 1993, Guidelines for the Study and Evaluation of Gender Differences in the Clinical Evaluation of Drugs were issued stating that women be included provided that appropriate precautions against becoming pregnant are taken and that women are counseled about the importance of these precautions. Efforts should be made to ensure that women participants are not pregnant at the time of enrollment and that women are informed about animal reproduction studies and teratogenic potential of the vaccine. Generally, however, such data are not available for experimental vaccines. In 2000, NIH issued Guidelines on the Inclusion of Women and Minorities as Subjects in Clinical Research [http://grants.nih.gov/grants/funding/women\\_min/guidelines\\_update.htm](http://grants.nih.gov/grants/funding/women_min/guidelines_update.htm)). In 2001, the U.S. Department of Health and Human Services released additional protections pertaining to research in pregnant women <http://ohrp.osophs.dhhs.gov/humansubjects/guidance/45cfr46.htm>). In these additional regulations, there must be direct benefit to the woman or fetus as a result of the research or there must be only minimal risk to the fetus, and the new information learned in the research cannot be obtained in any other way.

Phase II vaccine studies also involve healthy adults. Once preliminary safety has been established in the Phase I study, the screening to demonstrate the health of volunteers may be less rigorous. For example, the following may be

done: medical history, complete blood count, HIV serology, and pregnancy test.

### B. Considerations for Studies Involving Children and Infants

Pediatric vaccine trials are carried out in healthy children who have no personal or family history of immune deficiency. The exception to this would be a vaccine targeted for a particular population, such as a *Pseudomonas* vaccine for children with cystic fibrosis. Screening of healthy children generally involves only medical history and physical examination. Specific baseline data may be collected if there is specific concern about the potential vaccine side effects; for example, liver function tests are performed if a live viral vaccine might cause hepatitis.

Transmission of live viral vaccine strains to contacts through the stools or respiratory secretions is a particular concern in studies involving young children. Until it is demonstrated that the vaccine virus is not transmitted, initial live viral vaccine studies should not include children attending group day care or children residing in a household with an immunosuppressed individual.

Recruitment of children into vaccine trials is usually carried out through outpatient settings providing well child care, such as private practices, hospital clinics, and health maintenance organizations. The optimal method of approaching families varies depending upon the population served and the setting. In many centers, a study nurse and/or investigator approach the parent or guardian on the day they wish to enroll the child. Sending literature to the parents before the vaccine visit provides an important opportunity for the family to discuss the study and to contact the study personnel by telephone for further information before they must make the decision whether or not to participate.

## VIII. CONSENT

### A. General Considerations

The FDA regulations concerning informed consent are contained in 21 CFR Part 50. Consent is not an endpoint but a continuing communication between participant and investigator during which the participant receives all the information needed to participate in the study. The process should include ample opportunities for the free exchange of information and for the participant to ask questions. Consent should be obtained under circumstances that give the potential participant the opportunity to carefully consider the decision to participate with no coercion or undue influence. Such features as the place, the time, and the person who provides the information may affect a subject's ability to make an informed judgment.

The principles of informed consent include the following: (i) the purposes, procedures, and experimental nature of the protocol are described fairly; (ii) the discomforts and risks to be expected are described; (iii) information about appropriate alternative procedures (for vaccine studies, this might be information about the existence of a licensed vaccine for the same disease); (iv) information about whom

to ask for further information; and (v) the statement that an individual is free to withdraw his consent and discontinue participation without prejudice.

It is important that the information provided be understandable to the participants. This means that the information must be presented in the participant's language and that technical and medical terms must be explained or replaced with lay terms appropriate to the participant's level of education. Often a consent form can be simplified by using short, declarative sentences. In addition, the consent document should not include statements that release the investigator from responsibility or that waive the volunteer's rights. Consent must be documented in writing.

The FDA requires that the IRB review and approve the advertisements and other materials used to recruit participants. Recruiting materials are considered an extension of the consent process. These materials, such as advertisements and fliers, should not be misleading. The FDA recommends that the advertisement include only the following: (i) name and address of the investigator; (ii) purpose of the research and a summary of eligibility criteria; (iii) a description of the benefits (including payment); and (iv) the location of the research and person to contact for more information (FDA Information Sheet, "Advertising for Study Subjects," February 1989). It is important to avoid making claims about the vaccine.

It is also important that the payment of volunteers not be so much as to affect the ability of the volunteer to assess risks and benefits appropriately. Few research groups or organizations have specific standards [27–29]. Volunteer compensation scales should be carefully conceived to ensure that economically disadvantaged individuals are not unduly influenced by the financial compensation offered. This concern applies not only to economically disadvantaged individuals, but students and middle class populations as well. Dickert and Grady [30] describe three approaches related to volunteer payments. The first approach is the Market Model, which is grounded in the free-market principle that supply (availability of interested and eligible volunteers) and demand (the investigator's desire to complete a trial with a specified number of subjects within a defined time frame) determine how much subjects should be paid for participation. A second model is the Reimbursement Model, in which payment is provided simply to cover volunteers' expenses (travel, meals, parking, child care), similar to jury duty payments, such that the volunteers accrue no profit, thereby minimizing financial inducement. The third and most accepted model is the Wage Payment Model. This model purports that participating in research is similar to many other forms of unskilled labor in that it requires little skill and training but may involve some risk. In this model, subjects are paid for work that is valuable to society, based on a standard wage for unskilled labor. In general, volunteers should have characteristics that make them suitable for other jobs in the community, particularly entry-level jobs, to ensure that the decision to participate in research is truly optional.

Investigators who have conflicts of interest should make these known to volunteers in the consent form. A conflict of interest exists when an investigator has financial or personal

relationships that inappropriately influence the investigator's actions or judgment [31].

## B. Considerations for Studies Involving Children and Infants

Children are not empowered to grant informed consent until they have reached the legal age of majority or have been deemed emancipated. The degree of involvement of a child in the decision to participate in a vaccine trial depends upon the child's intellectual capacity and stage of development. Assent to participate usually should be obtained from children with an intellectual age of 7 years. In trials involving children, a parent or guardian assumes responsibility for the child and grants consent by proxy. This places an increased responsibility on the sponsor, the investigator, and the IRB to assure that risk is minimized, the study is fully understood by the parent, and that there is no coercion to participate. It is essential that the parent understands that participation is entirely voluntary and that the parent may withdraw the child from the study at any time. An investigator who also serves as the child's primary care physician has the additional burden to assure that the parent does not feel compelled to enroll the children to please the physician.

Remuneration for participation is a more sensitive issue in trials involving children than adults. Rewards must be only a token of appreciation and not of a magnitude to induce parents to enroll the child into the study. Generally acceptable compensation includes a small savings bond, free routine vaccinations, or payment for costs incurred by the trial, such as travel.

## IX. SUMMARY

Vaccine testing enters the twenty-first century using methods based on sound epidemiological and ethical principles by which the safety and efficacy of future vaccines will be established. Although vaccine development may be an empirical science, the methodological framework for clinical testing to determine safety and efficacy has been largely codified. Precedents have been set for the study of vaccines containing recombinant DNA and for methods to study the transmissibility of live vaccines. We anticipate that clinical vaccine testing will continue to be a productive and exciting area of clinical research as vaccines against infectious diseases, such as malaria, tuberculosis, HIV, and agents of bioterror, are developed.

Remarkable advances in biotechnology have enabled the rapid identification of antigens that elicit protective immune responses against infectious agents and are promising candidates as human vaccines. The profusion of new candidate vaccines has itself created challenges for the proper evaluation of these agents. Rigorous and meticulous scientific evaluations are required before the introduction of a vaccine into public health practice. In this chapter, we provide an overview of several methodological considerations which are relevant to field evaluations of the clinical protection conferred by vaccine candidates that have proved suitably safe and immunogenic in earlier animal and human studies.

### I. TYPES OF EVALUATIONS

Evaluations of the protection conferred by vaccines against clinical infections occur both before and after vaccine licensure. Before licensure, vaccines are conventionally tested in an orderly sequence of “phases.” In the Code of Federal Regulations, the phases of clinical trials are described by using Arabic numerals (Phase 1, Phase 2, Phase 3), whereas in World Health Organization publications Roman numeration is generally used (e.g., Phase I, Phase II, Phase III). Because of the international dissemination of this book, in this chapter we will utilize the latter. Phase I and II studies

evaluate the safety, immunogenicity, and transmissibility of vaccine candidates in relatively small numbers of subjects. For the relatively few diseases in which volunteer challenge models have been established, such as cholera, Phase II studies may also evaluate the protection conferred by vaccination against an experimental challenge of volunteers with the target pathogen. For vaccines found to be suitably safe and immunogenic in Phase I–II studies, Phase III studies are conducted to provide rigorous evidence about vaccine efficacy. Phase III studies are constructed as experiments with clear hypotheses and are conducted in a population that normally experiences the disease against which the vaccine is targeted.

After licensure, clinical protection may be monitored in several ways with Phase IV studies. Sometimes protection is assessed by evaluating postimmunization immune responses to vaccines administered in routine practice. When such studies are conducted in an area endemic for the target infection for the vaccine, it is necessary to evaluate immune responses in both vaccinees and nonvaccinees, so that immune responses attributable to vaccination can be distinguished from responses to natural infections. Examples of such studies include measurement of serum hemagglutination inhibition antibodies after measles vaccination and assessments of cutaneous delayed hypersensitivity to tuberculin after bacille Calmette–Guérin (BCG) vaccination [1,2].

Such studies may provide useful information about the immunogenicity of vaccines, and for those vaccines for which immunological correlates of clinical protection are well established, they can serve as appropriate methods for monitoring the protection conferred by vaccines that have been deployed in public health practice.

However, because immunological correlates of protection are not known for many vaccines, direct clinical assessments of vaccinees vs. nonvaccinees are often required to determine whether a vaccine, as routinely administered in public health practice, is suitably safe and protective. Recent examples of such postmarketing surveillance studies include assessments of the clinical effectiveness of *Haemophilus influenzae* type b polysaccharide vaccine in children [3], and of pneumococcal polysaccharide vaccine in subgroups of individuals who are at high risk for serious pneumococcal disease [4]. Because of ethical considerations, such studies are usually designed in an observational rather than an experimental fashion, often as cohort or case-control studies [5].

In this chapter, we primarily focus on the use of randomized clinical trials (RCTs) for Phase III vaccine evaluations. We also briefly discuss the approaches to evaluating the vaccine protection and safety in Phase IV studies.

## II. RANDOMIZED CLINICAL TRIALS OF VACCINES

### A. Overview

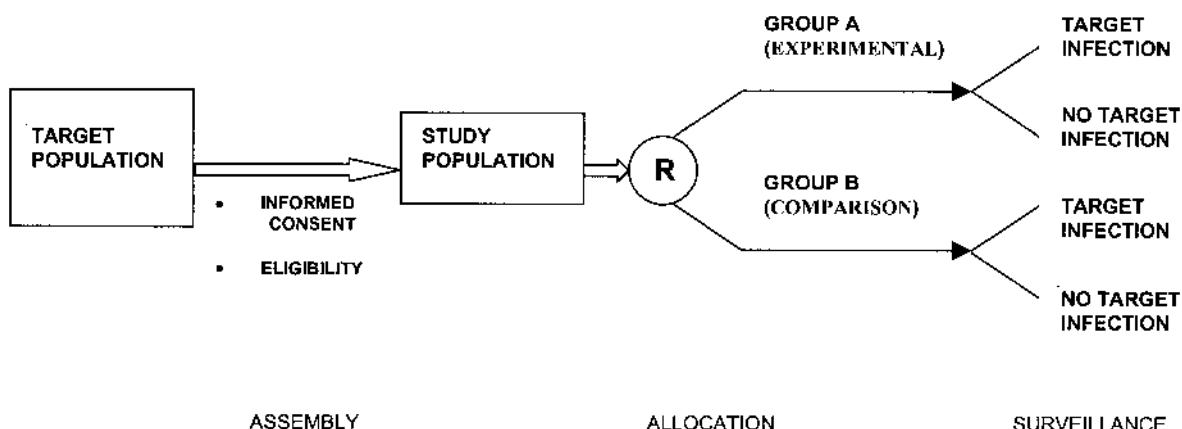

The RCT has become recognized as the most powerful research design for providing scientifically credible evidence about therapeutic efficacy [6,7], leading many national drug regulatory agencies to require evidence of efficacy from properly conducted RCTs before licensure of a new vaccine. Indeed, it may be anticipated that most, if not all, field evaluations of efficacy of experimental vaccines conducted in the future will be designed to conform to the RCT paradigm.

Figure 1 provides a diagrammatic outline of a simple, two-group RCT of an experimental vaccine. Individuals recruited from a target population are enrolled for the study after the acquisition of informed consent and ascertainment of eligibility. Study participants are then randomized to the experimental vaccine group or to a comparison (control) group. After randomization, study participants are followed concurrently to detect target infections with onsets during a defined period of follow-up. The incidence of the target infection in the different groups is then compared, to assess whether or not protection occurred in the group receiving the experimental vaccine, relative to the comparison group. Incidence may be expressed as a rate, the number of detected infections divided by the cumulative person-time at risk; or as a risk, the number of infected persons detected over some specified period of time, divided by the number of persons at risk.

If we take group B as the comparison group, such contrasts are typically expressed as rate ratios or risk ratios (RR), both based on the occurrence in group A divided by that in group B. The conventional index of protection, protective efficacy (PE), is then calculated as  $PE = (1 - RR) \times 100\%$  [8]. PE reflects the proportionate reduction of the incidence of the target infection in the experimental vaccine group relative to the comparison group. A value of 0% denotes no protection, that of 100% corresponds to complete protection, and negative values indicate a lower incidence in the comparison group than in the experimental vaccine group.

### B. Target Population

In any trial, it is first necessary to choose an appropriate target population for the evaluation. Clearly, it will be necessary to select a population in which the target infection occurs predictably and with a sufficient frequency to evaluate whether vaccination reduces the incidence of the target infection. Such populations may be defined on the

**Figure 1** A schematic of the sequence of events in a two-group, randomized, controlled vaccine trial. In this sequence, the study population is assembled from a target population and is then randomized to receive an experimental vaccine or a comparison agent. The experimental and comparison groups are then followed longitudinally and concurrently to detect target infections.

basis of geographic location as well as age, gender, and a variety of additional characteristics. For example, a classic trial of plasma-derived hepatitis B vaccine was conducted in homosexual men who resided in New York [9], and trials of newer generation vaccines against leprosy have focused on family contacts of known patients with leprosy [10]. Regardless of the target population chosen for the trial, it is necessary to enumerate and characterize the population before the trial to enable later assessment of whether or not the final group for the study was representative of the intended target population.

### C. Recruitment

After defining the target population for study, investigators must next recruit participants from this population. An important element of recruitment is informed consent. The specific requirements for obtaining informed consent may vary according to the age of the subject and the subject's legal capacity to give informed consent as well as the particular *milieu* for the trial. In general, acquisition of informed consent indicates that subjects have agreed to participate after understanding the purposes and elements of the trial, as well as the possible benefits and risks of participation, and after being guaranteed that their decision to participate and to continue participating are completely voluntary [11].

### D. Eligibility

Usually, consenting individuals must fulfill additional eligibility criteria before enrollment in a trial. At a minimum, these eligibility criteria should exclude any persons with absolute indications for, or contraindications to, any of the agents under evaluation [12]. Such exclusions are ethically necessary if the trial is to use an impartial allocation procedure, such as randomization, that assigns compared agents without reference to the individual needs or desires of the participants.

Additional eligibility criteria may be imposed to further restrict the characteristics of the population under evaluation. Persons with serious underlying illnesses, who may not respond to vaccination, may be excluded in some trials. Investigators may also choose to focus on immunologically "pure" individuals, who have not previously experienced the target infection and have not been immunized before with a vaccine against this infection. A trial may also limit participants to persons who are at very high risk of acquiring the target infection by virtue of a history of exposure or of relevant host characteristics. Although such restrictions are commonly imposed to increase the detectability of vaccine protection, they may also substantially modify the research question that the trial addresses.

### E. Allocation and Administration

Depending on the purpose of the trial, a group receiving an experimental vaccine may be compared with a group assigned to a different vaccine against the target infection, to an agent not anticipated to affect the risk of the target infection, or to no agent at all [13]. Postponement of alloca-

tion of the compared agents until after acquisition of informed consent and ascertainment of eligibility helps to ensure that decisions about recruitment, participation, and eligibility do not depend on which of the agents has been assigned [14,15]. Moreover, because this sequence ensures that only enrolled subjects are assigned to the compared agents, it minimizes irregularities created by persons who drop out of the study after assignment but before receipt of an agent under study. A powerful mechanism to prevent such biases in the intake of participants is to conceal the identities of the compared agents from both participants and investigators (*double blinding*) [16]. Double-blinded administration of agents also safeguards against a bias that can occur if participants are given the opportunity to choose additional measures to prevent the target infection on the basis of knowledge about which of the compared agents has been received.

It is important that the compared agents be allocated with a nondiscretionary method that, as far as possible, creates groups with equivalent baseline risks for the target infection under evaluation. The most powerful technique for accomplishing this goal is to allocate eligible subjects to different agents in a formally randomized fashion [17–19]. Formally randomized allocation, a prerequisite for modern trials of new vaccines, has the additional desirable property of providing a theoretical basis for statistical appraisals of differences in the occurrence of outcome events as well as other characteristics in the compared groups [20].

### F. Surveillance

Vaccine field trials typically conduct surveillance for at least four types of events. First, systematic surveillance must be instituted for the target infection that the vaccine is intended to prevent. Arrangements must be made for systematic collection of data relevant to the diagnosis of the target infection, and the study must be designed to ensure that members of the compared groups have an equivalent probability of receiving relevant diagnostic procedures when they develop the target infection [16]. It is also mandatory that the diagnostic evidence be interpreted in an objective manner that is not influenced by knowledge of which agent has been received. Double-blinded surveillance constitutes the most powerful method to safeguard against biased detection and ascertainment of outcomes, although alternative strategies are available when double blinding is not possible [21].

A second important goal of surveillance is to detect adverse reactions after vaccination. Preliminary studies before the trial will usually have identified likely candidate side effects as well as the time frame of development for these side effects, which is usually a period of a few days after vaccination. Participants should be monitored for these anticipated events as well as for the possibility of less likely reactions that may occur with longer latency periods after vaccination.

Immune responses to vaccination constitute a third category of events to be monitored. Evidence of expected levels of immune responses to vaccination document that the vaccine lots under evaluation were properly prepared,

stored, and administered. If a vaccine proves effective in preventing the target disease, the trial may permit assessment of the relationship between levels of response and the degree of protection.

A fourth category of events under surveillance, competing events, are outcomes other than occurrence of the target infection that terminate a participant's period of follow-up [14,15]. Follow-up arbitrarily stops at the end of a study but may also be prematurely terminated by loss from the study for such reasons as death, refusal to continue participation, and migration away from the study area. Such events are important for several reasons. Deaths, in addition to terminating follow-up, may themselves be important outcome events. Moreover, all of these events create the opportunity for unequal periods of follow-up among participants and therefore must be considered in calculating periods at risk for expressing the incidence of the target infection. Finally, if the tendency to become lost to follow-up differs in the compared groups, the losses themselves may create a differential opportunity to detect the target infection in the groups and may thereby influence estimates of the comparative occurrence of the target infection. As with surveillance for the target infection, suitably objective methods, such as double blinding, are necessary to prevent biased detection and ascertainment of side effects, immune responses, and competing events.

### **III. ADDITIONAL ISSUES FOR PHASE III RANDOMIZED CLINICAL TRIALS OF VACCINES**

Although the basic paradigm of a controlled vaccine field trial may seem reasonably straightforward, additional issues require consideration in both the design and the analysis of a vaccine trial. In the following sections, we outline several of these issues.

#### **A. Posing Research Questions for the Trial**

Posing the research questions for the trial appropriately and with adequate specificity is crucial to the success of a Phase III trial, because research questions guide the design, conduct, and analysis of the trial. Modern vaccine trials are designed to address primary research questions, evidence bearing on which will be considered by regulatory agencies in deliberations about vaccine licensure, and secondary questions, which address additional scientific issues of interest. Adequate formulation of primary research questions demands clear specification of the target population for the study; the formulation and constituents of the vaccine, together with its mode and schedule of administration; the comparison agent to be used as a control agent; the target infections whose occurrence will serve as the basis for estimating vaccine protection; the adverse event outcomes whose occurrence will serve as the basis for evaluating vaccine safety; and the immune outcomes whose occurrence will serve as a basis for assessing vaccine immunogenicity. Each of these features needs to be articulated in a way that accurately reflects how a vaccine will be used in practice, to

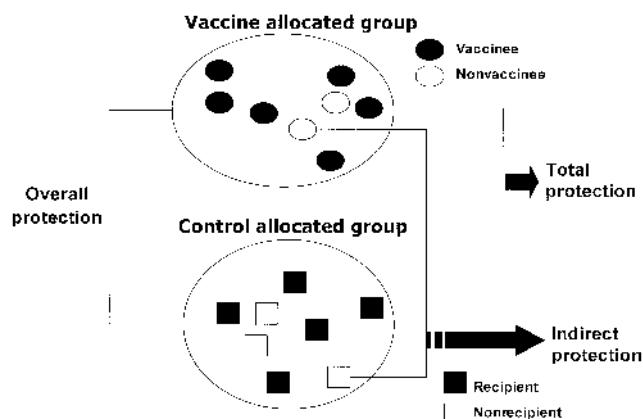

ensure that a trial's results will meet regulatory expectations for vaccine licensure.

#### **B. Demarcating the Type of Vaccine Protection to be Measured**

When we administer a vaccine to a subject, our hope is that the vaccine will elicit relevant forms of immunity that will make that subject less susceptible to becoming infected when exposed to the target pathogen. This protection, which reflects the effects of the vaccine on the individual independently of whether or not other individuals in the same population are also vaccinated, is called *direct protection* [22]. However, for most vaccines, we attempt to immunize populations rather than individuals. For pathogens that are transmitted from person to person, targeting a population rather than an individual for vaccination may have the added effect of reducing the intensity of transmission of the pathogen in the population. One possible result of this *indirect protection* is that nonimmunized, susceptible individuals may be protected because they are less likely to come into contact with the pathogen [22,23]. An additional possible result is that the protection of vaccines may be augmented, because the immunity conferred by many vaccines is greater against a small challenge inoculum of a pathogen than against a heavy challenge inoculum.

A Phase III trial of a vaccine can measure either direct protection per se or direct and indirect protection combined. To accomplish the former, allocation of subjects to vaccine and the comparison agents must not create high concentrations of vaccinees within the geographical units within which the pathogen is transmitted. This is usually accomplished by randomizing individuals rather than groups and by randomizing within blocks that balance the numbers of vaccines and controls within epidemiologically relevant groups of individuals. To permit the estimation of combined direct and indirect protection, an opposite strategy must be used: groups, rather than individuals, must be the units of allocation [24]. If we imagine a trial in which an agent with no activity against the target pathogen (e.g., a placebo) is randomly allocated to other groups, we can see that several subgroups of subjects are formed (Fig. 2): vaccinated and nonvaccinated subjects within the groups allocated to the vaccine, and recipients of the control agent and nonrecipients of the control agent within the groups allocated to receive the control agent. Comparison of the incidence of the target infection in vaccinees vs. that in recipients of the control agent estimates *total protection*, a combined measure of direct protection and of indirect protection of vaccines owing to any reduction of transmission. Comparison of nonvaccinees with nonrecipients of the control agent allows estimation of indirect protection of nonvaccinated members of vaccinated groups ("herd immunity"). Finally, overall comparison of the incidence of infection in groups allocated to the vaccine vs. groups allocated to the control agent, regardless of the agent actually received, permits estimation of the *overall protection* of vaccination in the entire group targeted for the vaccine [25].

Most regulatory agencies require that Phase III trials be individually randomized, presumably because of a prefer-

**Figure 2** A diagram of measurement of vaccine protection in a cluster-randomized vaccine trial. Two hypothetical clusters are shown, and the types of individuals to be contrasted for measurement of different types of vaccine protection are identified.

ence for estimation of direct vaccine protection per se, because direct vaccine protection reflects the “intrinsic” protection of the vaccinated individual, irrespective of the vaccine coverage of other persons in contact with that individual. However, a recently completed Phase III trial of pneumococcal polysaccharide–protein conjugate vaccines in Native American infants in the United States employed cluster randomization specifically because it was anticipated that this vaccine would induce indirect protection, which could be a major determinant of the vaccine’s public health value [26].

### C. Clarification of the Perspective of the Trial

To ensure the scientific credibility of the results, vaccine trials must be designed to safeguard against bias. However, even after a trial has been suitably designed to prevent bias, an additional fundamental decision remains: Should the trial be designed to measure the intrinsic effects of vaccination when it is given under ideal conditions, or should the design ensure that the results can be used to predict how well the vaccine will perform in public health practice? Trials designed to accomplish the former goal are often termed *efficacy trials*, and trials constructed to accomplish the latter objective are frequently referred to as *effectiveness trials* [24,27].

Each type of trial has different requirements for the selection of study subjects, choice of the compared agents, units of allocation, selection and definition of outcome events, and demarcation of the participants to be analyzed [24,28–30]. An efficacy trial may attempt to restrict study subjects to persons who are likely to respond to vaccination and are at sufficiently high risk for the target infection that protection will be readily detectable. For example, early studies of pneumococcal polysaccharide vaccine examined vaccine efficacy in otherwise healthy South African gold miners, who were documented to be at very high risk of

serious pneumococcal infections [31]. On the other hand, an effectiveness trial would study groups who are anticipated to be target groups for vaccination after licensure. For pneumococcal vaccine utilized in developed countries, the target group is composed of the elderly and others at high risk because of underlying disorders [32]. That the results of these two selection strategies are not necessarily interchangeable is illustrated by the controversy that arose when several post-marketing surveillance studies suggested that the high levels of efficacy of pneumococcal vaccine observed in healthy individuals were not exhibited by the debilitated groups targeted for public health application [33].

To enhance the detectability of vaccine protection, an efficacy trial tests vaccines whose formulations and regimens are designed to yield optimal protection and whose proper administration is assured by idealized experimental conditions. If ethically permissible, an efficacy trial will often contrast the group that receives the new vaccine with a comparison group that receives an agent not anticipated to protect against the target infection. In contrast, an effectiveness trial will test vaccines formulated in a manner that is most suitable for application in public health practice, conduct the evaluation in the realistic environment of a public health program, and, where appropriate, compare the performance of a new vaccine against that of a standard vaccine directed toward the same disease.

Past evaluation of Ty21a oral vaccine against typhoid fever illustrates these differences. An early efficacy trial conducted in Alexandria, Egypt, evaluated a preparation of high potency but with little applicability to public health practice because of its inconvenient formulation [34]. After demonstration of high efficacy in this early trial, later trials, conducted in Chile, evaluated more convenient enteric-coated capsule and reconstituted lyophilized “liquid” formulations [35,36,36a]. Whereas the early trials of this vaccine were placebo-controlled, a later trial, designed to answer practical questions relevant to public health implementation, compared only different regimens of active vaccine [36,36b].

To measure the intrinsic effects of vaccination, efficacy trials typically seek to measure only direct vaccine protection, because indirect effects are not intrinsic to the vaccine but depend on the pattern and extent of vaccine coverage of a population. Accordingly, the unit of allocation in an efficacy trial is typically an individual, rather than a group of individuals, and additional measures, such as blocked randomization, are often used to balance vaccinees and non-vaccinees within the groups in which transmission occurs. For live vaccines that can be excreted and transmitted to contacts, such as the Sabin oral polio vaccine, efforts are made to physically isolate vaccinees from controls to prevent “contamination” of the control group by inadvertent vaccination. In contrast, the pragmatic goals of an effectiveness trial are often best met by allocation of groups rather than individuals, because the goal is to capture the overall benefit of vaccinating a target population and because these benefits include direct as well as indirect protection of both vaccinees and nonvaccinees residing in the target population.

Trials of capsular polysaccharide–tetanus toxoid (PRP-T) conjugate vaccine against *H. influenzae* type b (Hib) in

Chile [37] and England [38] illustrate the use of group allocation in effectiveness trials. In the former, community clinics in metropolitan Santiago were randomized either to receive this vaccine mixed with diphtheria–pertussis–tetanus (DTP) vaccine at 2, 4, and 6 months of age or to receive DTP alone. In the latter, districts near Oxford were allocated to receive or not to receive PRP-T in conjunction with DTP at 2, 3, and 4 months of age. In both studies, all infants in the groups allocated to vaccine or no vaccine were followed for the occurrence of invasive Hib disease, regardless of whether or not they had received PRP-T.

The definition of the target infection for an efficacy trial aims to demarcate the biological events that are anticipated to be responsive to vaccine-induced immunity but that may be too narrow in scope to permit judgments about the usefulness of the vaccine in public health practice. For example, it was anticipated from North American volunteer challenge studies that the primary effect of ingestion of an oral B subunit-killed, whole-cell cholera vaccine would be to reduce the occurrence of clinically severe cholera [39]. An efficacy trial of this vaccine in Bangladesh was therefore designed with the primary goal of assessing vaccine efficacy against clinically severe infections [40]. Although prevention of life-threatening cholera is certainly an important public health goal, an effectiveness study might be concerned with the overall impact of vaccination against all diarrheal episodes associated with *Vibrio cholerae* O1 as well as the effect of vaccination on all episodes of clinically severe diarrhea and on diarrheal deaths.

Analyses of efficacy trials commonly consider only participants who have received a complete course of a properly administered agent. Among these analyzed participants, evaluations of such trials commonly restrict target infections to events that begin after a window of time during which it is anticipated that participants will have had an opportunity to manifest fully developed immune responses to vaccination. To minimize the possibility of bias caused by such temporal restrictions, they must be applied equally to each of the compared groups [30]. In contrast, effectiveness trials, which are concerned with the effects of a policy to administer a vaccine, would analyze all participants originally randomized to the compared agents and would include all events occurring after randomization. If groups constituted the units of allocation, all targeted members of the allocated groups would constitute the most relevant denominators. Although such an “intent to treat” analytical strategy can be justified based on the effectiveness perspective of a trial, it was also argued that this strategy for defining outcomes and populations at risk is necessary to avoid bias from distortion of the original groups created by randomized allocation [41].

The restricted populations, idealized regimens, responsive outcomes, and analytical strategies of efficacy trials will almost always reduce the sample size requirements of such studies and may also reduce associated costs and logistical demands. An efficacy trial thus constitutes a logical first step in the field evaluation of the protection conferred by a new vaccine [42]. Such efficacy trials typically form the basis for regulatory decisions about vaccine licensure. However, if a

vaccine yields promising results in an efficacy study but doubts still remain about the practical utility of a new vaccine for public health practice, it may then be appropriate to mount one or more effectiveness trials before decisions are made about the application of the vaccine in public health programs. Because of this complementarity of efficacy and effectiveness trials, it has been suggested that efficacy trials be termed “Phase IIIA” trials, and effectiveness trials be termed “Phase IIIB” trials [24].

#### D. Sample Size Estimation and Interpretation of Background Information

Methods for calculating sample sizes required for RCTs are described in detail elsewhere [43]. One formula [44] commonly employed for two-group trials in which equal-sized groups are desired gives the size per group ( $N$ ) as:

$$N = \frac{(Z_a + Z_b)^2}{d^2} [P_1(1 - P_1) + P_2(1 - P_2)]$$

In this formula,  $p_1$  is the expected incidence of the target infection in the comparison group;  $p_2$  is the expected incidence in the group receiving the experimental vaccine;  $Z_a$  is the  $Z$  score taken as the threshold for declaring the [ $p_1 - p_2$ ] differences as “statistically significant” (e.g., 1.96 for a two-tailed  $P$  value of 0.05);  $Z_b$  is the  $Z$  score for beta error, the maximum tolerated probability of missing a significant difference when one really exists (e.g., 0.84 for a probability of 0.20). Because enrollment of a suitably large sample is a prerequisite for any trial, the variables and parameters specified by this formula provide useful information that must be known or about which decisions must be made in planning a vaccine trial.

To estimate  $p_1$ , it is necessary to inspect earlier surveillance data for the target infection in the population contemplated for the trial. Predicting  $p_1$  can be particularly challenging for several reasons. First, for most infectious illnesses, a single year of surveillance will not be sufficient to estimate the expected incidence with confidence, as substantial year-to-year variation in incidence is common. For example, in Matlab, Bangladesh, where surveillance for cholera has been maintained for over 20 years, variations in annual incidence have been over 25-fold [45]. Because it is ethically imperative that trials be designed to maximize the likelihood of yielding statistically meaningful results, it is always desirable to be conservative in projecting the likely incidence of the target infection in the comparison group [46]. Second, because the expected incidence may differ dramatically, depending on demographic and other characteristics, it is important that estimates for the calculation be made for the group meeting the eligibility criteria for the trial. Third, investigators planning a trial must usually rely on earlier incidence data from routine public health surveillance, rather than from the special, prospective surveillance system that is usually instituted for a trial. Relatively loose clinical and microbiological criteria for defining infections are usually used in routine surveillance, tending to elevate the observed incidence in relation to that detected

with the much stricter diagnostic criteria employed in the prospective surveillance of a trial. Conversely, during a clinical trial, efforts are usually made to evaluate all patients who might have the target infection, many of whom would have been missed in routine surveillance, and to systematically deploy diagnostic tests on all such patients. This feature of surveillance during Phase III trials would tend to elevate the observed incidence in relation to that observed with routine surveillance. Because of the unpredictability of the net balance between the factors that would inflate and factors that would diminish the incidence in a Phase III trial, in relation to antecedent routine surveillance, conservatism is required in projecting incidence rates derived from earlier routine surveillance to be expected in a Phase III trial.

Yet, a fourth consideration in estimating  $p_1$  is that volunteers enrolled for a trial usually are not representative of, and often have lower rates of infection than, the population from which they are drawn. In a field trial of killed, oral cholera vaccines in Bangladesh, placebo recipients had a nearly 20% lower incidence of cholera than age- and gender-eligible persons who did not participate in the trial [47].

Fifth, projections about  $p_1$  for a trial must account for anticipated subanalyses. Many trials are designed not merely to estimate vaccine protection in the entire study population, but in subgroups of the population, such as those defined by age or other demographic variables. If such subgroups are of interest, the expected incidence of the target infection in each subgroup must be considered in designing a trial. Moreover, many pathogens have different phenotypes that may affect vaccine protection. For example, a field trial of killed, oral cholera vaccines found that the biotype of *V. cholerae* 01 (El Tor vs. classical) was an important modifier of vaccine protection [48]. If different phenotypes of a target pathogen circulate in the population for a trial and if phenotype-specific vaccine protection is to be measured,  $p_1$  must be estimated separately for each of the different phenotypes of interest in designing the trial and estimating sample size requirements.

As soon as the incidence for the comparison group has been estimated,  $p_2$  is readily calculable from the formula for protective efficacy. Therefore, investigators must determine what minimum level of protective efficacy should be detectable in the trial. Depending on the perspective of the trial, either of two strategies can be adopted. In a biologically oriented efficacy trial, evidence from earlier studies can be marshaled to arrive at a best guess about the likely level of protection. In a more pragmatically oriented effectiveness trial, the decision rests more on a minimum level of protection and a minimum duration of this protection that would be required to justify introducing a vaccine into public health practice. Such decisions must rely on quantitative analysis of numerous factors, such as the burden and costs of the target infection, the costs and side effects of the new vaccine, and the costs, benefits, and risks of alternative methods of prevention and treatment [49].

The minimum level of protective efficacy to be detected must also take into account the planned strategy of analysis, as described earlier. If only persons who receive a complete course of appropriately administered vaccine are to be analyzed, as is often carried out in efficacy trials, estimates

of protection can be desirable in efficacy trials, and estimates of protection can be based on the expected intrinsic potency of the vaccine. Conversely, if an intent-to-treat strategy is employed, whereby persons are analyzed according to their assigned agent regardless of whether the assigned agent was administered as intended, estimates of anticipated protection will have to account for the vagaries of incomplete and improper dosing that will inevitably occur in a proportion of participants.

Decisions about  $Z_a$  address what  $P$  value will be considered as the threshold of statistical significance for rejecting the overall hypothesis of no protective efficacy. These decisions must also address whether statistical tests used to estimate  $P$  values will be interpreted in a one- or two-tailed fashion. A  $P$  value of 0.05 is the traditional, if somewhat arbitrary, threshold for declaring that a difference in incidence between compared groups is unlikely to have arisen by chance. However, as described in more detail in Section III.H, a more conservative  $P$  value threshold may be desirable for a trial in which multiple analyses are planned [50,51]. One-tailed tests may be appropriate when differences in the occurrence of the target infection are of interest only if they occur in one direction (e.g., with a higher incidence in one group vs. another group), and if a difference in the other direction would be of so little interest that it would not be statistically appraised. For a one-tailed  $P$  value,  $Z_a$  will be substantially lower than that for the same probability interpreted in a two-tailed fashion, so this decision has important consequences for required sample sizes. A decision must also be formed about  $Z_b$ , or the  $Z$  score corresponding to the maximum tolerated probability of missing a significant difference if one really exists [52]. Probabilities for beta error are always interpreted in a one-tailed fashion; by convention, a beta error  $\leq 0.20$  ( $Z \geq 0.84$ ) is usually considered acceptable.

Although a complete discussion of sample size calculations is beyond the scope of this chapter, several additional points should be mentioned. The sample size must reflect the finally analyzed denominators. If these consist only of persons who receive a complete regimen of an assigned agent, it will also be important to consider the source population from whom this final sample is assembled. From individuals who meet the age and gender restrictions for the trial, some will be considered ineligible as a result of other exclusionary criteria, some will refuse, some will be absent at the time of vaccination, and some will receive the assigned agents in an incomplete or erroneous fashion. In addition, after initial assembly of participants, subjects may be lost to follow-up or may otherwise have their follow-up terminated, as described earlier. These events yield a population effectively under follow-up that is much lower than the source population, necessitating careful and conservative planning in the selection of the source population [43]. For example, in the field trial of killed oral cholera vaccines in Bangladesh, only 32% of the source population ultimately received a complete course of vaccine or placebo and were followed for the first year after dosing [46].

If vaccine efficacy is to be estimated for subgroups, it will be necessary to estimate the proportion of participants

who are likely to be included in each subgroup, and to calculate an overall sample size large enough that a statistically meaningful comparison will be possible for each subgroup of interest. If differences in vaccine efficacy between subgroups are to be evaluated, sample sizes substantially larger than those required for assessments of subgroup-specific efficacy will usually be required [53].

Because the calculated sample size requirements reflect the group of subjects successfully recruited for a trial, the size of the source population for recruitment must be considered. Investigators sometimes fail to realize that the finally analyzed subjects for trial occasionally represent a very small fraction of the population. In a field trial of killed, oral cholera vaccines conducted in rural Bangladesh, for example [54], in relation to the overall population of Matlab, Bangladesh, where the trial was conducted and where the entire population was assessed for eligibility and approached for informed consent, if deemed eligible, only about one-third of persons were fully dosed and followed for the first year of surveillance. If this latter group were to constitute the final group under analysis, the source population for recruiting these participants would therefore have to be three times as large.

Finally, sometimes merely rejecting the null hypothesis of no vaccine efficacy does not provide an adequate assurance that a good vaccine is good enough. For example, in response to the troublesome side effects of conventional whole-cell pertussis vaccine, acellular pertussis vaccines have been developed and tested. To be considered suitable for licensure, these vaccines must, in addition to being safe, be as protective as conventional vaccines. Sample size considerations of trials comparing acellular vaccines with conventional vaccines therefore had to demonstrate that the protective efficacy of acellular vaccines was not substantially inferior to that of conventional pertussis vaccines [55]. Demonstration of noninferiority of one agent in comparison to another requires a different approach to the calculation of sample size requirements. Instead of seeking to reject the null hypothesis of no difference between the agents with adequate power, this approach seeks to assure that the confidence interval for the difference in outcomes between the agents excludes values suggesting that the new agent (e.g., acellular pertussis vaccine) is unacceptably inferior to the standard agent (e.g., conventional pertussis vaccine).

## E. Issues in Allocation of the Compared Agents

Randomized allocation is such an important safeguard against bias that it should be regarded as essential in field evaluations of new vaccines. However, even if randomized allocation is planned, several issues still require attention.

An obvious decision to be made is whether the allocation procedure is to yield groups with similar or intentionally unequal numbers of subjects. Whereas groups of similar size are usually preferred in two-group trials, the decision is less straightforward for trials with more than two groups, particularly when a single nonvaccinated group is to be compared with multiple vaccinated groups. For such multiple-group trials, there is disagreement about whether equal or unequal sample sizes provide optimal statistical efficiency

[56]. Moreover, on ethical grounds, there may be compelling reasons to minimize the number of participants in the group that will not be vaccinated. If unequal sizes per group are desired, randomization procedures can easily be adapted to yield the desired allocation ratio.

Stratified allocation—in which subjects are randomly allocated to different agents within subgroups defined by relevant risk factors for the target infection, typically in a balanced fashion (with use of “blocking”) within these strata—has been advocated as a method to improve the similarity of baseline characteristics of compared groups [57]. This technique is helpful in safeguarding against bias in trials involving small numbers of participants, particularly when these participants differ greatly in their risks for the outcome under study. Such conditions commonly apply to clinical trials of therapy for ill persons who have substantially different prognostic expectations. This technique may also be relevant to vaccine trials with small sample sizes, but it is unlikely to confer great advantage over the use of simple randomization in assigning compared agents for large-scale field trials [58].

Blocked allocation is also commonly employed in small trials in which there is concern that simple randomization may not yield groups of the desired size. For example, in a two-celled trial of vaccine vs. placebo intended to compare groups of equal sizes, randomization might take place within blocks of every four consecutively assigned subjects to ensure that two subjects receive vaccine and two receive placebo [58].

As described earlier, it is conventionally recommended that randomization of subjects should occur only after enrollment procedures for participation have been completed. However, in practice, this prescribed sequence may be a difficult requirement to fulfill, particularly in less-developed settings, where communications may be inadequate to permit a vaccination team to contact a central randomization unit and where it may not be desirable to involve field teams in the task of allocation [21]. In such circumstances, it may be preferable to allocate the agents in a randomized fashion before recruitment and ascertainment of eligibility and to safeguard against biases in the enrollment of participants by administration of the compared agents in a double-blinded fashion. With this strategy, each member of an already characterized population can be randomly preassigned an agent, as in a field trial of oral cholera vaccines in Bangladesh [40], or doses of agents can be randomly ordered, either physically within storage containers or via a coded assignment list, and the doses can be given consecutively as participants are enrolled into the study.

Another issue requiring consideration is the unit of participants to be allocated to the compared agents. From a statistical viewpoint, it is most efficient to consider the individual participant as the unit to be allocated [43]. However, allocation of individuals may be difficult for vaccines that are excreted and transmitted from a vaccinated individual to nonvaccinated contacts, and it may not be applicable when an effectiveness rather than an efficacy perspective is selected. To evaluate the protection conferred by a transmissible vaccine, it is necessary to demarcate as units for allocation the groups of individuals between whom trans-

mission of the vaccine is unlikely. For example, in a trial of orally administered, live Ty2a typhoid vaccine in Chile, classrooms of students were allocated to the compared agents, in part to safeguard against the possibility of "contamination" of nonvaccinated controls by transmission of the vaccine organism [35,36a].

When calculating sample sizes in trials in which a group is the unit of allocation, it is important to account for the degree of clustering of the target infection within the groups to be allocated. Cholera, for example, occurs in highly focal outbreaks within a community, even in endemic area [45]. In general, the greater the magnitude of such clustering, the larger will be the number of subjects required for the evaluation. In addition, when groups rather than individuals serve as units of allocation, statistical techniques appropriate for this allocation strategy will be required in analyzing the results of the trial [59].

Finally, in addition to providing safeguards against biased allocation, it is necessary to measure whether the allocation created groups that were comparable in baseline characteristics which might affect the occurrence of the target infection [17–19]. Documentation of equivalent distributions in the compared groups reassures that the randomization procedure was appropriately executed, although some imbalances in the distributions of baseline features may be expected by chance [20]. Adjustment of estimates of vaccine protective efficacy for unequally distributed variables can be undertaken with stratified analyses or multivariate models. Comparison of these adjusted estimates with the crude estimates provides an indication as to whether distortions of vaccine protection could have arisen because of unequal baseline susceptibility to infection in the compared groups [20]. In addition to baseline characterization of participants, it also is important to document reasons for nonparticipation and baseline characteristics of the nonparticipants. Such data permit the assessment of whether participants were representative of the target population; if subjects were preassigned to different agents, these data can be analyzed to evaluate whether differential participation of those assigned to the compared groups was a likely source of bias.

#### F. Issues in the Administration of the Compared Agents

Several questions routinely arise about how the agents should be packaged and labeled, as well as about what data should be collected concerning the process of administration. Agents can be packaged as single doses or as containers with multiple doses. In general, it will be advantageous to package the agents in single doses, both to minimize vaccine deterioration in the field and also to circumvent human errors in measuring doses. If the agents are to be coded, as is necessary to maintain double blinding, several factors must be considered: simplicity, avoidance of errors in administration, and prevention of discovery of the identities of the agents. Whereas a unique code for each dose, usually with a number, provides the greatest protection against the unblinding of a trial, this strategy may increase the complexity of administering agents and of

recording what was administered, and it may also create logistical difficulties if the same agent is to be given on multiple occasions. Use of fewer codes may alleviate these problems but may make it easier for participants or investigators to detect the identities of the codes. Whatever system of coding is employed, letter or number codes are substantially simpler to work with than color codes. Because of the inevitable tendency of research workers to be inquisitive about the identities of the coded agents and in view of the difficulties in making truly identical agents for comparison in vaccine trials, it is also useful at the end of a trial to conduct a survey of investigators and other workers in the trial to assess opinions about the identities of the different codes. This exercise, which will permit an empirical estimate of the likelihood that the trial was indeed conducted in a double-blinded fashion, is particularly valuable if only a few different codes are used for the compared agents.

Several additional aspects of the administration of the agents require documentation. First, even if the agents are preassigned, it is important that vaccination teams record the code of what was actually given. If single-unit doses are administered, it is useful to employ self-adhesive stickers that give the code and that can be removed from each dose and affixed to a vaccination record book. This documentation is important, because errors in administration are inevitable. For example, in a trial of oral cholera vaccines in Bangladesh [40], 573 of 234,032 (0.2%) doses were not given as assigned, despite the use of a simple A–B–C coding system for the three compared agents. Second, it is desirable to record observations about the completeness of dosing. Incomplete dosing can occur with any route of administration, but it may be a particular problem for non-injectable agents. In the Bangladesh oral cholera vaccine trial, 6367 (3%) doses were not completely ingested, in part because of the large volumes (50–160 mL, depending on age) of the doses [40]. Although analytical strategies for handling participants who received erroneous or incomplete doses may vary according to the perspective of the trial, documentation of the frequency of such vagaries is always helpful in interpreting the apparent degree of vaccine protection.

If the agents under investigation require a cold chain to preserve potency, it will be desirable at each step in the itinerary, from the manufacturer to the recipient, to document that necessary thermal conditions were maintained. A variety of thermal monitors are available for this purpose. If a particular level of an immune response to vaccination is known to occur after proper administration of fully potent vaccine, assessment of immune responses in representative samples of the vaccinated and comparison groups may provide a useful indication of the adequacy of the manufacture, storage, and administration of the vaccine. Finally, samples of the batches of vaccine delivered to the field site for use in the trial should be preserved for evaluation of potency. All of these tactics are of particular interest for trials in which protection by vaccination is lower than expected, and it is necessary to distinguish deficiencies in the intrinsic potency of a vaccine from problems in manufacture, storage, and administration.

## G. Issues in Surveillance

The scope of surveillance activities in a trial may include detection of the target infection and other clinical events relevant to the assessment of vaccine protection, observations of side effects, assessment of immune responses, and recording of competing events. For each of these outcomes, decisions must be made about the approach to detecting events, the time frame for surveillance, as well as the methods to be employed to safeguard against biased detection of the events.

### 1. Scope

The range of detected events for assessment of vaccine protection may vary substantially with the method of detection. Passive surveillance of illnesses through monitoring of routine visits by patients to health facilities provides a logically simple approach to detecting outcomes. However, with passive surveillance, only those illnesses that are severe enough to prompt solicitation of medical care will be detected, and persons who have more ready access to treatment facilities or who are more “medicalized” in their use of health care facilities may be overrepresented. Moreover, the type of events detected may be affected by the focus of the treatment facility under surveillance. For example, a trial that uses infectious disease hospitals to detect outcome events may miss the neurological or cardiovascular side effects of vaccination. With an active surveillance strategy, the investigator maintains a schedule of contacts with each participant, regardless of whether the participant is ill or not, and thereby has the opportunity to detect illnesses that span a wide spectrum of severity and characteristics. In addition, with active surveillance, it may be possible to detect asymptomatic infections, whose interruption may be relevant to preventing transmission of disease. The salient disadvantage of active surveillance, however, is the considerable expense and logistical complexity of maintaining regular, active contact with an entire study population, particularly in studies that are large or that entail a prolonged period of follow-up.

For certain types of target infections, active surveillance will yield a greater apparent incidence than that noted by passive surveillance, thereby reducing sample size requirements for evaluation of vaccine protection. For example, in Matlab, Bangladesh, which has been a site for several cholera vaccine field trials, comparison of active and passive surveillance data for children aged under 2 years demonstrated that only about 6% of diarrheal illnesses detected by active surveillance were brought to treatment facilities for care [60]. However, investigators specifically interested in the effect of vaccination on clinically severe disease should remember that the overall incidence rates based on active surveillance may reflect primarily nonsevere infections. This difference in clinical spectrum may substantially affect the magnitude of vaccine protective efficacy if a vaccine acts to diminish the severity of the clinical manifestations of an infection, as has been noted for whole-cell pertussis vaccines [61] and inactivated oral vaccines against cholera [62]. For such vaccines, estimates of vaccine efficacy based on passive surveillance are likely to be higher than estimates based on

active surveillance. Thus choices between active and passive surveillance in a trial should not be based merely on trade-offs between logistical ease and disease incidence but should consider the possible impact of the surveillance technique on the magnitude of vaccine protection. Depending on the nature of the events to be detected, passive surveillance, active surveillance, or a combination of the two may be appropriate for detection of target infections.

Detection of adverse events following dosing, and comparing rates of specific adverse events in the groups under study are essential components of a Phase III trial. Indeed, Phase III trials, because of their large size, offer a unique opportunity for evaluating vaccine safety before a vaccine is licensed. In past years, the approach taken by Phase III trials was often to focus on documentation of frequent and expected adverse events, occurring only during the first few days after dosing. The focus was primarily on documenting common side effects, generally of mild severity. Often, these trials measured adverse events in only a small subsample of the trial population, as large sample sizes were not required to document frequent side effects, such as the occurrence of pain or erythema at an injection site. Some trials failed to conduct surveillance for adverse events altogether.

Several changes have occurred during the past several years in the approach to documenting vaccine safety in Phase III trials. First, it is now well recognized that not all adverse effects of vaccination are easily predicted. For example, intussusception following oral receipt of live rhesus rotavirus-reassortant vaccine, an event that is now well documented, was not an expected side effect of this vaccine, at least at the time that Phase III trials were undertaken [63]. Therefore, it is inappropriate in Phase III trials to constrain the focus of surveillance to adverse events that can readily be predicted. Second, it is no longer acceptable to target surveillance only to adverse events that occur quite commonly, nor to place only a subsample of participants under surveillance for adverse events. Newer-generation live oral rotavirus vaccines, for example, will be tested in Phase III trials that, in aggregate, will be large enough to detect an attributable incidence of intussusception of approximately 1 case in 10,000 vaccine recipients. Expanding the scope of surveillance in this fashion will have a major effect in increasing the size, cost, and complexity of future Phase III trials.

Surveillance for immune responses will almost always require actively scheduled tests, although immune testing of vaccinated participants who develop target infections and are detected in ordinary treatment settings may offer the opportunity to evaluate whether poor immune responses accounted for the illness in these vaccines [64]. If the goal of these immune assessments is merely to confirm that the vaccines under study elicited expected levels of immune responses, it may be necessary only to evaluate a sample of the trial population. However, Phase III trials also commonly attempt to evaluate the relationship between the magnitude of induced responses and the level of vaccine-induced protection. To achieve this latter objective, responses in vaccinees who ultimately developed the target infection are compared with responses of vaccinees who did not. Because breakthrough infections are usually small

in number in a trial of a protective vaccine, it will often be necessary to obtain postdosing specimens for immunological evaluation from most or all subjects in a trial to enable a statistically satisfactory evaluation of immunologic correlates of protection.

Detection of deaths and outmigrations is important to enable the calculation of the person-time at risk during follow-up of trial participants. Detection of these events may be possible by consulting vital event data routinely collected for the population under study, but detection of losses for other reasons (e.g., refusal to continue participation) as well as adequate characterization of the reasons for losses to follow-up will usually require an active strategy. Because the assessment of cause-specific mortality should constitute an element of surveillance for side effects in any Phase III trial, arrangements must be made to obtain clinical records for illness leading up to all deaths in trial participants or, lacking such data, it is important that relatives of decedents be interviewed to obtain “verbal autopsies.”

## 2. Time Frame

The time frame for surveillance must be planned to address the questions posed by the trial. Because field trials provide the best opportunity to evaluate the duration of protection conferred by vaccination, it will usually be desirable to plan for the possibility of long-term surveillance. However, investigators should not be lulled into the intellectual trap of extending the period of surveillance merely as a mechanism to raise the cumulative incidence of the target infection and thereby to reduce sample size requirements. If short-term efficacy is of interest, sample size requirements should be calculated on the basis of the expected incidence for the shortest duration of follow-up to be analyzed [46].

It is now appreciated that vaccine side effects can occur long after vaccine dosing. For example, quite unexpectedly, mortality rates during the third year of life were found to be elevated in female infants who received high-titered measles vaccines at 6 months of age [65]. As a result, national regulatory authorities are increasingly demanding that Phase III trials be designed to capture adverse events of any grade of severity; those that are predictable as well as those that are not; those that occur at any point during the follow-up of subjects in the trial, not just the first several days after dosing; and those that occur infrequently.

Similarly, although short-term immune responses are often measured to gauge whether the vaccine induced the expected levels of immune responses and to assess immune correlates of vaccine protection, serial surveys of immune responses may estimate the kinetics of decay of immunity over time.

The duration of a trial may be truncated if severe side effects are noted during vaccination, contraindicating further dosing, or if a large health benefit occurs in a group that receives an active agent, so that ethical considerations demand that participants randomized to other agents have the opportunity to receive the beneficial agent. This latter consideration is likely to be a major factor in the design of future trials of vaccines against human immunodeficiency virus, particularly if a vaccine that reduces the rate of

infection is identified [66]. Because investigators may have a vested interest in prolonging a trial in order to obtain estimates of long-term protection, it is desirable to place such decisions in the hands of monitoring committees of scientific peers who are not in any way involved in the trial and who can make decisions purely on behalf of the subjects in the trial [67]. Modern Phase III trials are usually monitored by at least two bodies external to the investigative team: a Data and Safety Monitoring Board (DSMB) and an Institutional Review Board (IRB). The DSMB is typically composed of professionals with expertise in disciplines relevant to the trial, such as biostatistics, epidemiology, and clinical infectious diseases. These individuals cannot have any role as investigators in the trial. Typically, a DSMB has the authority to review and approve the final protocol for the trial. It also serves to monitor the trial periodically by assessing both the performance of the trial in meeting its process goals, such as subject enrollment, and by evaluating the adverse events and study endpoints that are observed among trial participants. In the last activity, they are responsible for recommending early termination of a trial to the sponsor.

## 3. Detection Bias

Detection bias distorts estimates of vaccine efficacy via unequal surveillance of vaccines vs. controls for the target outcome. This bias can occur in at least three ways. First, if there are unequal losses to follow-up of study participants in the compared groups, there may be an unequal opportunity to detect outcome events [21]. Although analytical techniques, such as life-table analyses, are designed to adjust estimates of protection for unequal periods of follow-up in compared groups, such techniques may not adequately correct for a bias that may occur if the reasons for the losses and the characteristics of the lost subjects differ in the compared groups [14,15]. Losses to follow-up are less likely to create a bias if they are few in number and if decisions to drop out of the study are not based on knowledge of which agent has been received. Therefore, protection against this bias is best accomplished by choosing a study population that is likely to comply with the study protocol and to have a low rate of migration, by vigilant efforts to maintain contact with the study population, and by double blinding of the trial. Moreover, it is essential that the numbers and characteristics of subjects who are lost to follow-up, as well as the reasons for the losses, be analyzed for each group to permit judgments about whether or not unequal losses in the compared groups were likely to have created a bias.

Second, if subjects in the compared groups have an unequal probability of receiving diagnostic procedures that are necessary to detect outcome events, the comparative occurrence of the events in the groups may be distorted [21]. Double-blinded surveillance provides the most effective safeguard against this possibility. However, effective use of this safeguard will not always be possible in vaccine field trials. For example, in trials of BCG vaccination against tuberculosis and leprosy, it was not ethically permissible to employ a comparative agent whose side effects, including creation of a cutaneous scar, were similar to those of BCG [68,69]. For trials that are not conducted in a double-blinded

fashion, it is important that investigators employ alternative safeguards against biased diagnostic evaluations or at least that they evaluate whether a differential intensity of diagnostic testing of subjects in the compared groups was likely to have distorted estimates of vaccine protection [21]. For example, in field trials of BCG against tuberculosis, use of mass radiographic screening for pulmonary disease, irrespective of the presence of symptoms and of solicitation of clinical care, provided an important safeguard against biased application of diagnostic tests [68].

Third, even if bias has not resulted from differential losses to follow-up or from differential diagnostic surveillance, biased detection of outcomes can still occur if the evidence collected during diagnostic evaluations has not been interpreted in an objective fashion. In a truly double-blinded trial, bias caused by differential diagnostic ascertainment is not a major risk. In a trial in which double-blinded surveillance is not possible, alternative arrangements must be made to ensure objective diagnoses. For example, to prevent biased diagnoses in trials of BCG vaccination against leprosy, a useful tactic was to cover the injection sites of both vaccinees and nonvaccinees during physical examinations [69]. Similarly, in trials of BCG against tuberculosis in which mass chest radiography was used to detect potential cases of tuberculosis, an additional safeguard against biased diagnoses was provided by blinding radiologists to the vaccination status of subjects whose chest films were under evaluation [21]. In addition to such tactics for preventing biased diagnoses, it is also necessary to maximize the accuracy of diagnoses by ensuring that the diagnostic data have been collected in a systematic and accurate fashion and that appropriate and explicit diagnostic criteria have been uniformly applied to the collected data. Diagnostic inaccuracies, even if they occur in a random fashion, may substantially distort measures of the comparative occurrence of events in the groups under study [70].

Finally, in evaluating the possible role of detection bias in distorting estimates of vaccine protective efficacy, it may be helpful to inspect vaccine protection against an *indicator condition*—a disease whose diagnostic evaluation is similar to that for the target infection but against which no vaccine efficacy can logically be anticipated. If the vaccine under evaluation fails to protect against such a condition, the likelihood of detection bias is diminished. For example, in the trial of inactivated oral cholera vaccines in Bangladesh, it was demonstrated that neither vaccine conferred protection against bloody diarrheas, as had been predicted by expectations that protection would primarily occur against diarrhea due to *V. cholerae* O1 and enterotoxigenic *Escherichia coli*, but not against invasive enteropathogens [71].

## H. Issues in Analyzing Data

Although a detailed discussion of statistical strategies for analyzing data in vaccine field trials is beyond the scope of this chapter, a few general comments deserve emphasis. It is important that groups under analysis be assessed for their comparability at baseline (e.g., at allocation), and that the comparability of losses to follow-up be evaluated after baseline. If imbalances are detected, appropriate analytical

techniques should be used to check if the results might have been distorted by baseline and postbaseline imbalances and to correct denomination for losses to follow-up [20].

It is also important that analyses be planned in advance of the study. Before inspection of the data, explicit criteria should be developed for determining which participants will constitute the groups under analysis, and detailed criteria should be formulated for defining outcome events in these analyzed participants. Because the design and interpretation of analyses may be distorted by biases of the data analyst, it has also been recommended that analyses be undertaken and interpreted without knowledge of the agents received by the compared groups [16].

It is unwise for investigators to continuously inspect the occurrence of outcome events in the different groups as the data accumulate because such action poses several dangers. First, if the comparison group for the study receives an agent that is known to be inactive against the target infection and if vaccinated groups are protected, the observed differences in rates of the target infection may “unblind” the investigation and jeopardize the scientific quality of data as surveillance continues. Second, the apparent degree of protection by a vaccine may fluctuate widely with time. For example, during the initial years of follow-up in a trial of oral Ty21a vaccine against typhoid in Area Norte of Santiago, Chile, efficacy fluctuated from 0% to 100% during various 3-month intervals, although there was no consistent trend over time [36]. If investigators use accumulating surveillance data to determine intervals for evaluating “short-term” and “long-term” protection, such fluctuations may lead to the choice of intervals that severely distort estimates of protection. Of course, these considerations do not argue against ongoing inspection of data by an independent scientific committee, for ethical reasons outlined earlier. However, because of the danger of spurious conclusions that can be drawn during multiple scrutiny of the data [67], it is important that such committees employ suitably conservative statistical strategies in evaluating the data and that investigators be kept unaware of these analyses unless it is necessary to terminate the trial.

Multiple analyses of accumulating data constitute one facet of the more general multiple-comparisons problem, alluded to earlier [20,50,51,67,72]. The multiple comparisons problem arises when investigators undertake inter-group comparisons of several outcomes or if the inter-group occurrence of an outcome is compared between several pairs of agents (if more than two are under study), within several subgroups of participants, or at multiple points in time during follow-up. As more analyses are conducted, the overall probability of finding at least one “statistically significant” difference when no true difference exists also increases. For example, if  $P < 0.05$  is the threshold for declaring a difference significant, this means that the investigator is willing to tolerate a 1:20 chance of finding a statistically significant difference arising from chance fluctuations when, in fact, there is no difference between the groups under analysis. If 20 independent comparisons are evaluated, the overall probability that at least one will be statistically significant at  $P < 0.05$ , even if no difference exists, will be 0.64, not 0.05.

To compensate for this problem, several statistical techniques have been developed for reducing the  $P$  value chosen as the threshold for declaring an individual comparison as statistically significant [50,72]. However, because such techniques create progressively smaller  $P$ -value thresholds as the total number of comparison increases, the application of these methods in trials with numerous analyses would make it difficult or impossible to detect statistically significant differences. Application of these techniques is proper only for analyses that are anticipated in advance rather than being suggested after inspection of data [50,51]. These and other dilemmas have created controversy about the proper approach for dealing with multiple comparisons in the analysis of RCTs [51]. Although many strategies are possible, one approach would be to pose primary analyses, addressing the major questions of the trials, and secondary analyses, evaluating other topics of interest. Adjustments of  $P$ -values for multiple comparisons would be made only for the primary analyses, and the results of these analyses would be considered as rigorous hypothesis-testing assessments. Secondary analyses would employ ordinary (e.g.,  $P < 0.05$ )  $P$ -value thresholds but would be conducted as hypothesis-generating exercises requiring conservative interpretation [40].

Finally, an increasing emphasis is being placed on the use of confidence intervals in statistical evaluations of vaccine efficacy, rather than merely declaring protective efficacy as “statistically significant” at some arbitrary threshold (e.g.,  $P < 0.05$ ) [73]. This is because a statistically significant result for vaccine protection merely implies that the results for protective efficacy reject the null hypothesis of no vac-

cine protection; declaration of statistically significant protective efficacy provides no information about the range of values for protection that are statistically compatible with the observed level of efficacy. For the latter, the confidence interval surrounding the estimate of efficacy at a desired level of precision (e.g., 95%) must be calculated. In trials aimed at detecting whether or not the vaccine is protective, the lower boundary of the confidence interval portrays not only whether the results reject the null hypothesis (e.g., do not include 0% efficacy) but also how low protective efficacy might really be, allowing for the play of chance in the trial’s results. For trials designed to determine whether the efficacy of a tested vaccine is at or above some predetermined level, the lower boundary tells whether or not the tested vaccine’s true efficacy is likely to be at or above the desired level [55].

## I. Good Clinical Practice

In recent years, regulatory agencies have placed much emphasis on the concept of conducting vaccine trials leading to vaccine licensure with designs and procedures that conform to “Good Clinical Practice” (GCP) [74]. The essential elements of Good Clinical Practice are outlined in Table 1. In essence, these elements are designed as basic criteria to ensure that trials are conducted in an ethically justifiable fashion, are scientifically sound, and are verifiable. The last feature refers to the need to create sufficient documentation during a trial so that an independent auditor could verify that the findings of a trial accurately reflect the data actually collected.

**Table 1** The Principles of Good Clinical Practice<sup>a</sup>

1. Clinical trials should be conducted in accordance with the ethical principles that have their origin in the Declaration of Helsinki, and are consistent with GCP and the applicable regulatory requirement(s).
2. Before a trial is initiated, foreseeable risks and inconveniences should be weighed against the anticipated benefit for the individual trial subject and society. A trial should be initiated and continued only if the anticipated benefits justify the risks.
3. The rights, safety, and well-being of the trial subjects are the most important considerations and should prevail over interests of science and society.
4. The available nonclinical and clinical information on an investigational product should be adequate to support the proposed clinical trial.
5. Clinical trials should be scientifically sound, and described in a clear, detailed protocol.
6. A trial should be conducted in compliance with the protocol that has received prior Institutional Review Board (IRB)/Independent Ethics Committee (IEC) approval/favorable opinion.
7. The medical care given to, and medical decisions made on behalf of, subjects should always be the responsibility of a qualified physician or, when appropriate, of a qualified dentist.
8. Each individual involved in conducting a trial should be qualified by education, training, and experience to perform his or her respective task(s).
9. Freely given informed consent should be obtained from every subject prior to clinical trial participation.
10. All clinical trial information should be recorded, handled, and stored in a way that allows its accurate reporting, interpretation, and verification.
11. The confidentiality of records that could identify subjects should be protected, respecting the privacy and confidentiality rules in accordance with the applicable regulatory requirement(s).
12. Investigational products should be manufactured, handled, and stored in accordance with applicable good manufacturing practice (GMP). They should be used in accordance with the approved protocol.
13. Systems with procedures that assure the quality of every aspect of the trial should be implemented.

#### **IV. POSTLICENSURE OBSERVATIONAL STUDIES**

After a vaccine has been licensed, it is still necessary to monitor its safety and the protection it confers in practice. Various types of studies are commonly used to evaluate new vaccines once they have been introduced into practice. These include serological assessments of vaccine-induced immunity, evaluations of the levels of vaccine coverage of the intended target population, and assessments of the safety of new vaccines and their protection against clinical disease. A detailed consideration of all of these studies is beyond the scope of this chapter. Here we consider why it is necessary to conduct postlicensure studies of vaccine safety and clinical protection and briefly consider several of the more common designs for clinical studies of these issues.

##### **A. Reasons for Conducting Postlicensure Studies of Safety and Protection**

There are several reasons for continued vigilance in monitoring clinical safety and protection [75]. The spectrum of vaccine recipients in practice may expand beyond that studied in Phase III trials, and this expansion may lead to a decline in vaccine protection. For example, this phenomenon has been noted for conventional influenza vaccines, which often perform better in young, healthy subjects frequently used for testing than in elderly patients, who constitute one of the primary targets for these vaccines [76]. Alternatively, the target population may not change but may later be found to be less than optimally focused. For example, long after conventional measles vaccine was put into practice in the United States, it was discovered that administration of this vaccine at 12 months of age accounted for some vaccine failures, leading to a later recommendation that the vaccine be given at 15 months [77].

The vagaries of manufacturing practice may lead to the inadvertent release of lots of vaccine that are not fully protective, or are harmful. The former was recently illustrated by problems with the immunogenicity of certain postlicensure lots of PRP-OMP, a Hib capsular polysaccharide—*Neisseria meningitidis* outer membrane protein conjugate vaccine [78], while the latter was perhaps most dramatically illustrated by the Cutter incident, in which inadequately inactivated lots of Salk polio vaccine caused paralytic polio among U.S. vaccine recipients in the 1950s [79].

Even without manufacturing errors, the formulation or dosing regimen of a vaccine may ultimately prove unsuitable when the vaccine is administered on a large scale. Sabin oral polio vaccine is less immunogenic when given to infants residing in less developed settings. This observation has led to the conclusion that more doses of this vaccine may be required to protect infants and children in these settings [80]. Similarly, the titers of the three serotypes contained in the Sabin vaccine had to be modified when postlicensure studies found that the vaccine failed to confer suitable protection against type-3 infections in certain developing countries [81].

Appropriately manufactured vaccines may be responsible for rare or long-latency adverse effects that are not

detectable with prelicensure Phase III trials and only appear when the vaccine has been administered to larger numbers of persons over long intervals of time. Although prelicensure studies showed an inactivated vaccine against swine influenza to be safe, a putative association between vaccination and the rare development of Guillain–Barré syndrome emerged when the vaccine was applied on a mass scale [82].

The vagaries of public health practice may lead to errors in vaccine storage or administration that may vitiate vaccine protection. This phenomenon was noted for earlier generations of conventional measles vaccine, for which storage at unacceptably high temperatures led to reduction of vaccine potency [83].

Agents coadministered with vaccine in practice may cause unexpected reductions of vaccine potency. This problem was noted for human diploid cell rabies vaccine, whose immunogenicity is reduced by concomitantly administered chloroquine, explaining an unexpected vaccine failure in a Peace Corps volunteer who took both agents [84].

Finally, the mass administration of a vaccine may lead to higher levels of vaccine protection than were expected on the basis of Phase III trials, owing to the indirect effects of vaccination in reducing transmission of the target pathogen. This phenomenon was recently noted for PRP-conjugate vaccines against invasive Hib disease; despite moderate levels of coverage of targeted children in several industrialized countries, mass administration of these vaccines has virtually eliminated invasive Hib disease in these settings [85]. Although this cannot be classified as a postlicensure “problem,” it is important to document these indirect vaccine effects.

##### **B. Methodological Approaches**

After licensure, it is sometimes appropriate to evaluate new vaccines with RCTs. For example, it may be of interest to compare the performance of different licensed vaccines with one another or different regimens of such vaccines. Such an evaluation was recently reported in the “mix and match” study of different licensed PRP-conjugate vaccines, in which vaccine safety and immunogenicity were assessed in subjects randomized to various multidose regimens of the same vaccine or to different vaccines interchanged with one another within a given regimen [86].

Often, however, it will not be ethically permissible, logistically feasible, or scientifically appropriate to use RCTs to evaluate a vaccine after it has been licensed [11,12]. Ethical problems arise in any such design in which an indicated vaccine is withheld from study subjects who are experimentally allocated to an inert control agent. In addition, because of the expense of RCTs, it is not possible to consider performing a new trial for each question that arises about a vaccine after its introduction into practice. Scientifically, the questions posed after licensure usually address the performance of the vaccine as it is actually given in practice, and it may be difficult to fully replicate practice with a trial, even using the effectiveness trial approach outlined in Section III.B.

For these reasons, observational study designs are most commonly used to evaluate the safety and protection of a vaccine used in practice. These studies are called observational rather than experimental because the investigator does not allocate subjects to receive alternative agents according to some deliberate plan, such as randomization, but assesses the outcomes of receipt or nonreceipt of vaccine as occurs during routine clinical care [87]. Because clinical outcomes under study can be either adverse events or the target illnesses to be prevented by vaccination, these allow assessment of both vaccine safety and vaccine protection.

### 1. Indirect Approaches: Before-and-After Studies

Perhaps, the simplest way to evaluate a vaccine applied in practice to a population is simply to monitor the incidence of the outcome—a side effect or the disease to which the vaccine is directed—before and after the vaccine is introduced. Such evaluations have, for example, provided convincing evidence about the effectiveness of PRP-protein conjugate and measles-mumps-rubella (MMR) vaccines as well as oral polio vaccines, for which mass immunization has nearly or completely eliminated the target diseases [85,88,89]. When the overall incidence of the disease outcome before and after initiation of a vaccine program is assessed, the study is an indirect evaluation of vaccine performance, because vaccinees are not directly compared with nonvaccinees to evaluate the vaccine. Instead, the evaluation of the vaccine relies on the temporal trend of disease in the entire target population, regardless of the proportion of its members who became vaccinated.

Apart from situations in which there are dramatic vaccine effects upon diseases that, in lieu of vaccination, occur predictably year after year and in which disease surveillance is reliable and constant over time, such studies are difficult to interpret. This is because, without comparison of the experience of vaccinees with concurrently followed nonvaccinees, it is usually difficult to know whether temporal changes in the occurrence of disease outcomes reflect the effect of the vaccine, changes in disease epidemiology unrelated to the vaccine, changes in intensity or accuracy of surveillance for the disease, changes in other interventions that may modify the occurrence of the disease, or changes in diagnostic definitions or reporting of disease [87].

### 2. Direct Approaches

*Controlled, Cohort Studies.* If we consider the alternative approach of directly comparing concurrently assembled vaccinees and nonvaccinees for disease outcomes, the most straightforward design is a controlled cohort study [5,75,87,90]. In such a study, the compared groups are then assessed for the incidence of the studied outcome, determined through longitudinal surveillance after assembly. These compared cohorts can be assembled historically, in present time, or a mixture of the two. Similarly, the follow-up of the compared cohorts can occur during an interval prior to the investigation, pari passu with the investigation, or both. A major advantage of controlled cohort evaluations is that they allow comparisons of the cohorts for multiple

disease outcomes within a single study. As a result, if properly designed, a single controlled cohort study can evaluate multiple potential side effects and multiple potential protective effects of vaccination. Another advantage over simple before-and-after comparisons is that cohort studies enable direct estimation of vaccine protection by the same expression,  $PE = (1 - RR) \times 100\%$ , cited earlier for RCTs. This is because RCTs are themselves controlled cohort studies.

However, controlled cohort studies have several limitations. For adequate statistical power to detect vaccine effects, such studies must detect a suitable number of disease outcome events. These studies are thus best reserved for situations in which the studied outcomes frequently occur, thus ensuring adequate statistical power to detect intergroup differences. These investigations are also better suited for evaluations of outcomes that occur relatively shortly after vaccination, so as to minimize the logistical complexities and financial expense of prolonged follow-up of a study population. Examples of research questions well suited to cohort studies include evaluations of vaccine protection against common childhood diseases, such as measles [91], and assessments of vaccine protection during defined outbreaks of the target disease, in which the study population experiences a high attack rate of disease. Because most postlicensure assessments of putative vaccine side effects focus on long-latency or rare events, cohort designs are not commonly used for such evaluations.

*Case-Control Studies.* When the disease outcome under study is rare or occurs long after vaccination, it is usually more feasible to evaluate the vaccine by using the case-control study design [5,75,92]. With this design, groups are assembled not on the basis of being vaccinated or not, as in a cohort study, but on the basis of having developed the disease outcome (“cases”) or not (“controls”). Cases and controls are then contrasted for earlier receipt of vaccination. In a case-control study, cases and controls can be assembled with use of historical records, prospective surveillance, or a mixture of the two. However, histories of vaccination in these studies always rely on historical information.

Case-control assessments have several advantages. Because cases are directly sampled with these designs, case-control studies are well suited for studying rare disease outcomes of vaccination as well as outcomes that may occur with long-latency periods after vaccination. Moreover, because the investigator can arbitrarily select a statistically optimal number of controls for each case and can often enroll the required sample of cases and controls over a relatively brief period of time, the case-control design maximizes statistical power to detect outcomes associated with vaccination, minimizes sample size requirements, and substantially reduces the logistical complexity and financial expense of the investigation.

The case-control design does not provide an estimate of disease incidence in vaccinees and nonvaccinees; therefore, the RR component of the protective efficacy formula is not directly calculable. However, when the disease outcome for the study is rare or when suitable sampling strategies are used for selecting cases and controls [93], the RR from a

controlled cohort design is approximated by the odds ratio (OR) of vaccination in cases vs. controls, where  $OR = (\text{odds of vaccination in cases}) / (\text{odds of vaccination in controls})$  and  $PE = (1 - OR) \times 100\%$ .

A major disadvantage of this approach is that, because cases are defined only on the basis of one disease outcome, a case-control study can evaluate only one outcome of vaccination. However, with a well-focused research hypothesis, case-control studies can enable powerful assessments of vaccine performance in practice. For example, recent case-control studies have provided useful postlicensure evaluations of vaccine protection against such rare diseases as invasive Hib [94] and pneumococcal [4] infections. In addition, this design has proved extremely helpful in evaluating rare but serious potential adverse effects, such as Guillain-Barré syndrome following vaccination with swine influenza vaccine and serious pediatric neurological syndromes following vaccination with conventional whole-cell pertussis vaccine [82,95].

*Variant Designs.* It has been proposed that vaccine performance can sometimes be assessed in the context of prevalence surveys designed primarily to assess vaccine coverage of a target population [75]. At the time of the survey, respondents are asked about the date of past vaccination as well as the date of intervening disease, and vaccine protection is calculated as if a conventional controlled cohort study had been carried out on vaccinees vs. nonvaccinees. This design differs from a conventional controlled cohort study in that it evaluates only those members of the original cohorts of vaccinees and nonvaccinees who are still present at the time of the survey. It thereby ignores cohort members who have migrated out or died during the interval before the survey. Consequently, this design is sometimes referred to as a “residue cohort.” An interesting hybrid design was developed to assess pneumococcal polysaccharide vaccine protection [96]. In this design, isolates from cases of invasive pneumococcal disease sent to a referral center were typed, and histories of antecedent vaccination were obtained without knowledge of these types. Considering that conventional pneumococcal polysaccharide vaccine contains only a fraction of pneumococcal serotypes encountered in infected patients and because serotypes contained in the vaccine are not expected to protect against infections caused by other serotypes, the nonvaccine serotype infections can be considered a suitable control group for the vaccine serotype “cases,” and the expression  $(1 - OR) \times 100\%$  estimates vaccine protective efficacy.

Finally, because it is sometimes necessary to evaluate putative vaccine side effects in situations in which vaccine coverage is very high, leaving very few unvaccinated subjects for comparison, an innovative design, termed “case-series,” has been used. In this design, the incidence of the side effect of interest is compared within two windows of time for the same subject: a window of vulnerability, the postdosing interval in which the side effect is postulated to occur; and a window of invulnerability, another postdosing interval, reasonably proximate in time to the window of invulnerability, in which the side effect is postulated not to occur. This is analogous to cross-over designs used in RCTs, in which

the essential comparison is the within-subject occurrence of the target outcome before and after the cross-over from one agent to another. Interestingly, this design was used very successfully in the evaluation of intussusception following oral receipt of live rhesus rotavirus-reassortant vaccine, an event that is now well documented, was not an expected side effect of this vaccine, at least at the time that Phase III trials were undertaken [63]. Case-series analysis produced estimates of the relative risk of this outcome in vaccinees that were quite similar to estimates from case-control studies [97].

### 3. Increasing Importance of Population-Based Databases

Recent years have witnessed an explosion of allegations about putative serious side effects associated with receipt of vaccines. Some of these alleged associations, such as the occurrence of intussusception following oral receipt of live rhesus rotavirus-reassortant vaccine, have been verified by credible scientific studies [97,98]. Others, such as the alleged occurrence of inflammatory bowel disease or autism following MMR vaccine, have not been substantiated [99,100]. Because assertions about vaccine safety can threaten public confidence in vaccines used in routine practice, it has proved essential that credible, suitably controlled studies be undertaken and completed rapidly when such assertions arise. In the past, public health systems relied principally on side effects voluntarily reported by individual physicians. An example of such a system is the Vaccine Adverse Event Reporting System (VAERS) managed by the Public Health Service [101]. Because of the selective and incomplete reporting of side effects inherent in these systems, as well as uncertainties about the occurrence of denominators of vaccinees at risk and the occurrence of target side effects in nonvaccinees, special large-linked, computerized databases were created, such as the Vaccine Safety Datalink (VSD), which was established by the Centers for Disease Control [102]. These databases link histories of receipt or nonreceipt of vaccines in a defined population with comprehensive records of treatment encounters and hospitalizations for specific outcome conditions in the same population. In addition, information about demographic and socioeconomic variables for each subject are collected, to permit control for possible confounders in analyses of vaccine-side effect associations. If maintained for a suitably large cohort of the target population, these databases enable rapid, controlled analyses and provide the public health community with the evidence necessary for proper regulation of the usage of licensed vaccines. Unfortunately, although such databases are becoming increasingly common in industrialized countries, they are virtually nonexistent in developing countries, where there is an urgent need for postlicensure surveillance of vaccines [103].

### 4. Methodological Limitations of Observational Vaccine Evaluations

Postlicensure observational studies are indispensable tools for providing information about the safety of vaccines and the protection they confer as they are routinely given in

practice. Nevertheless, it is important that investigators be aware of certain general limitations of these studies. As already mentioned, the absence of concurrent controls and the indirect focus on populations rather than a direct focus on individuals constitute weaknesses of indirect before-and-after studies which can severely limit the inferences that can be drawn from these studies. However, even direct study designs can be limited by problems with the quality of information used, by bias, and by intrinsic difficulties in estimating the total protective impact upon the target disease, including both direct and indirect protection.

Most observational assessments of vaccines rely on retrospective information, either documented or recalled, to ascertain histories of vaccination and the occurrence of disease outcomes. The accuracy of this information can be reduced, sometimes significantly, by imperfect recall, inaccurate routine diagnoses, in accurate records, and incomplete records. These issues are not major problems for RCTs of vaccines, because vaccination is assigned in such trials and surveillance for disease outcomes is prospective, usually incorporating uniform diagnostic procedures and criteria as well as systematic recording of outcomes.

Bias in observational studies, which distorts the relationship between vaccination and disease outcomes, can arise either because of the way that a vaccine is given and outcomes are detected in practice, or because of the way the investigators choose groups for comparisons and collect information about individuals in these groups. Bias can arise when persons who are vaccinated in practice do not represent the target population for vaccination with respect to their risks of disease outcomes and when vaccinated and nonvaccinated persons do not receive equally intense and accurate diagnostic surveillance for disease outcomes. Moreover, in selecting vaccinees and nonvaccinees for a controlled, cohort study or cases and controls for a case-control study, there is the potential for biased choices to be made that can alter vaccine-disease outcome relationships. Finally, biases can occur in classifying the vaccination and disease status of study subjects if decisions about vaccination status are not made without knowledge of disease status and vice versa. As noted earlier, the randomization, double blinding, comprehensive follow-up, and systematic and accurate diagnostic procedures employed in an RCT of a vaccine provide the best available safeguards against these biases.

As noted earlier, for infections transmitted from person to person, attainment of a sufficiently high level of vaccine coverage of the target population has the potential not only to reduce the susceptibility to infection directly, via induction of protective immunity, but also to augment this protection indirectly by interrupting transmission of the pathogen in the community. However, because postlicensure observational assessments typically compare disease outcomes among vaccinees vs. nonvaccinees sampled from the same population, and because the benefits of reduced transmission within a population are shared by both vaccinees and nonvaccinees, these studies will usually fail to fully measure the indirect protective effects of vaccination in vaccines and will totally miss the herd immune benefits of vaccination that accrue to nonvaccinees [23–25].

Finally, despite past successes of the case-crossover design in evaluating the associations between vaccines and side effects, it must be realized that use of the design is limited to the relatively uncommon situations in which clear-cut windows of vulnerability and invulnerability can be defined in advance of the study. Moreover, because the serial order of windows of vulnerability and invulnerability are typically defined in the same way for each subject in a case-crossover study, and is not randomized as in a cross-over clinical trial, these studies are potentially vulnerable to biases which can occur if the incidence of side effects is confounded by ordered effects.

Citation of these limitations is not meant to denigrate the value or utility of postlicensure observational studies. Nor is it meant to detract from available tactics in the design, execution, and analysis of these studies that can minimize these potential problems [104]. However, it should be clear from this discussion that the double-blinded RCT serves as the gold-standard design for ensuring the validity of a vaccine evaluation and that postlicensure observational assessments can only strive to approach the assurance of validity provided by properly executed trials.

## V. COMMENT

In this chapter, we have attempted to outline the basic paradigm for the design of modern field trials to evaluate new vaccines. The broad outlines of the RCT paradigm are relatively simple and, in principle, are identical with well-established guidelines for designing trials of clinical therapies [87]. Despite this apparent overall simplicity, however, numerous subtle issues arise when the general principles are applied to the specific questions raised in a particular trial. The perspective of the research question must be clarified, and the design of the trial must be carefully adapted so that the study population, compared agents, and outcomes address this question. Wherever possible, strategies must be formulated to minimize the opportunity for distortion of results by bias while, at the same time, yielding estimates of vaccine protection, safety, and immunogenicity with acceptable statistical precision and generalizability. Extensive background data are required to plan a trial with these features, and great care is required to document the performance of the trial and the absence of bias at every stage of its execution.

We have not included any discussion of the additional complexities that occur when RCTs are conducted in a multicenter fashion or in less developed settings, nor have we addressed the many issues which are important in executing a field trial [105]. A minimum list of these issues would include scrupulous attention to fulfilling contemporary ethical requirements, which are rapidly changing [105–108]; the development and maintenance of productive relationships between the research project and the participating community as well as between scientific collaborators in the project; recruitment, training, and supervision of personnel; procurement and maintenance of supplies and equipment; supervision, coordination, and quality control of field and laboratory procedures; and proper collection and management of data. Even with an excellently designed study, suitable

attention to these issues will be required for the achievement of a successful trial.

Finally, we have attempted to underscore the importance of continued evaluation of the performance of a vaccine, even after it has been deployed in practice. Because such assessments must usually rely on observational study designs, they will be considerably more vulnerable to biases than Phase III RCTs. Nevertheless, when conducted with attention to safeguards against these biases, such studies provide critical information to public health workers in their attempt to ensure not merely that vaccines are delivered to a high fraction of the targeted population but also that recipients of the vaccine are being protected as expected and are not experiencing unacceptable vaccine side effects.

# Ethical Considerations in the Conduct of Vaccine Trials in Developing Countries

**Charles Weijer**

*Dalhousie University, Halifax, Nova Scotia, Canada*

**Claudio F. Lanata**

*Instituto de Investigacion Nutricional, Lima, Peru*

No single issue in the last two decades of the ethics of research has evoked as much controversy as the conduct of clinical trials in developing countries. Facets of the controversy include the following questions: Is there a single international standard for informed consent? Is there a role for community consultation and consent? Where should clinical trials first be conducted? Which standard of care, that of the host or that of the sponsor country, is the right standard? What is owed to research participants at the conclusion of the study? How to manage review of research by multiple ethics committees? Each of these questions ultimately emanates from global cultural diversity and inequities in the distribution of healthcare resources.

The debate was sparked by a 1997 article in the *New England Journal of Medicine* challenging the use of placebo in clinical trials testing short-course zidovudine for the prevention of perinatal transmission of HIV [1]. At the time of the trials, the ACTG 076 regimen was widely used in developed countries and was known to be effective in reducing the rate of perinatal transmission of HIV by approximately two-thirds. Thus, the authors argue, the use of placebo rather than the ACTG 076 regimen as a control treatment in these trials deprived research participants access to effective treatment. Permitting such trials to go forward would in effect, they believe, sanction a double standard for research in developed and developing countries.

Defenders of the short-course zidovudine trials point out that the call for these trials came from developing countries themselves [2]. Important differences relevant to perinatal transmission of HIV exist between developing and developed countries: Antenatal care is not widely accessible in developing countries; facilities for the intravenous administration of zidovudine required by the ACTG 076 regimen do not exist; mothers who are infected with HIV are none-

theless advised to breast feed; and the ACTG 076 regimen is simply unaffordable. Thus the relevant question to physicians and their patients in developing countries is not how the short-course regimen compares to an inaccessible treatment, rather how it compares to the best-available care locally, namely, nothing [3].

Vaccine research in developing countries has not been immune to controversy. A series of clinical trials in the United States and Finland demonstrated that the tetravalent rhesus rotavirus (RRV-TV) vaccine prevents serious rotavirus diarrhea in developed countries [4–7] as well as in developing countries [8,9]. After being approved by the Food and Drug Administration (FDA), it was recommended for universal use in the United States. However, once widespread vaccination in the United States was underway and 1.5 million doses were given, a transient association between RRV-TV vaccination and intussusception was observed. In October 1999, while the definitive studies to prove this association were under way, the vaccine manufacturer voluntarily withdrew the RRV-TV vaccine from the U.S. market. This led to dispute as to whether research with the vaccine should (or could) continue in developing countries [10].

The purpose of this chapter is to provide the vaccine researcher working in developing countries with an understanding of the basic ethical principles of research, international regulations, and current ethical controversies when conducting research with human subjects in developing countries.

## I. ETHICAL PRINCIPLES

The conduct of clinical research is guided by three ethical principles, first articulated in the *Belmont Report*: respect for

persons, beneficence, and justice [11]. The principle of respect for persons requires that researchers seriously take the choices of people who are capable of deciding for themselves. Furthermore, those who cannot decide for themselves are entitled to protection. The principle of respect for persons maps onto the moral rule of informed consent. It is the source of the researcher's obligation to obtain agreement from each research subject for study participation. For informed consent to be valid, the research subject must have the capacity to make the choice, to be able to make a free choice, to be adequately informed, and to understand the information with which the subject has been presented.

The principle of beneficence is typically expressed in terms of two complementary rules. First, do no harm; second, maximize potential benefits while minimizing risks. The complexity of risk analysis in research belies simplistic expressions, such as an "acceptable harm–benefit ratio" or "balance of benefits to harms." The first step in unpacking these metaphors is the recognition that clinical research may contain a mixture of procedures, some offering potential benefit to research subjects (therapeutic procedures), while others are solely administered to answer the study question (nontherapeutic procedures) [12].

Therapeutic procedures in clinical research are justified if there exists a state of honest, professional disagreement in the community of expert practitioners as to the preferred treatment [13]. This so-called state of clinical equipoise ensures that the medical treatment of a patient is not diminished by virtue of study participation. Nontherapeutic procedures, by definition, do not offer the prospect of benefit to individual study participants, and hence a harm–benefit calculus is inappropriate. Rather, nontherapeutic procedures are acceptable if the risks associated with them are minimized, and are reasonable in relation to the knowledge to be gained [12]. For a study to be allowed to proceed, the moral tests for both therapeutic and nontherapeutic procedures must be passed.

The principle of justice may be defined as an ethical obligation to fairly treat people. Researchers must neither exploit the vulnerable, nor exclude without good reason those who stand to benefit from study participation [14]. For proposed eligibility criteria to be evaluated, each criterion must be accompanied by a clear justification in the study protocol. The inclusion of a vulnerable population in research must also be justified. Research subjects may be vulnerable in one or more of three ways: they are unduly susceptible to harm (e.g., pregnant women); they are incapable of providing informed consent (e.g., children); or they are so situated as to cast the voluntariness of consent in doubt (e.g., prisoners) [15]. Finally, in so far as is possible and practicable, the study population ought to mirror the target clinical population.

## II. INTERNATIONAL REGULATION

International codes of ethics for research are a response to a history of abuses in research involving human subjects.

During the Nuremberg war-crime trials, an influential set of principles for research was drawn up in 1947, which were later known as the Nuremberg Code. Subsequently, the United Nations General Assembly signed in 1948 the Universal Declaration of Human Rights, which includes a right not to be experimented upon without informed consent. The World Medical Association (WMA) began drafting a code specifically for physicians conducting research in 1953. However, it was not until 1964 that the recommendations were adopted as the *Declaration of Helsinki*. The *Declaration of Helsinki* has been revised five times, most recently in 2000 [16]. The Council for International Organizations of Medical Sciences (CIOMS) published lengthy and detailed commentary on the *Declaration of Helsinki* with a special emphasis on research conducted in developing countries in 1993 called the *International Ethical Guidelines for Biomedical Research Involving Human Subjects*. This document was revised in 2002 [17]. In 1996, the International Conference on Harmonization published its *Guidance on Good Clinical Practice*. The document provides unified technical standards for clinical trials, so data generated in one country would be mutually acceptable by regulatory authorities the United States, Japan, and the European Union. Finally, in 2000, Joint United Nations Program on HIV/AIDS published *Ethical Considerations in HIV Preventive Vaccine Research* to provide guidance to HIV vaccine researchers [18].

Clearly researchers conducting vaccine trials in developing countries face a complex web of international regulations (Table 1). What guidance can be distilled for researchers?

The most relevant international documents to vaccine researchers are the WMA *Declaration of Helsinki*, CIOMS *International Ethical Guidelines for Biomedical Research Involving Human Subjects* (Table 2), and the UNAIDS *Ethical Considerations in HIV Preventive Vaccine Research*. As we shall discuss below, each of the documents contains controversial provisions. The documents also possess important elements in common. As each document is guided by the same moral principles, it is not surprising that there is considerable convergence among these documents. All of the documents require that proposals to conduct clinical research be submitted to an independent committee to ensure ethical acceptability (WMA 13; CIOMS 2; UNAIDS 6). Informed consent must be obtained from study participants (WMA 22; CIOMS 4; UNAIDS 12). If a research subject is incapable of providing consent, then the consent to study participation must be sought from the subject's legally authorized representative (WMA 24; CIOMS 4; UNAIDS 18). The potential benefits and harms of study participation must be carefully evaluated (WMA 16; CIOMS 8; UNAIDS 9,10). Finally, vulnerable populations in research are entitled to special protection (WMA 8; CIOMS 13; UNAIDS 7).

While this general guidance is of use to all researchers, those conducting vaccine trials in the international setting require more specific guidance, especially on issues of current controversy. The following guidance is based on provisions in one or more of the relevant international guide-

**Table 1** Chronology of International Ethics Guidelines for Biomedical Research

Year	Document	Issuing authority
1947	Nuremberg Code	
1948	Universal Declaration of Human Rights	United Nations General Assembly
1964	Declaration of Helsinki (1)	World Medical Association
1966	International Covenant on Civil and Political Rights	United Nations General Assembly
1975	Declaration of Helsinki (2nd revision—Tokyo)	World Medical Association
1983	Declaration of Helsinki (3rd revision—Venice)	World Medical Association
1989	Declaration of Helsinki (4th revision—Hong Kong)	World Medical Association
1989	Convention on the Rights of Children	United Nations General Assembly
1991	International Guidelines for Ethical Review of Epidemiological Studies	Council for International Organizations of Medical Sciences -CIOMS /World Health Organization -WHO
1993	International Ethical Guidelines for Biomedical Research Involving Human Subjects	Council for International Organizations of Medical Sciences—CIOMS/World Health Organization (WHO)
1995	Guidelines for Good Clinical Practice for Trials on Pharmaceutical Products	World Health Organization (WHO)
1996	Declaration of Helsinki (5th revision—South Africa)	World Medical Association
1996 <sup>a</sup>	International Conference on Harmonization (ICH) Guidance on Good Clinical Practice	International Conference on Harmonization/Committee for Proprietary Medical Products for the Pharmaceutical Industry
2000 <sup>a</sup>	Declaration of Helsinki (6th revision—Scotland)	World Medical Association
2000 <sup>a</sup>	Ethical Considerations in HIV Preventive Vaccine Research	Joint United Nations Program on HIV/AIDS
2000	Operational Guidelines for Ethics Committees that Review Biomedical Research	World Health Organization
2002	Surveying and Evaluating Ethical Review Practices	World Health Organization
2002 <sup>a</sup>	International Ethical Guidelines for Biomedical Research Involving Human Subjects (draft revision)	Council for International Organizations of Medical Sciences—CIOMS/World Health Organization (WHO)

<sup>a</sup> The four most-quoted guidelines for the conduct of biomedical research with human subjects in developing countries include: The Declaration of Helsinki, in its last revision, contains a terse articulation of 32 principles to guide the conduct of research. The Guidance on Good Clinical Practice of the International Conference on Harmonization of 1996 provide unified technical standards for clinical trials, so data generated in one country would be mutually acceptable by regulatory authorities the United States, Japan, and the European Union.

Ethical Considerations in HIV Preventive Vaccine Research of the Joint United Nations Program on HIV/AIDS of 2000, which were created to help the conduct of this type of research as a response to the current controversies. It contains 18 guidance points and is unique in its focus on international vaccine research.

The International Ethical Guidelines for Biomedical Research Involving Human Subjects (draft revision) of CIOMS/WHO 2002 are a lengthy and detailed commentary on the Declaration of Helsinki with a special emphasis on research conducted in developing countries. It is intended to help WHO country members to develop their own national ethical policies for clinical research, guiding them how to adapt international ethical principles to their local realities, and to establish adequate procedures for the ethical review of research protocols of studies with human subjects participation. These guidelines contain 23 major recommendations.

lines as interpreted through the lens of grounding moral principles.

### III. CURRENT CONTROVERSIES

#### A. Is There One International Standard for Informed Consent?

The obligation to obtain informed consent from research participants is well established. Precisely how informed consent is sought may reasonably differ from one context to another. The principle of respect for persons requires that

researchers be sensitive to beliefs and values of the group to which prospective study participants belong. If, as all of the documents require, study participants are to be adequately informed, the informed consent process must ensure that details of the research project are expressed in a way that is locally comprehensible. Thus the disclosure process must take into account local beliefs, literacy, and education.

Must research subjects sign a consent document? This concern flows, in part, from the requirement in U.S. regulation to document the consent process. However, from a moral rather than regulatory perspective, what matters is the quality of the disclosure process, and not whether a form is

**Table 2** The International Ethical Guidelines for Biomedical Research Involving Human Subjects (CIOMS, 2002)

Section	Guideline	Subject
A. Prerequisites of biomedical research	1	Ethical justification and scientific validity of biomedical research involving human subjects
	2	Ethical review committees
	3	Ethical review of externally sponsored research
B. Informed consent of subjects	4	Individual informed consent
	5	Obtaining informed consent: essential information for prospective research subjects
	6	Obtaining informed consent: obligations of sponsors and investigators
	7	Inducement to participate
C. Assessment of risks and benefits	8	Benefits and risks of study participation
	9	Special limitations on risk when research involves individuals who are not capable of giving informed consent
	10	Research in populations or communities with limited resources
D. Selection of research subjects	11	Choice of control in clinical trials
	12	Equitable distribution of burdens and benefits in the selection of groups of subjects in research
E. Biomedical research in special groups	13	Research involving vulnerable persons
	14	Research involving children
	15	Research involving individuals who by reason of mental or behavioral disorders are not capable of giving adequately informed consent
F. Confidentiality of participation and research data	16	Women as research subjects
G. Compensation of research subjects for injury	17	Pregnant women as research subjects
	18	Safeguarding confidentiality
	19	Right of injured subjects to treatment and compensation
H. Capacity building	20	Strengthening capacity for ethical and scientific review and biomedical research
I. International collaborative research	21	Ethical obligation of external sponsor to provide health-care services

signed. In some cultural and political contexts, signing an official form may be associated with different meanings than in the United States, and hence may be an inappropriate requirement. Thus the CIOMS guidelines observe: “Consent may be indicated in a number of ways. The subject may imply consent by voluntary actions, express consent orally, or sign a consent form (CIOMS 4).” In other cases, documentation of consent may pose a substantial risk to subjects if their medical condition is stigmatized. Thus a waiver of documentation of consent “may also be approved when existence of a signed consent form would be an unjustified threat to the subjects’ confidentiality (CIOMS 4).”

### B. Is There a Role for Community Consultation and Consent?

The ethical principles in the *Belmont Report* have been criticized for being unduly individualistic and for failing to take into account the interests of communities [19]. As a result, a novel principle of respect for communities has been

proposed. However, the new principle’s implementation poses difficult challenges for the researcher working with communities. When research is carried out in resource-poor communities, CIOMS guidelines require that research be “responsive to the health needs and the priorities of the population or community in which it is to be carried out (CIOMS 10).” Ensuring that research is responsive to a particular community’s health needs requires a dialogue between community and researcher. Thus “community representatives should be involved in an early and sustained manner in the design, development, implementation, and distribution of . . . research (UNAIDS 5).”

In some communities, for instance aboriginal communities, the burden of decision making may traditionally rest more with community leaders than with individual community members [19]. As the CIOMS guidelines point out: “In some cultures an investigator may enter a community to conduct research or approach prospective subjects for their individual consent only after obtaining permission from a community leader, a council of elders, or another designated

authority. Such customs must be respected (CIOMS 4).” The moral obligation to show respect for communities must be tempered with the simultaneous duty to demonstrate respect for persons. Thus community consent and individual consent have an asymmetrical relationship. The community’s refusal may preclude a researcher’s ability to approach community members for consent. “In no case, however, may the permission of a community leader or other authority substitute for individual informed consent (CIOMS 4).”

### C. Where Should Clinical Trials First Be Conducted?

For the outsider, one of the curious things about the rotavirus vaccine story, described above, is the fact that clinical trials of the vaccine were first conducted in developed countries, while the majority of mortality from the disease occurs in developing countries. A policy decision to test vaccines of interest to developing countries first in developed countries will predictably lead to two consequences. First, the adoption of useful vaccines in developing countries will be delayed as testing goes on elsewhere. Second, the practice has the unintended effect of setting the bar for adoption of a vaccine too high. A country with a low burden of disease will (appropriately) be less likely to accept even small risks associated with a vaccine than a country with a high burden of disease. A 1 in 10,000 risk of intussusception associated with RRV-TV vaccine is rightly interpreted differently in a country with a mortality rate of 1 in 200,000 from the disease and a country with a mortality rate of 1 in 200 from the disease [10]. Thus any absolute requirement to test a new vaccine in developed countries before testing in developing countries is morally problematic.

In other areas of clinical research, it is generally accepted that clinical trials first need be conducted in high-risk populations, for if a new treatment fails, it is unlikely to be of use to any population. The same follows for vaccine clinical trials. It is important to recognize that there is no insuperable ethical obstacle to conducting early clinical trials in developing countries. The statement found in the UNAIDS document might well be generalized to all vaccine clinical trials. Generally, earlier clinical phases of HIV vaccine research should be conducted in communities that are less vulnerable to harm or exploitation, usually within the sponsor country. However, “countries may choose, for valid scientific and public health reasons, to conduct any study phase within their populations, if they are able to ensure sufficient scientific infrastructure and sufficient ethical safeguards (UNAIDS 8).” Differential burdens of disease or important biological differences, e.g., pattern of disease, between developed and developing country would satisfy the requirement for “valid scientific and public health reasons.”

### D. Which Standard of Care, that of the Host or Sponsor Country, Is the Right Standard?

The perinatal HIV prevention trials, described above, highlight a deep divide in research ethics regarding the nature of the researcher’s obligation to research subjects [20]. A core concept in research ethics is that the medical care of the

research subject ought not be disadvantaged by virtue of study participation. In the *Declaration of Helsinki*, this requirement is expressed as: “The benefits, risks, burdens, and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods (WMA 29).” As there are inequities globally with respect to the distribution of healthcare resources, one might well ask: “Best current . . . therapeutic methods” where?

One might answer that the requisite standard should be that in a developed country or, alternatively, one might answer that it ought to be that in a developing country. Each possibility has its proponents; each set of proponents can point to international ethics documents to support its case. While the text of the *Declaration of Helsinki* is ambiguous on this issue, the intention of its authors is not. In a press release, the World Medical Association states: “The WMA opposes the notion that the nonavailability of drugs should be used as a justification to conduct placebo-controlled trials. Dr. Human [WMA Secretary General] said that ‘this would lead to poor countries of the world being used as the laboratory of research institutions of the developed world’ [21].” Adopting a local standard of care in isolation would surely present just such a risk to developing countries. However, no one to our knowledge is suggesting such a move.

Proponents of a local standard of care point out that other protections will prevent exploitation. Central to these protections is the requirement that research “responsive to the health needs and the priorities of the population or community in which it is to be carried out (CIOMS 10).” It is difficult to imagine an exploitative study of the sort Dr. Human is worried about that would both pass a local standard of care threshold and meet the health needs and priorities of the community in the developing country. Furthermore, the adoption of a local standard of care threshold also must not be allowed to take advantage of inefficiencies in a developing country’s healthcare system. One may morally distinguish between the stated policies and objectives of a healthcare system (*de jure* local standard of care) and its implementation in the field (*de facto* local standard of care). The former, and not the latter, should guide the choice of a control treatment for a clinical trial [20]. The UNAIDS document sets a similar standard calling for the “highest level of care attainable in the host country (UNAIDS 16).”

### E. What Is Owed to Research Participants at the Conclusion of the Study?

A further protection for research subjects and the communities in which they live is afforded by the obligation to share research benefits with study participants. However, the precise scope of this obligation is a matter of controversy. In the very least, researchers have an obligation to persons who actually participated in the trial. Thus the *Declaration of Helsinki* requires that: “At the conclusion of the study, every patient entered into the study should be assured of access to the best proven prophylactic, diagnostic and therapeutic methods identified by the study (WMA 30).” But might

obligation be reasonably construed as broader than this? Some have argued that it may be.

The UNAIDS document places a larger responsibility on researchers to not only provide treatment to those who participated in the study, but also to those “other populations at high risk of HIV infection (UNAIDS 2).” The CIOMS guidelines agree with this position stating that the researcher and sponsor have an obligation to ensure that “any intervention or product developed, or knowledge generated, will be made reasonably available for the benefit of that population or community (CIOMS 10).” The CIOMS document takes the further step in suggesting that researchers and sponsors have an obligation to “ensure that biomedical research projects for which they are responsible in such countries contribute effectively to national or local capacity to design and conduct biomedical research, and to provide scientific and ethical review and monitoring of such research (CIOMS 20).”

The feasibility of these recommendations for the provision of treatment to entire community, population, or country may be questioned. For instance, it would have been very difficult, or even economically impossible, after completing the rotavirus vaccine trials in peri-urban Lima where 800 infants participated to provide the vaccine broadly [22]. The cost of the vaccine when introduced in the U.S. market was \$27 per dose [23]. If the scope of the obligation were limited to infants in Lima (the community), this would require the vaccination, for free or at a substantially reduced price, of 150,000 children each year at a cost of \$12,000,000. If the scope were broader yet (the country), it would require the vaccination of the 600,000 infants that are born each year in the whole of Peru at a cost of \$48,000,000. And then ask the question for how long: One year? Five years? In perpetuity? Clearly, the obligation cannot be interpreted so broadly as to render impossible clinical trials designed to develop important vaccines for developing countries.

#### **F. How to Manage Review of Research by Multiple Ethics Committees?**

The review of research by multiple ethics committees poses numerous challenges to all researchers conducting multi-institutional research. Submissions to multiple committees inevitably result in lengthy delays. Worse yet, investigators are likely to encounter divergent responses from differing committees, and required changes from one committee may actually contradict required changes from another. As difficult as these problems are, they are commonplace and well recognized.

Researchers conducting vaccine trials in developing countries face what we believe is an even more difficult problem when research must be approved by ethics committees in both host and sponsor country. The commentary on CIOMS guideline 3 states, “Committees in both the country of the sponsor and the host country have responsibility for conducting both scientific and ethical review, as well as the authority to withhold approval of research proposals that fail to meet their scientific or ethical standards (CIOMS 3).” Conflict predictably ensues from the question: Whose ethical standards shall be followed?

The U.S. government now requires that any foreign institution conducting U.S. funded research sign a document affirming that it will comply with U.S. ethics standards (Assurance of Compliance). One result of this is that rigid criteria are applied to the consent forms used in developing countries. As a result, the length and complexity of information in consent forms has significantly increased over time, perhaps making it more difficult for prospective subjects to understand. When efforts are undertaken in the host country to simplify forms, ethics committees in the sponsoring developed countries often resist even the most reasonable changes.

Two solutions to this situation present themselves. First, the CIOMS guidelines allow for a separation of activities between ethics committees, although responsibility remains joint. CIOMS says, “When a sponsor or investigator in one country proposes to carry out research in another, the ethical review committees in the two countries may, by agreement, undertake to review different aspects of the research protocol (CIOMS 3).” Thus, by agreement, the ethics committee in the sponsoring country could have responsibility to assure the adequacy of the proposed scientific methods and the study’s capacity to answer the objectives of the study. On the other hand, the ethics committee in the host country could then focus on ensuring that the study responds to the needs of the country, selection of study participants is equitable, and informed consent will be appropriately obtained.

Second, the United States must utilize the so-called protections at least equivalent clause. Research funded by the U.S. government generally must abide by provisions set out in the U.S. federal *Common Rule* as well as applicable international regulation [24]. Recognizing that international standards may not be identical to U.S. regulations, the *Common Rule* has a provision allowing for other regulations to be followed. It states that:

[if] a Department or Agency head determines that the procedures prescribed by the institution afford protections that are at least equivalent to those provided in this policy, the Department or Agency head may approve the substitution of the foreign procedures in lieu of the procedural requirements provided in this policy [45 CFR 46.101(h)].

U.S. regulators have yet to specify exactly which international regulations fulfill the protections at least equivalent clause, thereby limiting its application.

#### **IV. CONCLUSION**

There can be little question that many challenges face the vaccine researcher in planning and conducting research in a developing country. The task is made more difficult by divergence among ethics guidelines. We hope that future revisions of current guidelines will provide guidance on current controversies and will aim to minimize divergence among documents. It is encouraging that separate bodies in developed countries, such as the U.S. National Bioethics Advisory Commission or the Nuffield Council on Bioethics

in the United Kingdom, have indicated that solution to these controversies are not to be found in increased regulations, but in closer ties with developing countries and their institutions and researchers [25].

We agree with this approach. Dialogue and investment are required to join the divide between developed and developing countries in the context of research. There is an urgent need for investment in local capacity for research in developing countries. Only with funds and training from developed countries will researchers in developing countries be able to design and implement their own clinical trials addressing local health priorities. Investment is also required in the development of infrastructure and training for the ethical review of research. The Nuffield Council on Bioethics correctly observes “the guidelines and the *Declaration [of Helsinki]* will not be effective unless they are accompanied by training and the necessary resources to allow its adequate implementation in developing countries [26].”

## Vaccine Economics: From Candidates to Commercialized Products in the Developing World

**Amie Batson and Sarah Glass\***

*The World Bank, Washington, D.C., U.S.A.*

**Piers Whitehead**

*VaxGen Inc., Brisbane, California, U.S.A.*

### I. INTRODUCTION: THE IMPORTANCE OF ECONOMICS

The development and commercialization of vaccines depends not only on the scientific knowledge underpinning a candidate but also on the economic costs, risks, and returns associated with the required investments. Ultimately, assuring the best use of limited resources, or economics, is an important factor in all vaccine decisions, whether it is which candidates to develop, which vaccine to scale up, what presentation to select, or which vaccine to purchase for use in national immunization programs. Every step of the development process, from vaccine concept to marketable product, is gated by investment decisions. Understanding the economics guiding these decisions will help scientists and public health experts to achieve the objectives of accelerating the development and availability of priority vaccines, particularly for the developing world.

The private sector's<sup>†</sup> current investment in developing and manufacturing vaccines benefiting developing countries is not as large as would be desirable from the public sector<sup>‡</sup> perspective. In 1992, only 4% of the \$55.8 billion spent globally on healthcare Research and Development (R&D) focused on diseases that account for most of the disease burden in the low- and middle-income countries [1]. This imbalance persisted in 2000, when a study by the Global Forum for Health Research found that only 10% of global research funds were dedicated to the 90% of disease burden

that affects the world's poorest people [2]. More specifically, research and development of vaccines against leading infectious killers, such as human immunodeficiency virus (HIV), malaria, and tuberculosis, remained critically underresourced. For example, in 1999, only \$350 million were spent by the public and private sectors on the development of prophylactic acquired immune deficiency syndrome (AIDS) vaccines and nearly two-thirds of this amount was disbursed by the National Institutes of Health (NIH) [3,4].

This mismatch between disease burden and investment demonstrates that product development is not determined solely, or even largely, by public health need or scientific knowledge. To illustrate this point, consider that industry has invested hundreds of millions to develop vaccines against Lyme disease and drugs against baldness, but very little in vaccines against high mortality infections such as dengue fever, meningococcal A disease, or malaria.

Understanding the economic factors encouraging or inhibiting investment in priority products allows public agencies to work with the vaccine industry in both industrial and developing countries in new ways such as public-private partnerships designed to share risks and returns. These partnerships will enable the public sector to play a more active role in shaping the economics governing critical investment decisions.

In this chapter, the role economics plays in vaccine development and commercialization is discussed, with a focus on the developing world. We describe the characteristics of the vaccine market and the costs to develop and produce a product and explore the economic bottlenecks impacting investment in vaccines, illustrating the issues with a case study of an HIV/AIDS vaccine. Finally, we discuss a series of options for addressing the economic challenges, categorized as "push" and "pull" approaches, and the types of public-private partnerships needed to implement them.

\*Current affiliation: Stanford University, Stanford, California, U.S.A.

†Private sector defined as commercial vaccine manufacturers.

‡Public sector defined as governments, academia, foundations, United Nations (UN) agencies, development banks, and other nongovernmental organizations.

## II. THE MARKET: VACCINE DEMAND, SUPPLY, AND PRICING

The global vaccine market grew at an annual rate of approximately 9% from 1992 to 2000 from \$3 to \$6 billion [5]. In a study in early 2002, Mercer Management Consulting analyzed the market, segmenting by both product and customer groups. Mercer identified four product groups—basic pediatric [e.g., oral polio vaccine (OPV), measles, diphtheria–pertussis–tetanus (DPT), tetanus toxoid (TT)]; enhanced pediatrics [e.g., hepatitis B-containing and/or *Haemophilus influenzae* type b (Hib)-containing combinations, acellular pertussis]; proprietary pediatric (e.g., pneumococcal conjugate vaccine); and adult/travel—and four customer groups—low-, middle- and high-income buyers of pediatric vaccines and of adult/travel vaccines.

As shown in Figure 1, all of these product segments have grown except the basic pediatric category. Most of this growth has come from the high-income countries purchasing enhanced and new proprietary pediatric products. The proprietary products, including the most recently introduced product, Prevnar (a pneumococcal conjugate vaccine manufactured by Wyeth), is by far the fastest growing segment. In 2000, the year of its introduction, sales of Prevnar reached nearly \$500 million and in 2001, roughly \$900 million [6].

Revenues from basic pediatric vaccines, the core of the expanded program on immunization (EPI), have declined significantly since 1992. This decline reflects reduced use of the basic products in Organization for Economic Cooperation and Development (OECD) countries as they are replaced by enhanced pediatrics products. However, despite their relatively small contribution to revenues (13%), basic pediatric vaccines account for over 80% of the total vaccine doses produced globally as shown in Figure 2. In contrast, three proprietary pediatric products, pneumococcal conjugate, meningococcal conjugate, and varicella, represent \$1.7 billion (i.e., nearly 30% of total vaccine revenues in 2000),

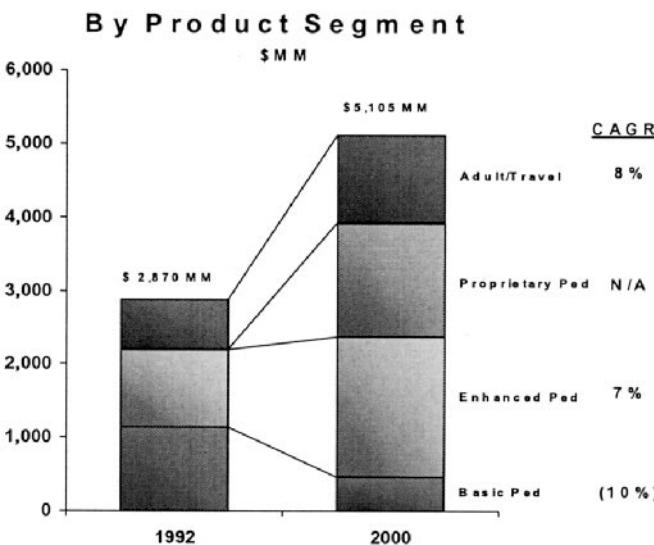

Figure 1 Vaccine market by product and buyer segment. (Source: Mercer analysis, 1992 Vaccine Report.)

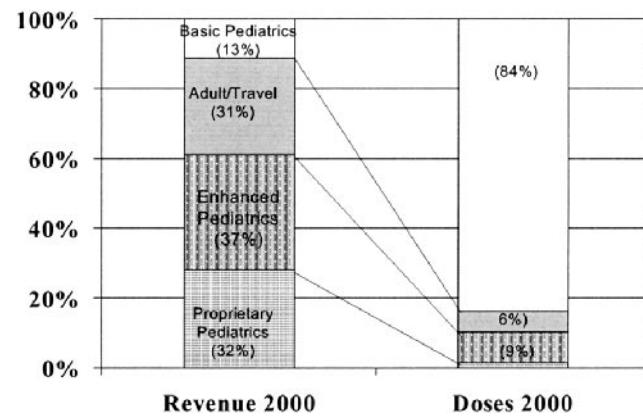

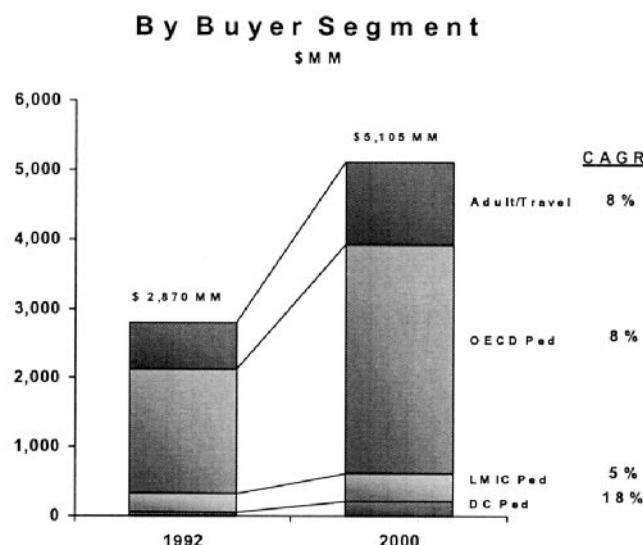

Figure 2 Value-volume skew in the vaccine market. (Source: Mercer analysis.)

but account for only 1% of the total market volume [5]. This illustrates one of the unusual characteristics of the vaccine market—its strong value-volume skew—by which large volumes of vaccines account for a small percentage of the global revenue.

The success of a few new proprietary products has been an important signal to vaccine firms that substantial revenues and profits can be made from the development of new vaccine products targeted at high-income countries. This strategy is comparable to the “blockbuster drug” strategy that has driven the pharmaceutical firms over the last decade.

### A. Vaccine Pricing

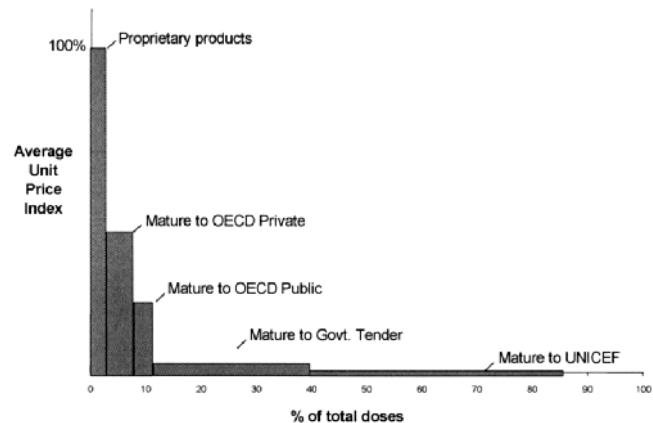

The low prices charged for vaccines in developing countries relative to prices charged in industrial markets is the result of differential pricing (also called tiered pricing, equity pricing,

and price discrimination), whereby different prices are charged for the same products in different markets. Using differential pricing, manufacturers can charge a low price in the poorest developing country markets, allowing these countries access to the product, and charge higher prices in the industrialized markets, allowing the manufacturer to recoup their research and development expenditures. This is a common business strategy, practiced in many industries including airlines which target the business traveler with higher prices by differentiating the product (e.g., open, changeable tickets, no weekend restrictions) and the sales channels (e.g., purchased through a travel agent). Arguably the result of historical accident more than planned strategy, the vaccine market has a segment with the lowest tier price for governments purchasing through international agencies, such as United Nations Children's Fund (UNICEF) or Pan American Health Organization (PAHO), and using multidose rather than monodose vials. Oral polio vaccine offers one compelling example of tiered pricing: In a given year, the highest price at which polio vaccine was offered was, on average, 30× the lowest price (Figure 3)\* [7].

Figure 3 illustrates the distortion in manufacturer's product portfolios created by differential pricing; a few products have very high unit prices and very small volumes, while others have enormous volumes and low prices. Vaccine manufacturers must manage the perception of this price-volume imbalance both within and outside their company. Parent pharmaceutical firms often question the value of supplying the high-volume-low-price market, especially as the price differential between old and new vaccines grows. As shown in Figure 4,\* the proprietary pediatric vaccines are priced significantly higher than basic pediatric vaccines. In 1990, Hib conjugate vaccines established new price points for routine childhood vaccines at roughly \$5/dose for the U.S. public sector and \$15/dose for the U.S. private sector. In just over 10 years, price points for new introduction vaccines in the United States have escalated to \$46–60/dose. From industry's perspective, the introduction of higher margin products, such as Prevnar, makes investment in low-margin vaccines for the developing world even less attractive.

The magnitude of price tiering seen in the vaccine market has been facilitated by a number of factors. First, both high- and low-income markets have historically purchased the same product, allowing manufacturers to recoup their fixed cost investments through higher prices in high-income countries while enabling them to charge lower prices covering only direct costs to low- and middle-income countries second. Tiered pricing was enabled by excess production capacity that existed for several "mature" vaccines. The excess capacity allowed the manufacturer to serve more marginal markets, thus improving utilization of existing facilities, but without requiring any additional investment. Third, the fact that the majority of costs incurred in vaccine manufacture are relatively fixed (i.e., not related to volume)

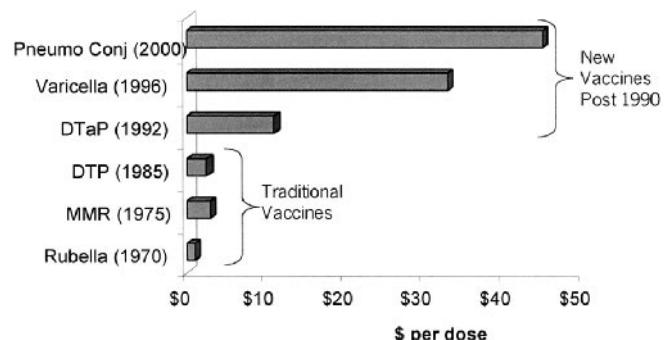

**Figure 3** Typical vaccine market profile for a supplier.  
(Source: UNICEF, Mercer analysis.)

has allowed manufacturers to offer widely differing prices once the core fixed costs are covered. Finally, the acceptance by both suppliers and governments of different prices for different segments of the market has been critical.

Pooled procurement has helped facilitate differential pricing. UNICEF and PAHO purchase large quantities of basic pediatric vaccines at very low prices. The ability of the international procurement agencies to negotiate low prices, the willingness of governments to accept radically different prices depending on national wealth, and the willingness of various manufacturers to supply vaccine at these prices have all been important factors in the success of national immunization programs. As important as pooled procurement has been, it should be noted that the objectives of regional procurement—striving for the lowest price for a region rather than the poorest countries—threaten the equity notion underpinning tiered pricing.

Tiered pricing, however, has also some less desirable consequences. In comparison to other products and markets, the UNICEF and PAHO market generates little revenue and even less profit for many manufacturers—two key factors driving a company's decision to maintain production lines and to invest in R&D and new capacity. This places a burden on companies to justify internally their continued involve-

**Figure 4** Price of traditional and new vaccines.

\* From Economics of vaccines: From vaccine candidate to commercialized product. In: Bloom B, Lambert P-H, eds. The Vaccine Book. New York: Elsevier Science, 2003:345–370.

ment in this “marginal” market. The result is low levels of investment in vaccine R&D and production capacity for the products needed by the poorest countries and little incentive to improve manufacturing processes. The growing divergence between products used in high- and low-income countries and the switch by many developing countries to newer products, such as combinations, which have limited production capacity, reduce the potential for tiered pricing [8].

## B. Diverging Products

The decline of basic pediatric vaccines and the growth of enhanced and proprietary vaccines illustrate the increasing divergence between industrial and developing country markets [9]. The divergence of products is the result of new vaccines targeting regional rather than “global” priorities, whether disease- or safety/efficacy-driven and second-generation vaccines substituting for older products that were once used globally.

In the past, a disease was typically controlled by one vaccine used in both industrial and developing countries. However, today, the same diseases are being controlled with different vaccines, depending on geography and cost. For example, in the 1990s, the majority of industrialized countries adopted diphtheria–tetanus–acellular pertussis (DTaP), containing a purified acellular pertussis, as the vaccine of choice over diphtheria–tetanus–whole cell pertussis (DTwP), containing whole cell pertussis [9]. Although more expensive and, as some believe, not as efficacious as DTwP, DTaP vaccine has fewer moderate adverse events associated with it and has enjoyed a greater acceptance among parents in industrialized countries [10]. The divergence in the number and the type of vaccines used in developing and industrial markets is illustrated in Table 1.

## C. Demand

The six antigens that comprise the basic pediatric vaccines in most developing countries [measles, bacille Calmette–Guérin (BCG), diphtheria, tetanus, pertussis, polio, hepatitis B, and hemophilus influenzae type b] are mature, off-patent products that have been available for decades. These vaccines are widely used around the world and reach between 50% and 80% of infants in developing countries each year. Due in part to increasingly efficient production resulting from both learning over time and economies of scale (i.e., cost per dose declines as volume increases because of increased spreading of fixed costs) and the influence of competition, these vaccines have been sold at very low prices and have provided low marginal rates of return to producers [11].

The introduction of newer vaccines, such as Hepatitis B and Hib conjugate, into developing countries has been very slow, notwithstanding that they have been available in industrial countries for many years. As shown in Figure 5, by the year 2000, 18 years after its introduction in the United States, hepatitis B vaccine had been introduced in less than 15% of sub-Saharan African countries. While these vaccines were provided to developing countries at prices well below those charged in industrial markets, the prices were still much higher than those of basic pediatric products. For example, as demand has shifted from diphtheria, tetanus, and pertussis (DTP) toward DTP combination products containing hepatitis B and/or Hib antigens, the prices being offered to countries through UNICEF and PAHO have increased from around \$0.10/dose to between \$0.90 and \$3.50/dose [12]. In addition to the deterrent effect of these prices, various other barriers have prevented rapid introduction of cost-effective, life-saving vaccines. These include weak delivery systems, inadequate national disease burden data, and unwillingness of governments and donors to increase investments in immunization [13].

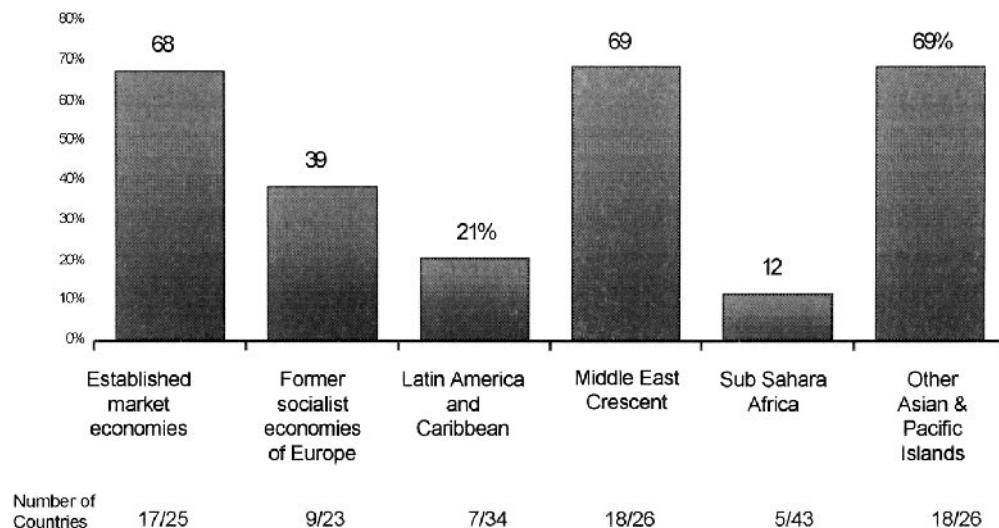

## D. Low-Income Market: Need Does Not Equal Demand

The slow introduction of priority new vaccines in developing countries has created costly confusion between the public and the private sectors. Typically, when public health organ-

**Table 1** Diverging Products Used in Developing and Industrial Markets

Disease target	Developing country product/formulation	Industrial country product/formulation
Measles	Measles	MMR
Diphtheria, pertussis, tetanus	Diphtheria–tetanus–whole cell pertussis (DTwP)	Diphtheria–tetanus–acellular pertussis (DTaP)
Polio	Oral polio vaccine (OPV)	Inactivated polio vaccine (IPV)
Tetanus	Tetanus toxoid (TT) (Td in some areas)	Tetanus–diphtheria
Hepatitis B	Monovalent, combined with DtwP	Monovalent, combined with DTaP, IPV, HepA
Hemophilus influenzae type b	Monovalent, combined with DTwP, HepB	Monovalent, combined with DTaP, IPV, HepB
Meningococcal	Meningitis A/C conjugate (wanted)	Meningitis C conjugate, (Meningitis BC conjugate)
Pneumococcal	11-valent conjugate-wanted	7-valent conjugate-licensed; 11-valent under development
Product presentations	Multidose, thimerosal	Single dose, no thimerosal

izations and vaccine manufacturers each refer to “developing country demand,” they are defining demand differently. Public health organizations have often defined “the market” as those countries where there is a need for the vaccine (i.e., high-incidence countries). Annually, 64 million infants are born in low-income countries, and another 48 million are born in middle-income countries [14]. However, the *actual* market is the portion of this need that translates into revenue or demand for a given quantity of a vaccine at a given price. Thus while the need for a vaccine may be large given the number of individuals who would benefit from it, the actual demand is much smaller because many of those who need the vaccine are least able to pay for it. Despite 85% of the global population living in low- and middle-income countries [14], the vaccine market in the developing world is estimated to be only 10% of the global vaccine market of \$6 billion and less than 0.2% of the global pharmaceutical market (\$340 billion annually) [5,15].

Historically, the public health community’s estimates of vaccine need (confusingly called demand) have been far larger than actual national or international willingness to pay for the vaccine (Table 2). The resulting gap between expected demand, based on public health need, and real de-

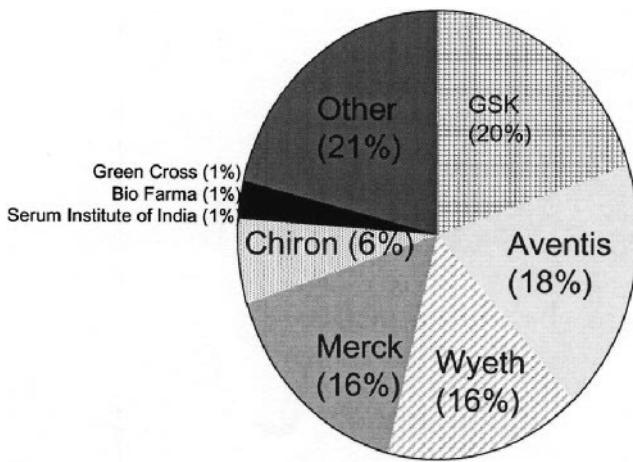

mand, based on willingness and capacity to pay, has had expensive implications for manufacturers. Several manufacturers have, in the past, built production capacity and planned their production runs to meet these inaccurate forecasts. Given the long lead times required to produce and to control batches of vaccines, these decisions were made 12–18 months in advance of expected uptake. When actual uptake was much lower than anticipated, manufacturers had to manage excess inventory and sudden changes in production schedules—both of which are inefficient and costly. The poor quality of forecasting has increased the risk (and cost) of serving the developing country market. It has also undermined the credibility of public sector agencies urgently calling for investment in new vaccines “needed” to combat such diseases as diarrheal diseases (e.g., rotavirus, *Shigella*) or malaria.

### E. Vaccine Supply

The vaccine industry is currently dominated by a small number of multinational firms (Figure 6): GlaxoSmithKline, Aventis Pasteur, Wyeth, and Merck. These firms have seen their share of the vaccine market (measured by revenues) rise

**Table 2** Who Uses and Who Buys Vaccines?

Children are the main recipients of vaccines; receiving between 8 and 12 different vaccines protect children from deadly and debilitating diseases such as measles, hepatitis, and diphtheria. In most countries, however, families do not purchase vaccines. As a preventive intervention that protects not only the individual child but also all who come in contact with the child, immunization has “positive externalities” and is primarily financed by governments and public health agencies including bilateral donors, multilateral institutions, development banks, and foundations. Each country relies on a different mix of funding sources for their immunization program; however, typically, the government finances the majority of the program’s costs [16]. The decision by governments, donors, and bilaterals to purchase vaccines depends on the absolute resources available and how these resources are allocated given other needs. Disease burden, the potential impact of the vaccine, the vaccine’s price, and the cost to deliver the vaccine to each child are all important considerations in deciding the amount of scarce resources to allocate to immunization [13].

**Figure 6** The vaccine players in the vaccine market.

from approximately 50% in 1988 to about 70% today. Small- to medium-sized companies, notably Chiron, and emerging companies in Korea, India, and Indonesia comprise an additional 10%, with the remaining revenues attributable to local OECD and developing country producers [5,15].

Until recently, uncertainty about market growth and profitability, combined with rising costs and growing fears of liability, resulted in a dramatic decline in the number of industrial country vaccine manufacturers. Many manufacturers merged, sold, or shut down their vaccine business. Of the 20 internationally active companies in the 1960s, fewer than 12 remained by the early 1990s [17]. However, the vaccine market is now looking much stronger. Even before the interest in vaccines stimulated by bioterrorism concerns, new product opportunities were creating revenue growth expectations in double digits for the years ahead [15]. Many of the new entrants to the vaccine-manufacturing field are smaller and based in middle- and low-income countries.

Since 1992, there has been an increase in not only the number of these emerging and local suppliers but also their overall production capacity and product range. However, most of the vaccines produced by local and emerging suppliers are still licensed and used primarily within the home market. The World Health Organization (WHO) conducted a series of studies on behalf of the Children's Vaccine Initiative (CVI) evaluating domestic vaccine production in 10 countries from 1993 to 1995 [18–24]. These studies found that while local producers were important supply sources, many faced significant structural, legal, and economic challenges. For example, vaccine prices, or worse, fixed budgets were often set by the government and, in many cases, did not cover the full costs of production, making it difficult for these publicly owned suppliers to maintain the facilities, to train staff, to expand production, or to invest in new vaccine R&D. In addition, many manufacturers did not have the authority to hire or to fire staff or to set competitive salaries. A few emerging suppliers have overcome these difficulties and represent an attractive low-price supply source for basic pediatric vaccines. However, these suppliers do not have a strong track record in new product development.

Given the quickly evolving vaccine market, both multinational and emerging suppliers will be important supply sources for the world. Multinational firms are likely to be the primary source of newly developed products for the short to the medium terms, while emerging suppliers may become the low-price supply source over the long term for the developing country markets.

### III. BRINGING A VACCINE TO MARKET: COSTS, RISKS, AND CONSTRAINTS

Each firm has a portfolio of R&D projects within which it allocates investments. While the public sector supports a great deal of basic research, private manufacturers usually finance most of the product development, production scale-up, and sales costs. Assessing and financing the risk associated with these investments is a major part of the pharmaceutical business. These risks span all the stages in bringing a vaccine to market and include not only the scientific and technical risks but also political and market-based factors. This combination of known costs and benefits plus possible risks determines a company's decision to invest in a product or not. Firms continually compare investments across the products in their portfolio. Products with high potential profits and low risk are more attractive investments than those with limited expected earnings and/or high risk. The expected profits, often measured as a percent of investment or "return on investment" (ROI), are a function of expected costs, risks, probable demand, and thus expected profit. Firms must not only ensure each project is viable but also that the total product revenues cover the R&D costs of ongoing and new projects. Given the relatively lower prices available in developing country markets, manufacturers are, not surprisingly, less willing to accept all the risk associated with vaccine investments for these markets. Understanding the risk–return trade-off, and possible areas over which the public sector has influence, provides the public sector with an opportunity to intervene in a manner that may diminish risks. Table 3 (footnote a) illustrates the average number of candidates, the time of development, and the cost of development for one successful product. On average, one successful product is registered for every five candidates supported in preclinical trials.

#### A. Baseline Development Costs in a Perfect World

There is a set of defined costs which constitutes the investment needed to develop, to scale up, and to sell a vaccine in the absence of any failures, complications, or delays in a perfect world. These baseline costs include basic preclinical research, clinical trials, production scale-up, licensing fees, ongoing production, quality control, and marketing. The costs vary based on the particular characteristics of the disease, the vaccine, and the production technology. For example, because the incidence rate is lower, trials of an HIV/AIDS vaccine need to be larger and thus more expensive than trials of a vaccine to prevent pneumococcal ear infection.

The baseline costs associated with product development correspond to four distinct stages: (1) basic, preclinical

**Table 3** Average Vaccine Development Costs per Product

	Pre-clinical	Phase 1	Phase 2	Phase 3	Pre-registration	Registration	Launch	
Time	2.4	2.0	1.8	1.4	1.1	1.3	Total 10 years	
Market entrance probabilities %	22%	39%	54%	68%		98%

research; (2) identifying a promising vaccine candidate through early clinical studies in humans; (3) developing and testing a candidate for a target market; and (4) scaling up manufacturing capacity for that market. Based on an analysis of the cost to develop an HIV/AIDS vaccine [25], Figure 7 shows the relative magnitude of these investments—turning each new stage into a decision gate initiating a reevaluation of the investment given the product’s risks and potential return.

Assuring a vaccine for global use requires two additional stages of investment: (5) “relevance”—adapting and testing a vaccine to ensure safety and efficacy in additional populations; and (6) “supply”—ensuring adequate manufacturing capacity and funding/pricing structures to enable broad developing country access. To make a new vaccine broadly available at the earliest possible technical and regulatory opportunity, a manufacturer must make development and capital investments explicitly to support supply to the developing world markets. To have a business case for such incremental investments, a return must be available either directly from the developing world market or through other special financing interventions. In the case of vaccines for which no significant industrial market exists such as malaria, it follows that the developing country market and the associated financing must fund, and provide a return on, the entire investment.

## B. Vaccine Production

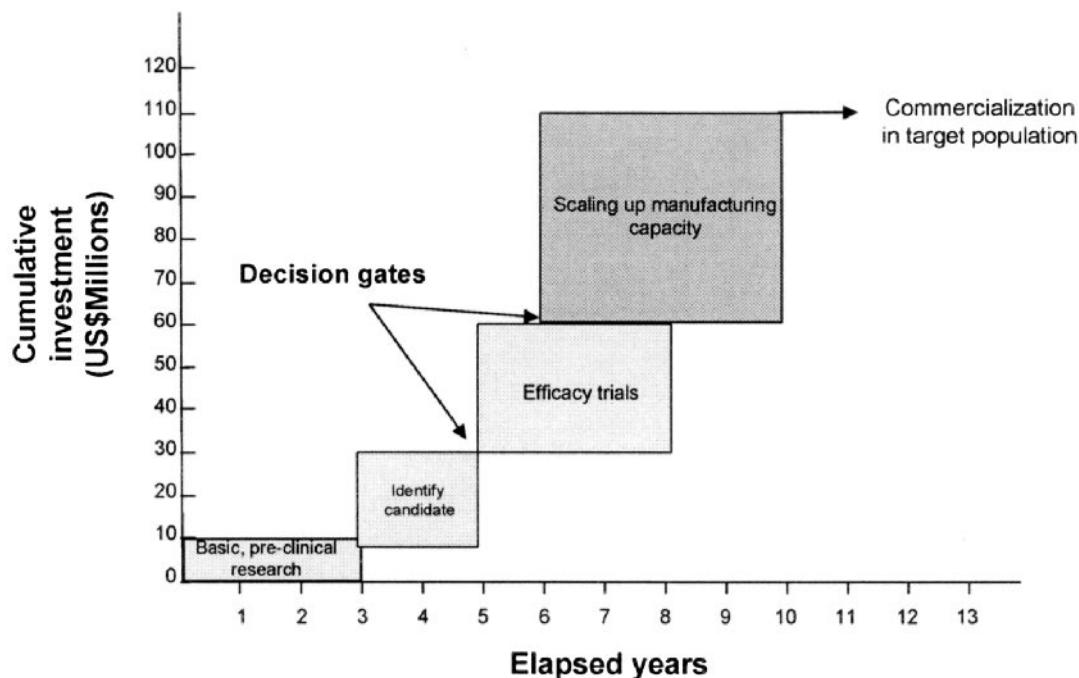

Vaccine production has two primary stages: (1) bulk production consisting of activities such as growing or fermenting the active ingredients harvesting, and potentially

attenuating the live virus or bacteria; and (2) fill/finish consisting of activities such as blending, filling vials, lyophilizing, labeling, and packaging. All firms require Good Manufacturing Practice (GMP) production facilities with appropriate quality control and quality assurance.

The costs associated with vaccine production can be categorized as variable (unit cost is constant for each vial), semivariable or batch fixed (unit costs associated with each batch), and fixed (unit costs are independent of volume and are fixed at the site level). Vaccine production is a “fixed cost business,” in that roughly 85% of costs are fixed at either the batch or site level (plant, equipment, animals, labor), leaving only 15% truly variable (vials, stoppers, raw materials). As a result, unit costs fall rapidly with increases in volume. Importantly, however, the capacity for a given vaccine is largely determined at scale-up and is thereafter expensive and time-consuming to increase.

The cost to produce vaccine varies significantly from product to product. The primary factors affecting the cost are outlined in detail below and include the presentation, the scale of operations, the vaccine inputs, the supply location, the batch size, and certain vaccine production characteristics. Understanding the economics of production can guide public sector in its choice of suppliers, its policy decisions such as the optimal presentation of the vaccine and its strategy options such as the timing of commitment to purchase.

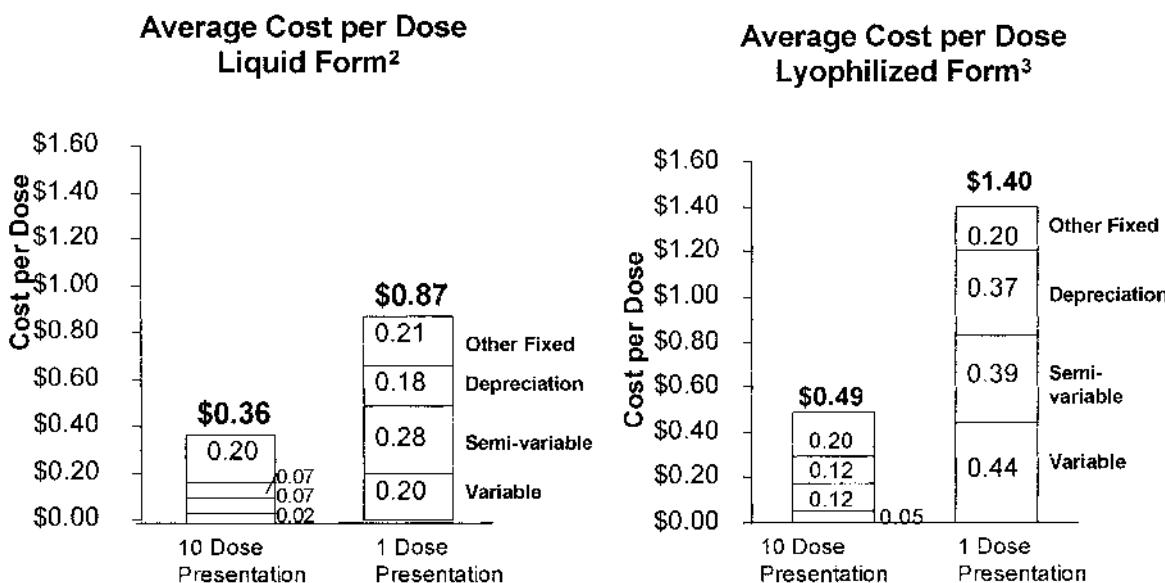

1. Presentation: Presentation (e.g., the number of doses per vial, labeling) is determined by the buyer rather than the supplier and so must be carefully considered when there are limited resources. As shown in Figure 8, single-dose presentations are significantly more expensive to produce than multidose presentations because of their impact on

**Figure 7** Baseline investments and decision gates in developing an HIV/AIDS vaccine for one target population. (Source: Batson, Ainsworth. Bull WHO, 2001.)

filling lot size. Lots of single-dose vials require almost the same labor and equipment as multidose vials, but with far smaller output. For an industrial country supplier, it was estimated that single-dose presentations added approximately \$0.50/dose to the cost of a liquid vaccine and \$1.00 to the cost of a lyophilized vaccine [5].

2. Scale of operations: Given the manufacturer's cost is a function of the number of doses produced, vaccine production is a very fixed cost business, which means that almost the same level of investment is needed whether 50 or 200 million doses are produced. However, obviously the per dose cost drops as volume increases. The importance of scale

<sup>1</sup> Multinational producers only; <sup>2</sup> Includes TT, DTP, Hep; <sup>3</sup> Includes MEA, MMR, Hib.

**Figure 8** Average cost per dose across vaccines to produce liquid and lyophilized 1 and 10 dose vials. (Source: Mercer Management analysis.)

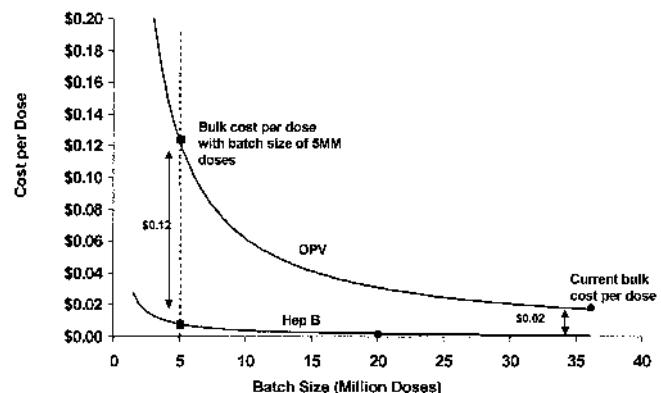

is best illustrated by comparing suppliers from the United States and Europe. U.S. vaccine firms are higher-cost producers relative to European firms because of the former's overall lower volume levels (fewer than 100 million doses annually vs. over 1 billion doses for certain European multinationals). The cost impact of this "scale effect" is estimated to add as much as \$0.65/dose in cost for U.S. firms [5].

3. Reliance on inputs for vaccines: Having to purchase certain expensive inputs for a vaccine rather than producing them within the firm can dramatically impact the costs. As the demand for combination and conjugated vaccines has grown, almost all firms have been forced to purchase either antigens or protein carriers from outside firms. The increase in outsourced components significantly impacts the economics of vaccine production. First, outsourcing increases variable cost so the *marginal* cost of vaccines with significant outsourced components will likely be higher than those produced entirely in-house. Second, although it is not known, it is likely that these arrangements increase the *absolute* cost of the vaccine in question because the overhead costs and profit margin of the component supplier must also be factored in.

4. Supply base location: All else being equal, industrial country suppliers are higher-cost producers than large emerging suppliers because wage rates for pharmaceutical labor in lower-income countries, such as India and Indonesia, are less than 10% of comparable wage rates in high-income countries. This wage rate impact is estimated to give emerging suppliers as much as a \$0.12/dose advantage over industrial country suppliers.

5. Vaccine batch size: The size of bulk batches is an important cost factor as shown in Figure 9.\* Because the cost to manufacture and to test a batch is largely fixed, an increase in batch size results in lower per dose costs. Batch size is largely determined at the time of manufacturing scale-up. Once a plant is in place, there are two ways to increase batch size. The first is to add capacity, a process that requires additional capital, may disrupt production, and certainly requires regulatory approval and GMP certification. The second is to wait and to allow the experience effect to drive yield improvements and consequent increases in effective batch size. Although some vaccines, such as recombinant hepatitis B, appear to have experienced very rapid and dramatic improvements in yield, the available data suggests that for most vaccines, it takes years before batches are large enough to serve the developing country market. Given the difficulties of increasing batch size once a plant is built, the optimal strategy to assure capacity and relative affordability is to influence batch size at the time of scale-up, perhaps through early commitment to purchase.

6. Vaccine production characteristics: Different vaccines have differing testing and labor requirements, antigen combinations, and production process cycle times, each of which has impact on the cost of production. However, these differences have been estimated to have a relatively minor impact on total costs [5]. As an example,

**Figure 9** Batch size effect on bulk production costs (based on a representative sample of multinational suppliers). (Source: Mercer Management analysis.)

vaccine to produce at the bulk stage is OPV. However, the fact that this vaccine is manufactured by high-scale producers in large batches of multidose presentations results in one of the lowest per dose production costs of any vaccine.

### C. Risks

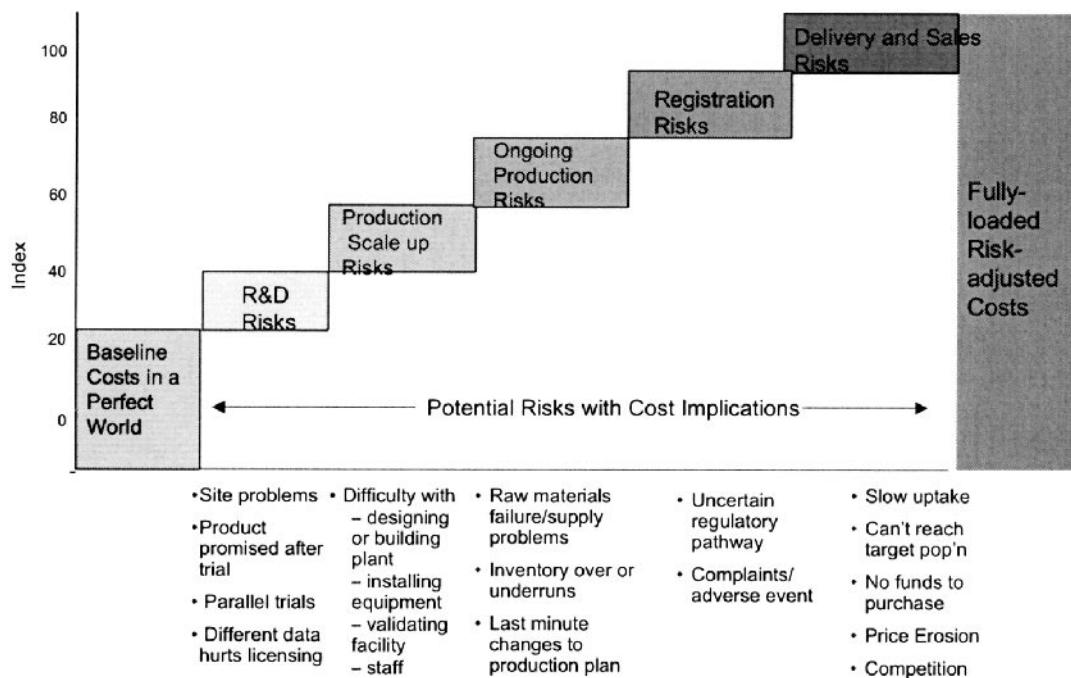

In addition to the expected R&D and production costs, every product faces a range of semipredictable and unpredictable risks. Should they become real, any one of these risks can necessitate significant additional investment or—if the product fails entirely—result in wasted investment. Figure 10 illustrates some of the risks that exist at each stage of the product's life from earliest research to final sales. These risks build on the expected development, production, and sales costs and, ultimately, impact the estimated total or risk-adjusted costs of the product. For example, for a certain vaccine, a planned \$50-million investment would result in a cost of \$0.20/dose; however, if there is an unexpected 1-year delay in launching the clinical trial (costing \$4 million) plus an unexpected problem with validating the new plant (adding another \$10 million) and unexpectedly slow introduction of the product resulting in both extra inventory costs and lost revenues, a number of unplanned costs must be factored in. Added together, these unexpected events could increase the total costs to roughly \$70 million, resulting in a unit cost of \$0.30/dose, significantly over original expectations. Obviously, not all the things that could go wrong do go wrong. However, cost expectations should reflect the more realistic risk-adjusted estimate.

The following are more detailed descriptions of the different types of risks that contribute to the full costs of developing and producing a vaccine.

1. Research and development: Faced with finite human and financial resources to support R&D projects in the pipeline, the decision to invest in one candidate will absorb resources that could have been used for other products. The opportunity cost of supporting one project vs. another has real costs to the firm and must be factored into decisions.

Given the cost of efficacy trials, companies seek to minimize the risks of a trial failing or being delayed. How-

\* From Economics of vaccines: From vaccine candidate to commercialized product. In: Bloom B, Lambert P-H, eds. The Vaccine Book. New York: Elsevier Science, 2003:345–370.

**Figure 10** Potential risk with cost implications over product's life cycle.

ever, if there are not good animal models or correlates of immunity to help predict the probability of the product successfully protecting humans, such as, e.g., with HIV/AIDS vaccines, then investments in expensive Phase III trials for a vaccine candidate are even riskier. In addition, each additional trial to test efficacy in a different epidemiological region can add between \$10 and \$30 million to the product's development cost. Moreover, clinical trials conducted in developing countries with different epidemiological conditions may present risks to licensure in industrialized countries that outweigh the potential revenues from the developing country market.

Each product may also have unique risks. For example, as the number of antigens in a combination increases, so does the risk that at least one of the antigens will have reduced immunogenicity or efficacy or that an adverse event associated with one antigen will reduce demand for the combined product.

2. Production scale-up: Companies most often invest in the production scale-up before the final data from the Phase III trials is available. This early investment is for two reasons. First, it is a condition of licensure for any biologic that the company demonstrates that it can make its product in a repeatable fashion at commercial scale. Second, to assure timely availability of new products, a production facility must be fully operational as soon as the product is proven to be efficacious. However, if the product fails at a late stage, the firm risks losing most or all of its investment. Investment in production capacity is particularly difficult because many firms face growing internal competition for these resources. The opportunity cost and risks of building or using a facility for one product vs. another must be considered.

Sizing a facility appropriately, given uncertainties about future demand, is also difficult and risky. On one hand, a larger facility requires greater investment, but, because of economies of scale, can result in more efficient, lower-cost production in the long run if large volumes of the product are demanded. However, if demand is lower than expected, the facility will be underutilized, a costly waste of resources. On the other hand, a smaller facility requires less total investment, but the firm is less able to take advantage of economies of scale, thus the long-term cost per dose may be higher. If demand is greater than expected, then the company not only loses the market to a competitor but must also invest in resizing its facility, a costly and time-consuming mistake.

3. Regulatory and licensing issues: Regulatory requirements have become increasingly stringent and preparation of applications for marketing authorization is hampered by the differing requirements across countries. Obtaining separate authorizations for each market in which a manufacturer proposes to sell a vaccine is a long, costly, and uncertain process.

In addition, the growing difficulty in finding appropriate regulatory pathways for developing country vaccines produced in the United States and Europe increases the risk to licensure. Most new vaccines are produced in either the United States or European countries. The Food and Drug Administration (FDA) and the European Agency for the Evaluation of Medicinal Products (EMEA) each have a responsibility to regulate products for their home markets. However, these agencies are also called upon to regulate products intended for developing countries, which are developed and produced by manufacturers situated within

their borders. If these agencies decline to or are prevented from applying their regulatory expertise for products that will not be marketed within their borders, the risks and costs to the companies will increase significantly.

Even once licensed, unexpected adverse events identified through postmarketing surveillance may result in a decline in demand for the product such as in the case of Wyeth's Rotashield. The millions of dollars invested in developing and scaling up production for this vaccine were lost once the product was associated with the risk of intussusception, a rare but severe complication.

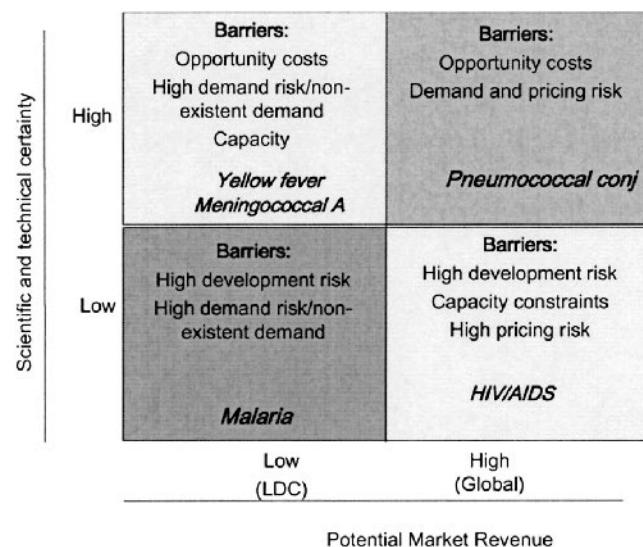

Finally, intellectual property rights (IPR) are intended to safeguard returns on new products, enabling manufacturers to recoup their investment. Weak IPR protection increases the risk (in the eyes of the firm that made the initial investment) of multiple suppliers competing for the same market—without having invested in the R&D. This risk may be so significant that it reduces a firm's interest in developing a high-priority vaccine. Concern for IPRs has been less of a problem for vaccines than drugs because vaccines are, in large part, also protected by technical "know-how," the knowledge of how to scale up and consistently produce a biological product, as well as stricter import controls.

4. Ongoing production: Once a product is fully developed, licensed, and ready for production, firms face production risks that can occur at any time. A component of the close regulatory oversight around vaccine manufacture is that every batch is tested before being released. Seemingly inconsequential changes to the production materials or process, such as a change in brands of cleaning fluid used to wash out a fermenter, can cause a batch to fail and hence the investment in the batch to be lost. These failures can be particularly costly, given the relatively lengthy period required to produce a batch of vaccine (9–15 months). Batch failures and unexpected changes in demand can be costly to manufacturers as they may result in excess inventory, market shortages, or last-minute changes to the production schedule.

5. Delivery and sales: All of the investments will be meaningless if no market for the product materializes. A market may "disappear" if there is a change in the perceived risk of a disease or the national immunization priorities, the immunization delivery systems within a country is not able to reach the target population, or there is limited funding.

While public-private partnerships, such as the Global Alliance for Vaccines and Immunization (GAVI), provide support to strengthen immunization infrastructure and purchase new vaccines, in many countries, less than half the target population is immunized [26] and decisions to introduce the vaccine still depend on national decision makers having the necessary national data at hand.

The potential future market (e.g., demand at a given price) needs to offset all of the costs on a risk-adjusted basis and to provide a return, if private sector investment is to be attracted. However, for the developing country market, there is a great deal of uncertainty about not only which vaccines will be demanded and financed by governments and partners but also when these vaccines will be demanded and introduced. The slow and uncertain uptake discussed earlier in the chapter has greatly increased uncertainties,

**Figure 11** Barriers given degree of scientific certainty and potential market revenue.

and therefore perceived risk, in serving the developing country market.

#### D. Each Vaccine Is Different

The relative importance of different risks varies from vaccine to vaccine. Each vaccine faces a unique mix of obstacles that may be best overcome by different types of interventions. Figure 11 shows two key factors that influence how attractive or risky a vaccine is perceived to be—the potential market revenue and the degree of scientific certainty. For instance, a vaccine against a disease like malaria, which has low scientific certainty [27] and low-revenue potential, faces both high development and demand risk. By contrast, a meningococcal A conjugate vaccine intended primarily for Africa has high scientific and technical certainty, but a very limited revenue opportunity. In such a case, the primary barriers are the opportunity costs, the constraints on capacity, and the high demand risk. HIV vaccines, for which the revenue opportunity is high but the scientific and technical certainty is low, represent a tantalizing, often frustrating, opportunity for manufacturers. Accelerating its development may require incremental investments to tailor a vaccine to the needs of developing countries once a successful approach is discovered as well as innovative ways to ensure affordable pricing.

#### IV. A CASE STUDY OF THE RISKS, COSTS, AND CONSTRAINTS TO BRINGING A VACCINE TO MARKET: HIV/AIDS VACCINES

Despite the obvious need for an HIV vaccine, and the rhetoric endorsing this view, investment in both the public and the private sectors in HIV vaccine research and devel-

opment has significantly lagged both need and rhetoric. Worldwide, combined public and private expenditure on R&D for preventive HIV vaccines was estimated to be only \$350 million in 1999 [4]. While the public sector, most notably the NIH, has more than tripled its investment in HIV vaccine research from \$100 million in 1995 to an estimated \$360 million in 2002, the private sector has, for many of the reasons discussed in the preceding sections, proceeded cautiously with investment in the development of an HIV/AIDS vaccine for the developing world. Estimated industry investment in HIV vaccine development was in the range of \$50–124 million in 1999 [4].

Hundreds of millions, even billions, of people around the world would benefit from an HIV vaccine. So why is the commercial sector so cognizant of market size, proceeding with such modest effort? In 1998, the World Bank AIDS Vaccine Task Force commissioned a study, cosponsored by the International AIDS Vaccine Initiative (IAVI), to understand the low levels of private investment [25]. Through interviews with various experts from vaccine manufacturing, biotechnology firms, and academia, the study concluded that while scientific obstacles remained a short-term impediment to AIDS vaccine development, a low expectation about the probable return on the investment was also a significant deterrent.

#### A. Barriers to Increased Investment

In 1998, the low levels of investment in an HIV vaccine could be partially explained by the inability of companies to foresee a realistic commercial return. At that time, companies feared that the industrial country market would consist only of high-risk individuals and, of course, the developing country markets were not expected to generate significant revenues. However, companies also cited the scientific risks as an equally important barrier. Respondents to the study stressed that it was the combination of scientific and economic risks including unpredictable industrial country uptake, questionable developing country market, perceived low probability of success of any existing candidates, and the high profile of some failures that in combination created corporate reluctance to increase investment.

The scientific barriers arise from a number of factors. First, two of the three approaches most commonly used for existing human vaccines (i.e., live attenuated strains of the virus and whole virus inactivated) have not been considered appropriate for an HIV/AIDS vaccine. Given the nature of the virus, safety concerns have prevented the testing of candidates based on these approaches. Inactivated vaccine candidates have also been hampered by concerns about potential manufacturing difficulties. The failure to neutralize primary isolates in preclinical testing has prevented most first-generation subunit candidates from entering efficacy trials although one improved recombinant subunit product started such trials in 1998 [28]. As a result, the bulk of current efforts are focused on approaches that have few or no current vaccine analogues and hence involve greater scientific uncertainty.

This scientific uncertainty is further compounded by the limited understanding of the virus, not knowing the corre-

lates of immunity, and the lack of relevant animal models—all of which contribute to a much higher degree of uncertainty about the potential efficacy of a vaccine candidate than is typical when industry considers investing in large and expensive Phase III efficacy trials. Study respondents noted that Phase III trials are normally supported only once there is relatively solid evidence that the product is viable and highly likely to be efficacious. In the case of an HIV/AIDS vaccine, firms would have to finance expensive trials to explore the product's efficacy without an early success predictor based on surrogates of efficacy.

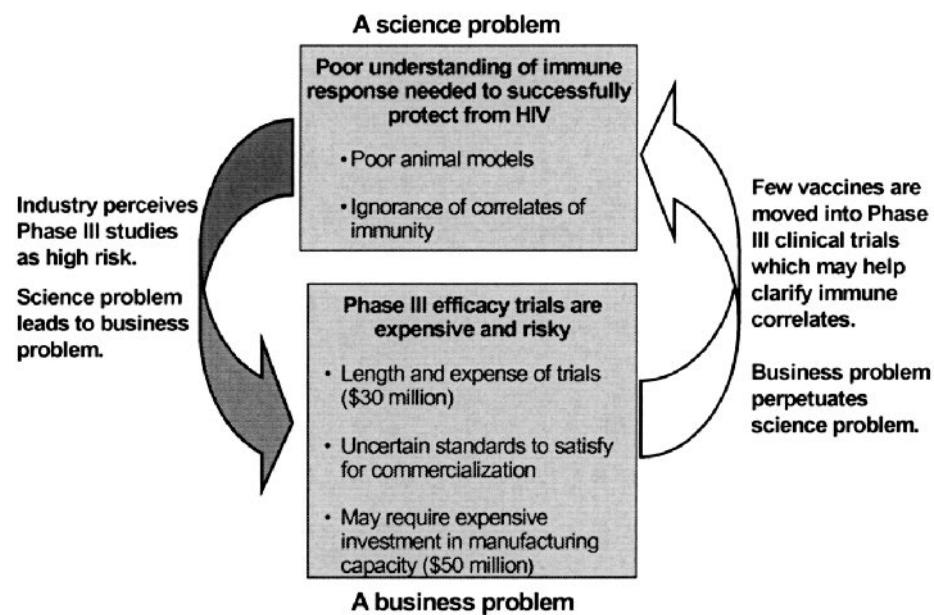

The costs of these trials represent a significant investment: \$30 million/trial was a frequently quoted figure. Respondents pointed out that while trials could be conducted in both industrial and developing countries, each had its own costs. A relatively low incidence of new HIV infections in industrial countries makes for large, expensive trials of uncertain statistical outcome. In developing countries, where the incidence is often much higher, allowing for more reasonably sized studies, significant political and infrastructure barriers were feared to raise costs. A further barrier noted by the respondents was the investment in process development and manufacturing capacity that must accompany efficacy trials if timely licensure of the product is desired. Investments in limited production capacity for an unproven product may be on the order of tens of millions of dollars; significant additional investment would be needed to scale up manufacturing capacity to meet global, rather than just industrial country, demand. All or most of this investment is lost if a viable commercial product does not result from the efficacy trials, or if demand does not materialize as predicted.

The firms interviewed noted the dilemma between scientific and business objectives created by the high risk of investment in development and production capacity (Figure 12).<sup>\*</sup> The scientific uncertainty that makes it hard to predict what type of approach will likely protect against HIV makes industry reluctant to take on the costs of Phase III trials. However, without the knowledge learned from these trials, it will be difficult to identify the most promising approach. The result is a vicious cycle in which the failure to undertake Phase III trials perpetuates the lack of scientific knowledge that underlies industry's reluctance to invest in the trials in the first place.

Not surprisingly, the uncertainty surrounding the science and the future markets for an HIV vaccine translated into difficulty in raising private funds for vaccine development. Nearly all the smaller biotechnology companies cited difficulty in raising capital as a major barrier. Most smaller companies either limited their HIV vaccine activities to those covered by public sector grants or pursued HIV vaccine research in a low-profile fashion, often as part of a larger "platform" research effort. The difficulties faced by the small companies in raising finance were, in all probability, symp-

---

\* From Economics of vaccines: From vaccine candidate to commercialized product. In: Bloom B, Lambert P-H, eds. The Vaccine Book. New York: Elsevier Science, 2003:345–370.

**Figure 12** A vicious cycle: Scientific barriers make industry reluctant to invest in the Phase III studies that may be required to solve the scientific barriers.

tomatic of the lack of confidence of the larger companies who are typically a major source of investment in smaller companies and arguably give a lead to the venture capital markets.

HIV/AIDS vaccine illustrates the importance of having a market with credible demand, i.e., the willingness and the ability to pay for a product. While there may be a large *potential* market for HIV vaccines, those who would most want and need a vaccine are those least able to afford one. Taking into account that over 95% of all new HIV infections occur in developing countries [29] and that the average annual per-capita total health expenditure in low-income countries was estimated to be less than U.S. \$20 in 1998, it is clear why industry would be concerned about its ability to recoup R&D and other costs and earn a return [30].

The public health agencies who are dedicated to improving health can influence the investment decisions of private vaccine firms. Detailed analyses, such as the study conducted on HIV/AIDS vaccine, help to identify the specific barriers limiting investment in a vaccine and, through this, the most appropriate solutions.

## V. PUSH AND PULL MECHANISMS: CHANGING THE ECONOMIC EQUATION

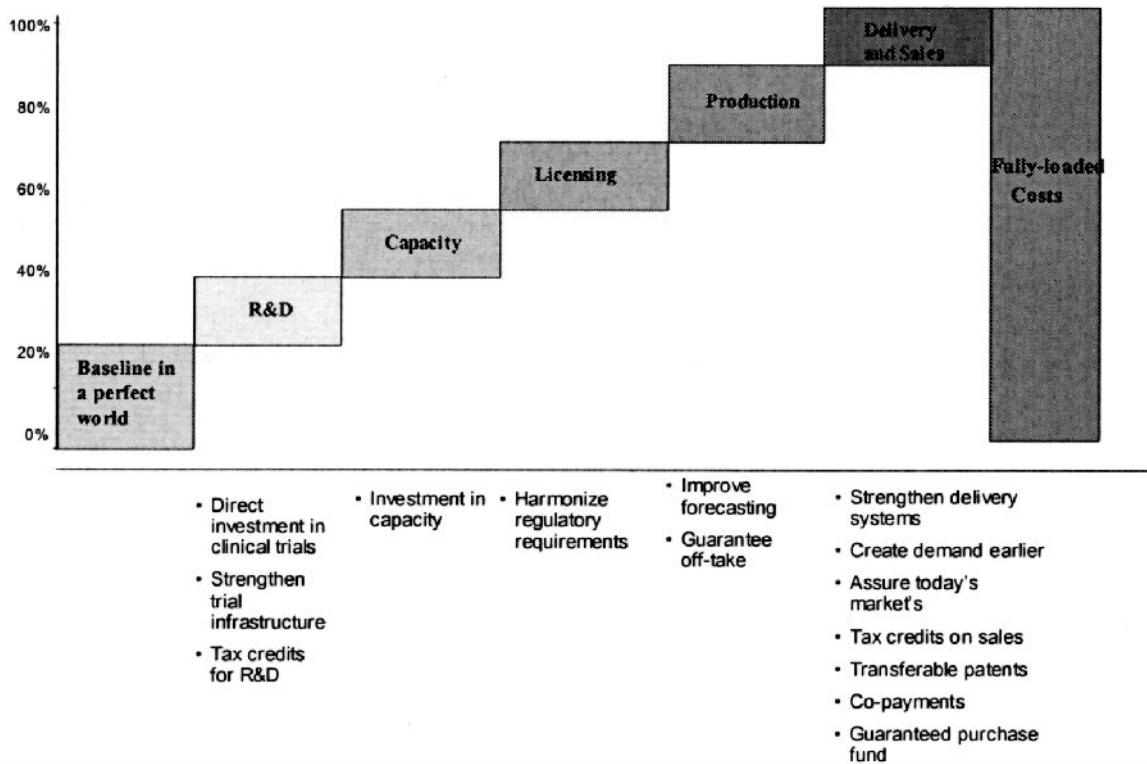

The decisions to invest in the development and commercialization of vaccine, while tied to and influenced by scientific progress, are based largely on an evaluation of economic factors: the costs, risks, and timing of investments and the expected return on future sales. To influence these economic factors, the public sector is seeking new ways to assess and to share risk.

There is no “silver bullet” solution. Not only do the issues vary between vaccines, but public and private entities, while both seeking to promote widespread use of priority vaccines, do so with different objectives and incentives.

The public sector would ideally avoid all risk, only buying a product once it is developed, widely demanded, and available at a very low price. In contrast, the private sector would ideally only invest once there were solid market commitments, e.g., guarantees to purchase the product at a given, likely higher, price. Furthermore, neither the public nor the private sector wants to make investments if the risks of failure are high. Creative public–private partnerships that share specific risks and costs and protect the interests of all partners are essential for these high-risk products and markets.

There are two categories of strategies to accelerate the development and introduction of priority vaccines: push and pull mechanisms. Push mechanisms are those which reduce the risks and costs of investments, while pull mechanisms assure a future return in the event that a product is produced. While the merits of push and pull interventions have been debated extensively [31–33], much work remains to translate the two concepts into action. Historically, the public sector has invested substantially in early stage push mechanisms, particularly basic research and some early product development. There are fewer examples of pull mechanisms. However, the Global Alliance for Vaccines and Immunization (GAVI) and its sister entity, the Vaccine Fund, are a recent example, providing 5-year commitments to purchase newer vaccines for the poorest developing countries.

It is unlikely that the global immunization community will ever have the resources either to finance all the costs of

**Figure 13** Approaches tailored to address specific risks.

vaccine development and production (100% push) or to purchase vaccines at prices equivalent to those paid in the United States or Europe (100% pull). The public sector must therefore leverage its resources by targeting its actions and its funds as directly as possible to the particular obstacles inhibiting a vaccine's progress. If the risks are linked to uncertainty about the science, such as in the case of an HIV/AIDS vaccine, then push mechanisms may prove more valuable than pull mechanisms which are too far in the future and too low probability to have much impact [25]. If the risks stem from the market despite the technical ability to produce the vaccine, such as in the case of the meningococcal A conjugate vaccine, then pull mechanisms become more important. As shown in Figure 13, different mechanisms can be tailored to best address risks occurring at different stages of the life cycle.

#### A. Push Mechanisms

Push options offer a number of benefits, the most important of which is that they reduce risk and thereby encourage investment where it might not otherwise occur (e.g., by funding a clinical trial in a geography that a manufacturer has little incentive to choose). Another important benefit is the familiarity with, and proven track record of, certain push interventions, which have been successfully used in the past. When structured to support broad objectives, such as the development of animal models, field studies of the natural

exposure, and resistance to disease, this mechanism can also help advance the development of all products targeted against a given disease.

However, certain types of push mechanisms, such as financing a clinical trial of a vaccine, necessitate specifying or picking one candidate or project. It is possible that better options may emerge at a later date, or that unsupported manufacturers will drop promising candidates. Product "failures" must also be expected, when one product is selected early in the process. Finally, push options do not promise a successful outcome. When projects or products do fail, the money will already have been spent and, in most cases, will be unrecoverable. The following are several possible push strategies that are or could be applied to vaccines.

1. Direct financing: Direct financing is used to fund or directly implement activities necessary to develop a vaccine. The main goal of this type of intervention is to increase the number of candidate vaccines and to generate data needed to assess a vaccine and to recommend its use. Public sector funds may go toward financing either platform activities or product-specific activities. In the category of platform activities, the public sector might fund research on geographical disease burden, diagnostics, impact of different vaccine presentations, correlates of immunity, animal models, or reagents. The public sector could also play a role in helping the private sector to navigate regulatory requirements and to establish clinical trial infrastructure. For specific products, the public sector can support clinical trials, particularly the

expensive Phase III efficacy trials. While the private sector expects to fund trials relevant for licensing the vaccine in industrialized countries, it has fewer incentives to finance trials in developing countries. Not only are developing country trials primarily of value to introduce the vaccine into this “uncertain, weak” market but also there is a risk that they can generate data or negative publicity that can threaten licensing in the industrial market.

The public sector could also help finance production scale-up. For some vaccines, the incremental costs of scaling up production to meet developing country demand may be too high, given the expected market return. Without public sector help, the private sector may be unwilling to incur these costs.

2. Facilitating research: Aside from providing money, there is an important role for the public sector in two other areas of clinical trial work: facilitation of the trials and adherence to ethics. Potential activities for the public sector include: working with local officials to inform and to educate country participants of the need for, and importance of, clinical trials and assisting in managing any problems that arise during the trial. Education is extremely important, particularly for diseases such as HIV/AIDS and malaria. Enrollees must understand that participating in the trial will not necessarily protect them against the disease and, equally important, that if they do contract the disease, their participation in the trial is not the cause. The public sector could also help manufacturers to clarify expectations and mechanisms for post-trial access to the vaccine. It is not uncommon for clinical trial participants to assume that their community will have guaranteed and continued access to a vaccine being tested. However, as the time between a clinical trial and a licensure of a vaccine is often lengthy and the introduction of a vaccine into developing countries even longer, this expectation needs to be addressed. In cases where the private sector is already ambivalent about conducting a trial in a developing country, demands for post-trial vaccine access may further reduce interest.

3. Harmonizing regulatory requirements: The development and ultimate use of biological products, such as vaccines, are carefully regulated to ensure their safety, immunogenicity, and efficacy. This regulatory function is carried out by the National Regulatory Authority (NRA) which is responsible for licensing and controlling the quality of all biological products used within the country. Currently, many NRAs have their own unique licensing requirements, compelling manufacturers to prepare and to submit separate licensing applications, an expensive, time-consuming, and, many argue, inefficient process. Efforts are underway to harmonize requirements in order to ensure product safety, but minimize the time and the cost of making a vaccine available to populations [10].

4. Tax credits for vaccine research: Structuring tax credits to encourage vaccine R&D is another push intervention under consideration. Like direct financing, tax credits have the benefit of being a familiar policy tool with a proven track record. The tax code of the United States currently contains an allowance for a 20% credit on R&D expenditures; although it must be renewed on an annual basis, it is noncontroversial and nearly unanimously supported by

members of Congress and the industry. There remain two issues with using tax credits for vaccine R&D as a push mechanism. First, like other push mechanisms, the existence of the credit does not guarantee results. Second, tax credits can be difficult to implement and monitor.

## B. Pull Mechanisms

At the other end of the spectrum, pull mechanisms can also help to reduce the risks of investing in priority products. For the public sector, pull mechanisms may be less risky as they can be structured so that money is committed only if a desirable and affordable vaccine becomes available. However, if financial commitments to specific products must be made early, it will be very difficult to determine the desired outcomes and prices far in advance of having an actual product. If a “winner” is chosen and a price is agreed, the public sector runs the risk of being “locked in” to an outcome that may prove not to be the best. Finally, the fact that these mechanisms have not been tested and so will only prove themselves well into the future increases their risks. For example, a future purchase commitment might be subject to political “changes of heart.” For manufacturers who must invest early and heavily, changes of heart have serious financial implications. The following are a number of examples of different types of pull strategies.

1. Accelerating the uptake of existing vaccines: Increasing the uptake of existing vaccines sends a clear, credible signal to industry that the public sector is committed to purchasing and introducing new vaccines. The immediate allocation of hard cash is the best way to strengthen the market. However, while strengthening the market is the most credible way to assure industry of public support for vaccines in the long term, it is likely to be inadequate on its own to overcome the immediate financial risks and costs inhibiting development.

2. Prizes and tournaments: In this context, prizes are offered to whoever achieves a prespecified goal or product, while tournaments offer a reward to whoever has progressed farthest toward the target by a given date. The size of the prize usually corresponds to the level of investment required to win. While structured slightly differently, prizes and tournaments have similar advantages and risks. Both mechanisms encourage competition and therefore increase the number of potential vaccine candidates. They are also relatively easy for the public sector to implement. For the private sector, good public relations may be a valuable side effect of winning a prize or a tournament. Industry’s lack of enthusiasm for this strategy, however, may limit the effectiveness of the prizes or the tournament model. Industry representatives have commented that they are “in the business of making vaccines, not winning prizes” [25]. Another serious drawback to prizes and tournaments is they do not guarantee that a viable, affordable vaccine will result. Nonetheless, the prize or tournament prize must be awarded to the winner regardless.

3. Co-payments: A co-payment—probably some amount not equal to the full price of the vaccine—is guaranteed to manufacturers in lieu of trying to lock in to a particular price for a vaccine. Co-payments are attractive to

industry because they are viewed as a commitment today, which is more credible than a promise for future payment. They are attractive to the public sector because they delay negotiations on the full price for a vaccine. However, it is unclear how the “correct” co-pay amount should be derived, and if the co-payment amount, which could end up being a fraction of the vaccine price, would offer enough of an incentive to industry.

4. Differential [tiered] pricing: In order for differential pricing to work, there must be a segmented market, minimal risk of parallel imports, and a willingness to accept and enforce differential prices, particularly in the markets with the higher prices. Differential pricing is currently the only mechanism that allows affordable access to a vaccine in developing and industrialized countries while still allowing industry to recoup its investment on a vaccine. In many cases, the time lag before the product is fully mature and has a significantly lower tiered price is 15 to 20 years. However, allowing industry to charge “what the market will bear” in industrial countries provides a significant incentive for investment, an incentive that would not exist if the price was set by the purchasing ability of sub-Saharan Africa. Finally, differential pricing is a familiar mechanism because it has been used in nearly every other sector from toothpaste to batteries and is often integral to wide spread use of products. Differential pricing, however, is difficult to implement. Safeguards must be instituted to prevent lower-tier prices from becoming the index down to which wealthy countries negotiate. The risk of products flowing back into wealthy markets either between countries or in the same country, while small to date, must also be managed. Finally, for differential pricing to be successful, government procurement agencies, politicians, and the public in industrialized nations must be willing to pay more for vaccines than the poorest developing countries, an idea that is often at odds with political agendas.

5. Market assurances: Market assurances are a type of “guaranteed” takeoff. The assurance may be structured as a commitment to an individual manufacturer or as a commitment to purchase a product from any manufacturer. Three variables may be part of a guarantee between the public to buy and the private sector to supply a given vaccine (1) the specific product, (2) the number of doses, and/or (3) the time frame. The contract or agreement may be backed by either “soft” or “hard” money guarantees, depending on the trade-off between opportunity cost and credibility: Money put aside now is the most credible to industry, but it carries the highest opportunity cost. Although the credibility of market assurances for future products can theoretically be increased through legally binding commitments, in reality, it is difficult to imagine how they would be enforced against public institutions such as WHO, UNICEF, or the World Bank. More credible is the development and implementation of contracts for today’s products, a strategy being explored by GAVI and the Vaccine Fund. Industry’s interest is likely to vary by vaccine as the commercial return promised by a market assurance may be extremely attractive for some vaccines, but be deemed too distant and uncertain for others.

6. Intellectual property right (IPR) enforcement/protection: IPRs are the foundation upon which the profit of pharmaceutical companies is based. When IPRs are vio-

lated, the incentives for industry to invest in vaccine R&D are greatly diminished. The public sector has already taken steps in this direction [e.g., setting up the World Trade Organization (WTO) to enforce the agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS)], but improvements remain to be made. However, simply put, IPRs provide continuing incentives for industry to invest in vaccine R&D, development, and distribution. IPRs, however, are difficult to implement, difficult to enforce, and politically unpopular with those who contend that cheap drugs need to be made available to bridge the gap between the “haves” and the “have nots.” Questions remain about whether or not it will be possible to enforce TRIPS, and whether this mechanism provides enough of an incentive to ensure adequate investments.

7. Tax credits for vaccine sales: Like tax credits for vaccine R&D, tax credits for vaccine sales are perceived as a credible and familiar policy tool. From the standpoint of the public sector, tax credits are attractive because money is only spent once a product has been developed and sold. However, industry has not expressed much interest in this mechanism, possibly because tax credits on vaccine sales are too far in the future to justify investment that may not even result in a successful vaccine. In the event that a tax credit is enacted, it may be difficult to determine the appropriate level of credit. Finally, it is unclear how priorities will be set in the event that a number of these vaccines become available simultaneously, all competing within the same authorized cap.

### C. Implementing Push–Pull Mechanisms: Public–Private Partnerships

The push and pull mechanisms discussed in the previous section are potential solutions to the economic challenges inhibiting rapid development and scale-up of priority vaccines. However, many of these ideas have yet to be tested. Public–private partnerships that allow the sectors to share the risks and costs of developing and introducing priority vaccines in novel ways may be a solution. However, both sectors have concerns about entering partnerships. A history of low uptake of vaccines and changing public priorities reduces industry’s incentive to partner closely with many public sector entities. Conversely, concerns about industry’s motives, the risk of failure, and the perceptions of the popular press are disincentives for the public sector to work with industry.

Despite these fears, partners on the GAVI Board believe that by harnessing the strengths of both private industry and public partners, they can achieve the ambitious goal of developing and making accessible priority vaccines for developing countries. To move forward with credible partnerships, two basic conditions must be met. First, both public and private partners must understand the costs, risks, and benefits driving the partnership. With this knowledge, partners can identify those costs and risks that are important and sensitive to public sector support—those with the highest “leverage.” Second, both public and private partners must be confident that the mechanisms or agreements that define the partnership protect each of their interests. For the public sector, this means ensuring public invest-

ments result in more rapid development, expanded capacity, and/or lower prices. For the private sector, it means public “promises” translate into real financial commitments that cover investments.

## VI. NEXT STEPS AND NEW APPROACHES

Daunting as the science is, the risks and uncertainties of vaccine development are amplified by the economic implications of each investment decision. By understanding the current vaccine market and its suppliers and the investment decisions occurring along the pathway from candidate to commercialized product, the reader can understand the role played by economics in shaping the vaccine world. Public sector partners are increasingly using this growing knowledge to explore possible solutions—push and pull mechanisms—that might change the economics of high-priority products for the developing world.

New mechanisms and partnerships will provide concrete evidence about both the critical obstacles inhibiting progress on specific vaccines and the value and feasibility of particular push and pull mechanisms. This evidence will increase the immunization community’s understanding of the economic forces influencing the development of and access to the highest-priority vaccines.

The successful development and introduction of vaccines against the great plagues of our time will be the ultimate test of the immunization community’s scientific knowledge and economic acumen. No one mechanism, either push or pull, and no one partner, either public or private, will single-handedly resolve all the issues relating to vaccine availability and access. By working together, public and private partners can identify the most feasible, high-impact solutions to jointly tackle some of the most formidable challenges facing the world, i.e., the development and the implementation of vaccines that can prevent HIV/AIDS, malaria, and tuberculosis.

## Development and Supply of Vaccines: An Industry Perspective

**Michel Greco**

*Aventis Pasteur, Lyon, France*

### I. THE WORLD VACCINE MARKET, PRESENT AND FUTURE

The notion that vaccines are a market is fairly recent. Apart from Smallpox (Jenner), Rabies (Pasteur), and inactivated whole-cell parenteral typhoid vaccine (Wright and Pfeiffer) (see Chapter 1 “Vaccines and Vaccination in the Historical Perspective”), all vaccines have been discovered in the twentieth century, and most in the second half of the century. Also, within the pharmaceutical industry, vaccines have long been set apart, closer to public health authorities, and basically viewed as not-for-profit activities [1,2]. As a result, as recently as in the late 1980s, most pharmaceutical companies were leaving the field of vaccines [3]. Through a number of factors that shall be examined in more detail, the tide was reversed in the last decade of the twentieth century so that today vaccines are a much more competitive area [4]. Nevertheless, the field remains at best a “qualified” market that is strongly regulated and has high entry barriers and supply constraints, is largely “monopsonistic” in nature, and must adjust to specific price setting mechanisms [5].

The vaccine “market” actually comprises three major subsets:

—*Closed markets* where local producers supply the local needs with mostly Expanded Program on Immunization (EPI) monovalent vaccines, which generally cannot be exported, mainly for regulatory reasons, and which value can hardly be assessed [6,7].

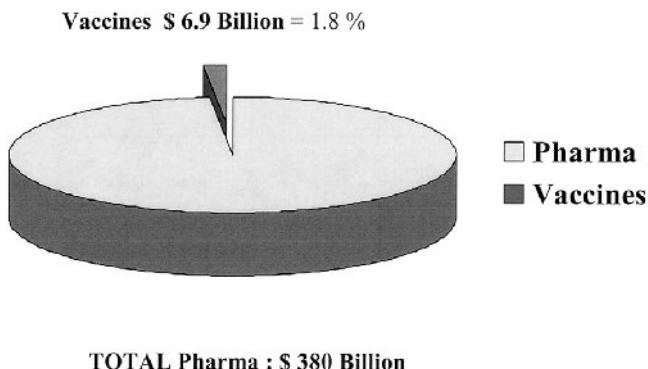

—*Donor markets* managed by international organizations [World Health Organization (WHO), United Nations Children’s Fund (UNICEF), Pan American Health Organization (PAHO), Global Alliance for Vaccines and Immunization (GAVI)...] who buy mostly EPI vaccines for routine or mass immunization in poor or developing countries, generally in multidose presentations and at tiered prices [8–10]. Although the value of this segment

has increased in the past, it remains a minor part of the overall vaccine market in value, if not in doses.

—*Commercial markets* are those markets, strongly regulated—public or private—where competition does exist and where pricing is implemented in a more classical way so that companies can fund their research and development activities, invest in state-of-the-art industrial facilities, and return a profit to the companies’ shareholders. This is by far the largest part in monetary value of the global vaccine market [1,2,4,5], which will be analyzed in more detail in this chapter.

The commercial market is a small, fast-growing, concentrated market. As recently as the late 1980s, the market was worth less than \$1 billion worldwide. At that time, it was mostly spread among basic bacterial vaccines and some viral vaccines, among many small national public institutes or companies and generally sold at low prices. In the course of the last 10 years, this market has increased around sixfold to reach \$7 billion. But even at \$7 billion, it must be emphasized that vaccines represent less than 2% of the global pharmaceutical market (Figure 1) around the same figure as a single lead pharmaceutical product. Looking to the future, it is expected that the market will continue to grow at double-digit rates throughout the decade to reach at least \$15 billion (risk adjusted) by 2010 (Figure 2) [1]. Linked to the generally higher prices in North America, this part of the world represents 40% of the market value with Western Europe and the “rest of the world” representing 30% each (Figure 3). It is noteworthy that although the value of the Japanese market is significant (more than \$400 million), the number and type of vaccines used there is more limited than in most developed markets. It appears likely that this situation will substantially change in the coming years.

In this chapter, the main reasons for growth of the vaccine industry, past and future [1,11], will be analyzed in some detail.

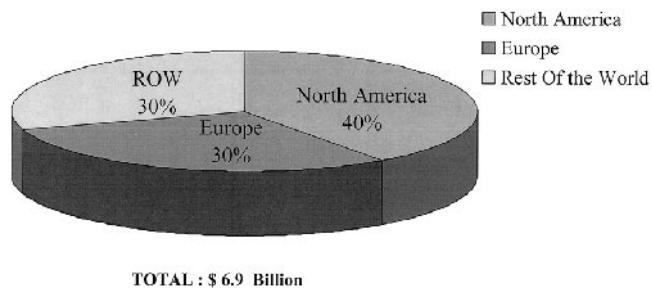

**Figure 1** Vaccines market share in the global pharmaceutical market 2001.

#### A. Innovation

Innovation has been and will remain the key driver of growth. What clearly drove the growth in the last 10–15 years was primarily the introduction of major new vaccines such as recombinant Hepatitis B, *Haemophilus influenzae* type b conjugate, Hepatitis A and, more recently, attenuated varicella, and meningococcal and pneumococcal conjugate vaccines.

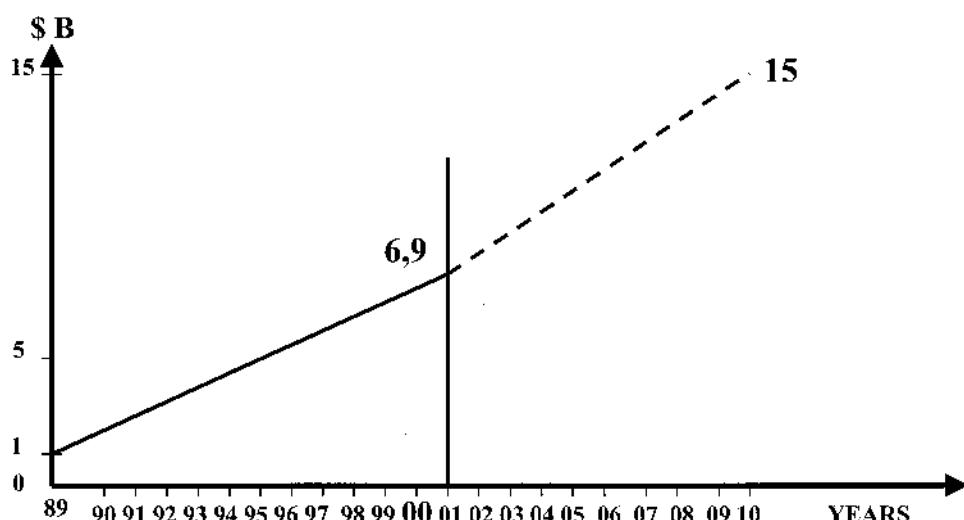

Another contributor to growth of the market is the array of innovative combination vaccines for pediatric and adult use, both for primary immunization and for booster use (Figure 4). The future should witness an acceleration of innovation, despite increasing risks. Indeed, currently there are approximately 400 new vaccine projects under study around the world. Obviously, many will not make it to the end [3,12–14]. Nevertheless, never before has there been so much research activity in this field.

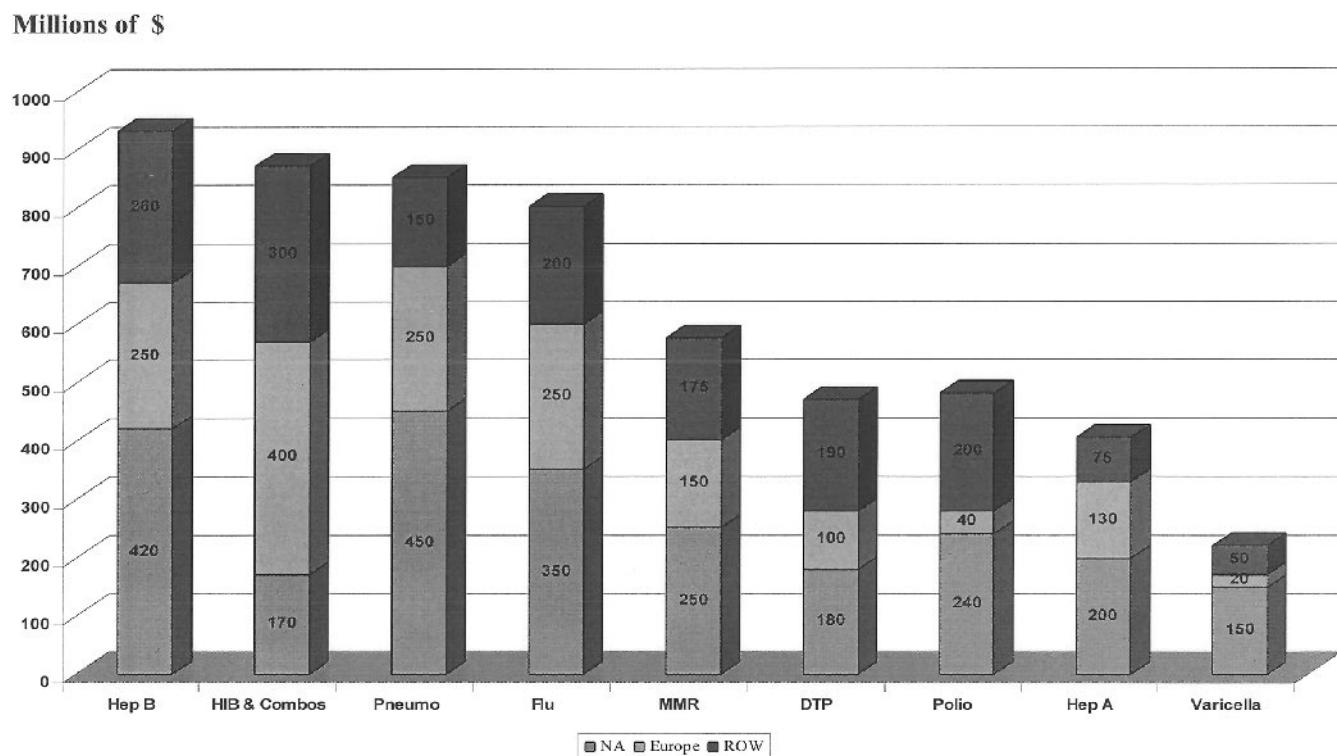

**Figure 3** Global vaccine market geographical breakdown 2001.

Some of the reasons responsible for stimulating this research include:

1. Vaccines remain primarily directed to the prevention of infectious diseases, including bacterial infections that antibiotics are supposed to cure. The widespread use of antibiotics has led to increasing resistance of microorganisms to these compounds. Thus, in some instances, overuse of antibiotics “opens the way” for vaccines. This was true in the development of vaccines against *H. influenzae* type b and is even truer for pneumococcal vaccines. This is likely to extend to other bacteria such as group A *Streptococcus pyogenes*, *Staphylococcus aureus*, and many others for which vaccines would provide both appropriate medical and economic answers.
2. The progress of medical science and the improved understanding of the immune system have led to a better knowledge of the etiology and pathogenesis of infectious diseases. For example, it has been

**Figure 2** Global vaccine market evolution from a “nonmarket” to a sizable one.

**Figure 4** The top nine vaccine families represent 90% of the market in 2001.

shown that many chronic diseases could have an infectious origin, such as ulcers (*Helicobacter pylori*), coronary heart disease (*Chlamydia pneumoniae*), and some cancers (e.g., papillomavirus in cervix cancer, Epstein–Barr virus in nasopharyngeal carcinoma, and Hepatitis B virus in hepatocellular carcinoma).

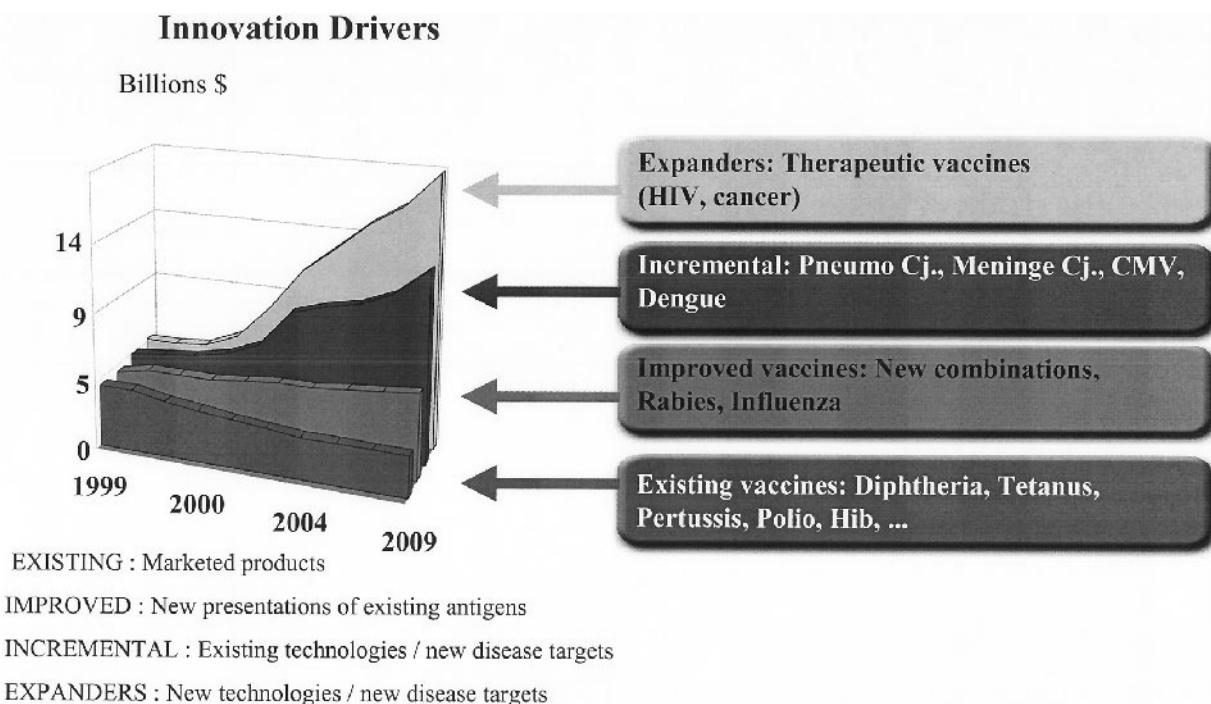

3. Also, vaccines, which heretofore have been used mostly as preventative agents, are now being considered as possible therapeutic ones linked to scientific developments, and to economic or ethical reasons [15].
4. The emergence of biotechnology and molecular biology has led to the development of new tools allowing the more rational design of new products. New developments such as the sequencing of the human genome will further broaden the field of development and use of potential new vaccines.
5. Other aspects such as the development of new immunization systems also contribute to this innovation process: combined vaccines, safe syringes, needless injections, transcutaneous administration, mucosal delivery, transgenic animals and plants, DNA immunization, and many more developments will, over time, completely change the approaches to immunization.
6. The development of information technology, including bioinformatics, allows an accelerated review of a much larger number of approaches.

All these and other reasons explain why innovation should remain a key driver in the expansion of the vaccine area generating many new projects (Figure 5; Table 1)

## B. Demography

Demography is another key growth driver for the vaccine field, in many different ways.

1. Volume-wise, immunization is primarily driven by the continuing growth of the population in less-developed countries. More than 80% of the vaccine doses produced in the world are currently directed to those markets.
2. In industrialized countries, apart from innovation, the growth of immunization is largely driven by the “senior citizen” segment of the population that is continually expanding. Already, with vaccines directed at the prevention of influenza, pneumococcal infections, and soon zoster, in addition to the expanding use of booster immunization, this segment has a large growth potential. In a more general trend, immunization, which used to be directed mostly to infants, is extending to all stages of life.
3. Travel and migrations (whether voluntary or not) constitute another major potential source of clinical infectious diseases, which are quite often vaccine preventable. This includes specific “at-risk” populations such as deployed military contingents.

**Figure 5** The future of vaccines: an industrial perspective.

The overall consequence of these demographic trends is an ever-expanding demand for existing and new vaccines and a market structure where the balance of sales is progressively turning to adult/senior immunization as opposed to infants' vaccination (Figure 6).

### C. Prevention

Among other key factors impacting the demand for vaccines is the realization that *prevention* makes sense both from a

medical standpoint (avoiding disease, resistance to therapy, side effects of drugs, etc.) and from an economic standpoint (pay a little now to reduce the public health bill down the road both in terms of direct and indirect costs). In this respect, a better recognition of the "value" of vaccines both in the developing and developed world will contribute to better vaccination coverage and to further increased efforts for the research of new vaccines. It is anticipated that the ever-greater use of pharmaco-economic studies will increasingly support the expansion of immunization.

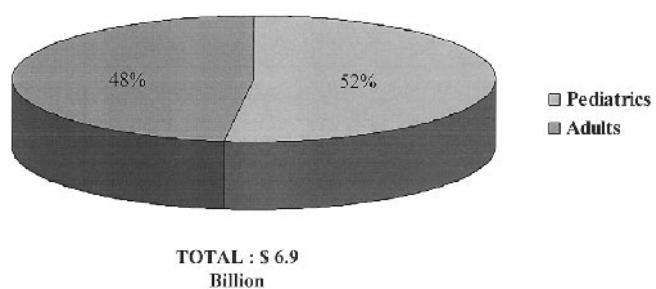

### D. Equity

In a global world, it is becoming increasingly unacceptable to see children in the poor countries continue to die from

**Table 1** More than 400 New Vaccine Projects Worldwide

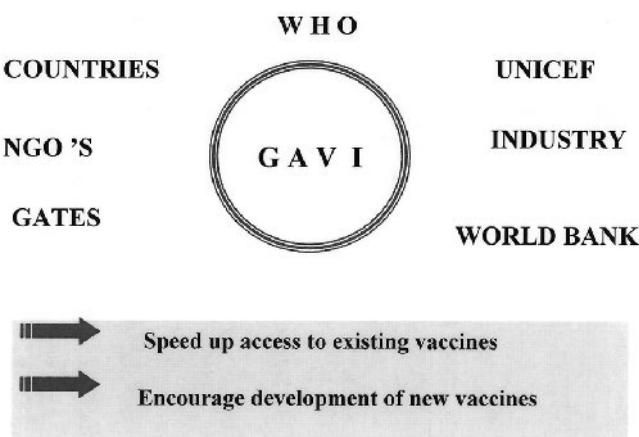

#### Main future vaccines

-New Combos (DtaP, MMR, Hep, meninge, others	-Pneumo-conjugate
-Rotavirus	-Meningo conjugate
-Lyme	- <i>H. pylori</i>
-ETEC	-New flu
-HSV	-JEV
-RSV	-Dengue
-Zoster	-CMV
-EBV	-HPV
-Hep C	-Meningo B
-Gonococcus	-Tuberculosis
-Hep E	-Schistosomiasis
-NT HIB	-Strep A
-Malaria	-Strep B
-Urinary tract	-HIV prevent/therapeutic
-Otitis media	-Haemorrhagic fevers

- Partnership in support of immunization

**Figure 7** The future of vaccines: an industrial perspective.

vaccine-preventable diseases when the needed vaccines exist and can often be obtained at reduced prices [16,17]. This has led to a major initiative by the international community, including WHO, UNICEF, and a number of public or private organizations such as the Gates Foundation, and Industry, culminating in formation of the Global Alliance for Vaccines and Immunization (GAVI) [12,18,19]. Industry believes that, for the first time, such an initiative has a good chance of succeeding because all the actors are present (Figure 7), and a methodology exists to plan and implement activities and to guarantee that the results are monitored. Also, funding has been available from the onset and should be sustainable, driven by the Vaccine Fund.

#### E. Bioterrorism

Last but not least, the emergence of *bioterrorism* in the late 1990s and the cataclysmic event that will go down in history

as “September 11” has reignited demand for vaccines against bacteria or viruses that can be used as agents in biological warfare, including smallpox and anthrax [20]. This has led many authorities to question whether immunization could ever be stopped for diseases such as polio where final eradication is in sight, not to mention more exotic diseases. All these factors clearly indicate that the demand for existing and new vaccines will remain strong for the foreseeable future.

## II. THE VACCINE INDUSTRY

The vaccine industry is fairly young. It finds its origin in national public institutes or companies that were set up to ensure that the basic health needs would be provided to the population, mostly for the prevention of diphtheria, tetanus, pertussis, and poliomyelitis.

With the development of additional new bacterial and viral vaccines, recombinant vaccines, and, more recently, of new technologies, and with the need to scale up production and heavily invest in capacity and compliance, a number of local producers—whether in developed or less-developed countries—have disappeared or been acquired; as a consequence, the vaccine industry has become increasingly concentrated with a few key players [1,2,10,21,22] (Figure 8).

—Aventis Pasteur is probably the oldest one among the major actors, with the broadest vaccine range and geographical coverage. It results from the merger in the late 1980s of Institut Mérieux, Pasteur Vaccins, and Connaught Laboratories Limited.

—GSK Biologicals originated in a small Belgian operation called RIT, which was acquired by Smith-Kline and French, and, subsequently, through mergers, became SmithKline Beecham (SB Biologicals), and, finally, Glaxo SmithKline Biologicals. A small operation until the mid-1980s, the company extensively grew based on its Hepatitis vaccine franchise (recombinant Hepatitis B and Hepatitis A). It then broadened its product range to include infant combination vaccines and expanded its international distribution.

#### • Industry structure

- Institut Mérieux / Pasteur Vaccins/Connaught → AVENTIS PASTEUR
- RIT → SB → GLAXO SMITHKLINE BIOLOGICALS
- BEHRING / SCLAVO / CHIRON / EVANS / WELCOME / MEDEVA / SBL / Powderject → CHIRON VACCINES
- LEDERLE / PRAXIS → WYETH
- IMMUNO / NAVA → BAXTER IMMUNO
- MERCK
- .....ETC.....

**Figure 8** The future of vaccines: an industrial perspective.

–Merck Vaccines is a specialized division of Merck and Co. that has long been the U.S. market leader. It expanded in Europe through a joint venture with Aventis Pasteur but otherwise still has a limited activity in international markets.

These three players each represent between 20% and 25% of the world market.

–A fourth company, Wyeth, long a market leader in the United States, actually stopped distributing some basic pediatric vaccines before staging a resurgence at the end of the century with a pneumococcal conjugate vaccine (from a market perspective, possibly the first “blockbuster vaccine”), as well as a meningococcal C conjugate vaccine.

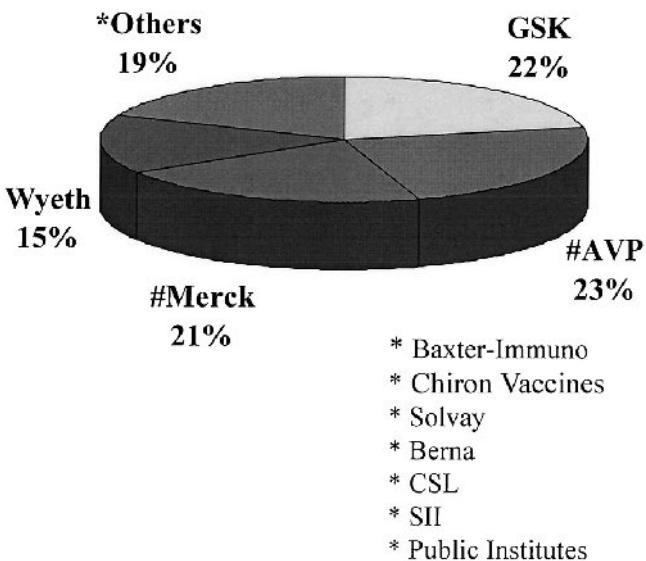

These four companies encompass approximately 80% of the world commercial vaccine market (Figure 9).

–Other less-dominant actors have resulted from the concentration of smaller companies, such as:

- Chiron Vaccines (Chiron, Behring, Sclavo, Evans, Welcome, SBL...)
- Baxter Vaccines (Immuno, Nava...)
- Berna (including Rheinbiotech)
- Etc...

–The remaining manufacturers in developed countries are mostly dependent on major manufacturers for supplying their needs and are generally meaningful only in their home markets (Australia, Japan, Korea, Netherlands...).

One can expect the future to bring even more amalgamation of vaccine manufacturers and the likelihood that the

**Figure 9** Manufacturers' market shares 2001. <sup>#</sup>The sales of Aventis Pasteur MSD, a European joint venture between Merck and Aventis Pasteur are split 50/50 between the two companies.

relative positions may well change again linked to the pace of innovation in the various companies and the success of the development projects that they have chosen to support. Apart from these already established companies, new actors should appear:

- Some major pharma companies may become involved in a selective manner in a particular therapeutic field, acting as “cherry pickers.”
- Biotech companies are increasingly becoming involved in the innovation process as major companies outsource an increasing share of their R&D. In the future, some will try to develop into fully integrated operations.
- Also, producers from major less-developed countries (such as Serum Institute of India, Biopharma in Indonesia, Chinese producers, Brazilian companies, Cuban manufacturers, etc.) should become more prominent, especially as developed country manufacturers rationalize their product ranges, particularly with respect to “monovalent” vaccines such as measles, BCG, DTP, etc. It can be expected that as a result, over time, the developing country manufacturers will increasingly gain expertise and become more competitive with the main actors.

### III. THE ENVIRONMENT OF VACCINES

Despite all the positive factors described above, the field of vaccines remains at best a “qualified” market, with many specific constraints or features, among which some deserve to be highlighted.

–Many vaccines are designed for populations everywhere, regardless of where they live or their income level, and it is increasingly argued that immunization is a fundamental right and that vaccines are “Public Goods” rather than “for profit” pharmaceuticals. This raises issues of equal access to vaccines, dual pricing, etc.

–Vaccines are given to healthy individuals to prevent disease. This leads to some interesting consequences: total efficacy is generally expected, side effects are viewed as unacceptable (a situation quite different from pharmaceuticals which are mostly used to cure sick people).

–Also, linked to the fact that some vaccine-preventable diseases have almost disappeared from many industrialized countries and to the trends in modern society (individual rights, access to information, etc.), more and more constituencies, particularly in industrialized countries, are arguing that personal decision should determine whether they or their family members should be immunized [23]. As vaccine-preventable diseases disappear, such attitudes become increasingly more prevalent because the fear of the vaccine sometimes becomes more important than the fear of the disease (Figure 10) [24].

- As a corollary to these emerging concerns on safety, individual rights, information, the “principle of precaution” is increasingly taking precedence over that of protection of Public Health. In turn, this is raising major issues in terms of liabilities and Public Health policies [5].
- Even as the vaccine market is concentrated on the supply side, it is quite often equally concentrated on the buyers’ side, whether at the world level (UNICEF), in global regions (PAHO), or in specific countries (industrialized as well as developing) where large public institutions acquire vaccines. This makes for a “monopsonistic” seller/buyer relationship, in which availability of supply plays an increasing role.
- Both for historical reasons and because vaccines are potentially directed to the total population, they have long been treated as commodities trading at low prices. In view of the increasing levels of investments in R&D, scale up, production, quality, and regulatory areas, this is no longer sustainable both for existing and new vaccines.

All these points make for a paradoxical market that is at the same time somewhat protected (the barriers to entry are high) and quite attractive (with demand constantly outpacing supply), but also very constrained by ever-increasing regulations and by its stakeholders and the environment at large. This is true both for the Research and Development Process and for the Supply Process.

#### **IV. DEVELOPMENT AND SUPPLY OF VACCINES: MAJOR ISSUES FACING THE INDUSTRY**

A large demand—present and future—and a limited number of existing or potential suppliers are facing a complex process of researching, developing, manufacturing, and supplying vaccines to the world at large. Without elaborating on each step of the process, some of the key issues or hurdles for the industry will be highlighted.

#### **A. The Research and Development Process**

Although the different stages of the Research and Development process (Figure 11) may look quite similar for vaccines as for pharmaceuticals, in general they are very specific in a number of ways and have substantially changed over the past few years.

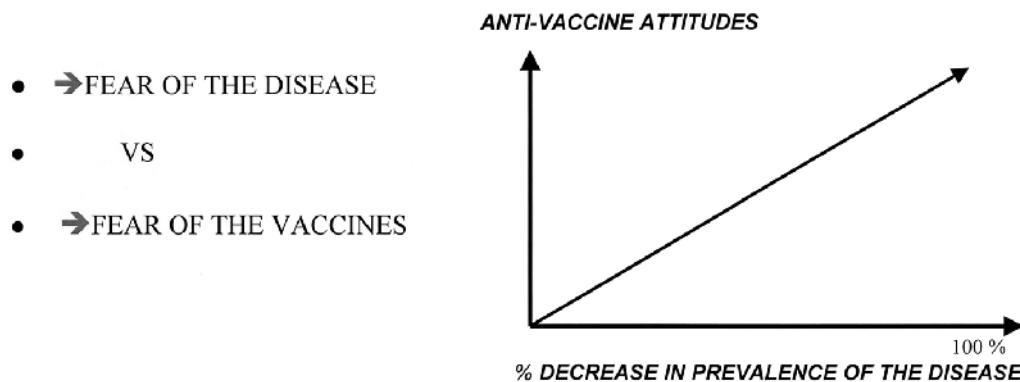

##### **1. Lead Generation**

Lead generation used to be somewhat limited but fairly predictable. A vaccine in development would have a chance of success ranging from 10% to 100%, whereas figures for the Pharma Industry were running in a 1/10,000 range.

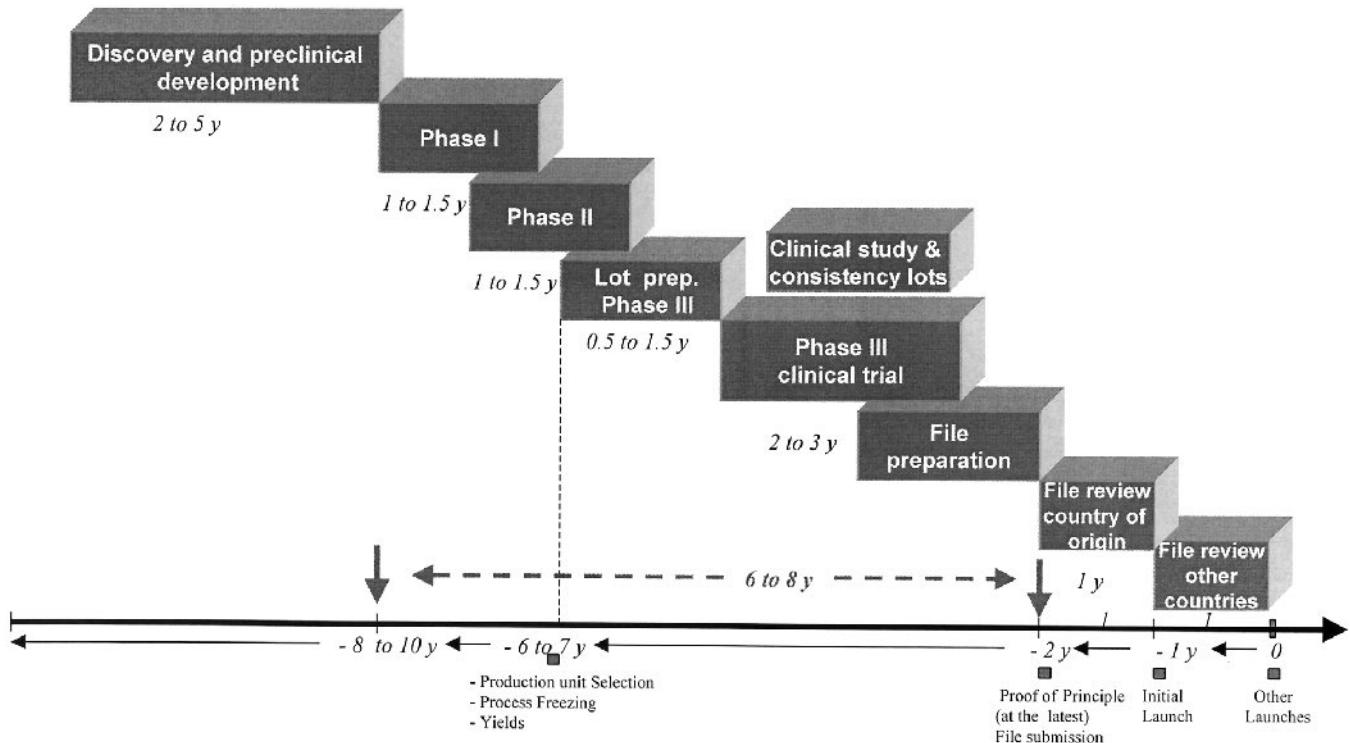

The “easy” vaccines have already been made. Paradoxically in some respects, the advent of biotechnology tools has resulted in more than 400 vaccine projects worldwide and many more at preclinical stage [1,11]. Moreover, they are more rationally designed and avoid, in principle, a number of pitfalls of traditional vaccines. Yet in practice, one finds a much higher failure rate and an increasing difficulty to determine early correlates of efficacy, therefore leading to a delayed proof of concept (Figure 12) [3,12–14,22]. In many cases, the proof of concept is only reached at the end of large efficacy trials, thereby leading to skyrocketing R&D costs.

##### **2. Clinical Development**

In the clinical field, linked to regulatory, safety, and quality requirements, time and costs have escalated. Especially, the need to detect very rare side effects for diseases that are themselves becoming less prevalent has led to huge increases in the number of clinical cases requested for safety and protection trials. Where a few hundred cases were needed a decade ago, the numbers have climbed to the thousands to reach sometimes 20,000 in the mid- to late 1990s. More recently, following the withdrawal of Wyeth’s Rotavirus vaccine, a new candidate vaccine had to plan a 67,000-subject study. It is widely expected that in the not too distant future, studies requiring 100,000 subjects could be required. One can easily imagine the impact on timing, costs, and

**Figure 10** Evolution of vaccine perception.

**Figure 11** General concept of development phases.

pricing of such requirements. For timing, 10 years is now considered as a minimum, as shown in Figure 11, assuming a good initial understanding of the immune mechanism for the disease. It can only be much more when the virus is elusive or when the disease mechanisms are not always well understood (such as in HIV, malaria, tuberculosis, etc.).

For costs, where vaccines used to be quite cheap to develop compared to pharmaceuticals, the costs easily run in the hundreds of millions of dollars and clinical trials can sometimes only be conducted with the support of large public institutions, especially for the more costly late development phase [2]. The example in Figure 13 shows a typical distribution of costs among the various phases. These costs are based on an average size project and a fairly straightforward process with no major difficulties and do not include the now much more significant amounts to be spent on the regulatory process and on postmarketing surveillance. For

these reasons and others, proper planning that allows as many activities as possible to be run in parallel is a key to the competitiveness of companies in terms of time-to-market (Figure 14).

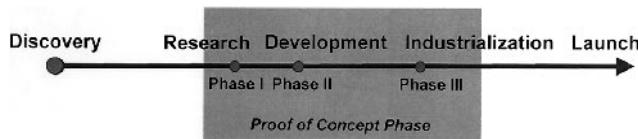

### 3. Formulation Development

Again, in relation to the ever-increasing safety concerns and improved quality standards, new vaccines have to avoid a number of agents that have long been shown to be useful and sometimes indispensable for vaccine formulation [25].

—*Bovine material* (mostly fetal calf serum) has been used in most vaccines as a growth medium. Following the Bovine Spongiform Encephalopathy (BSE) scare, this material had to be sourced from the so-called BSE-free countries. For new vaccines, avoiding bovine material has become the rule.

—*Human albumin* has long been used in the formulation of a number of vaccines to improve their stability. For similar reasons, the trend is to replace it by recombinant substances or other materials deemed more acceptable.

—It has long been shown that to optimize vaccine immunogenicity, adjuvination was needed and that aluminum salts (hydroxide or phosphate) provided the best results. Now questions are being asked on the appropriateness of using these adjuvants, when no proof has been provided to show that alum has noxious properties. Many companies are involved

**Figure 12** Research-to-Launch Process is a long process: spanning over 8–12 years.

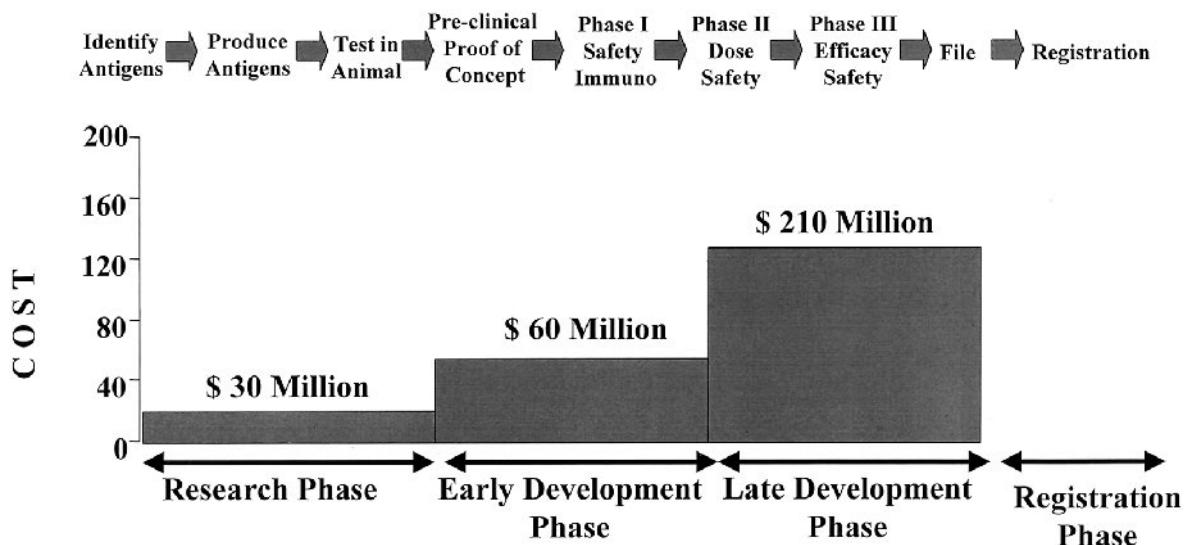

Figure 13 Vaccine development costs: Typical profile for a \$300 million project.

in the development of new adjuvants. In most cases, these candidates seem to yield positive results in animals. But in moving from mice to men, none has yet matched results obtained with alum.

In the same manner, preservatives have been used for many years to protect vaccines from bacterial contamination during the manufacturing process or downstream during product handling. This has proved necessary especially for multidose vaccines or to support WHO's "open vial" policy. In the year 2000, the American Academy of Pediatrics ruled that the use of mercury salts in vaccines was to be avoided [26], while not establishing a causal relationship between the presence of these compounds and specific undesirable or toxic effects in man. In developed countries, this has led to an overall move to single-dose vials that contain no preservatives but has also resulted in a strengthening of manufacturing procedures. Although feasible, it has led to major disruptions in the supply of vaccines to these markets as well as substantial price

increases. Should these decisions be enforced across the world, this would imply huge shortfalls in the supply of vaccines to less-developed countries, with the disappearance of a number of multidose vaccines, a resulting shortage in manufacturing capacity for monodose vaccines, and a steep increase in prices.

Among other sensitive points, contrary to the general pharmaceutical industry, the vaccine industry still has to make extensive use of animals for its toxicity studies and for control of vaccines [27]. While it has been working hard to develop alternative cell-culture-based solutions, Industry still has to use mice, rabbits, and monkeys. Linked to pressures from lobbying groups, this is becoming increasingly sensitive and difficult and could also negatively impact the supply of vaccines.

More generally, in relation to the pressures from regulatory authorities, in particular the Food and Drug administration (FDA), companies have had to reinforce the quality and compliance of their processes [28]. This has meant very large financial and human investments to perform the needed experiments and develop the requested documentation, adding to the cost, slowing down the overall process, and sometimes resulting in technical improvements that are difficult to implement.

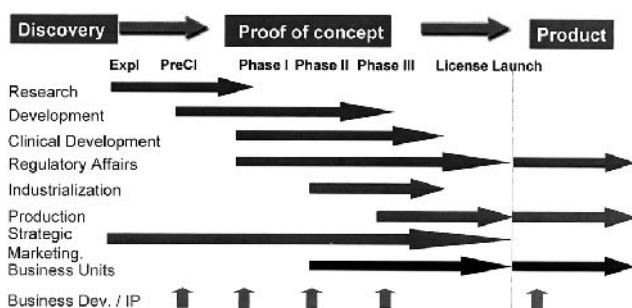

Figure 14 The Research-to-Launch Process involves many functions.

## B. The Manufacturing Process

Many issues relevant to vaccine research and development are equally applicable to manufacturing, with the additional need to scale up from the bench level to the pilot stage and the industrial stage, all the while ensuring consistency [2,3,14,27–31]. This raises scientific and technical issues, including validation, testing, and quality assurance. It also

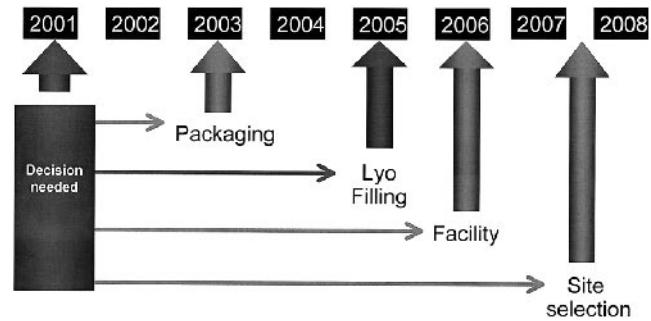

raises capacity and financing issues linked to heavy investments in buildings, facilities, equipment, and headcount.

In this respect, vaccines are clearly much more labor-intensive than pharmaceuticals. It is quite common to have 50% of the total headcount of vaccine companies in the industrial area. Also, apart from direct production, many more competencies are needed. The rule of thumb is that for two persons employed in production, at least one is needed in Quality Control. Quality and Compliance are enforced both internally by ever more stringent procedures Good Manufacturing Practices (GMP) and externally through inspections by public health authorities that can result in “remarks,” “warnings,” “consent decrees,” or even to outright closures of plants [28]. This has now affected all major manufacturers one way or another and is adding to the issues relevant to costs, supply, and productivity.

In vaccine manufacturing, time is crucial, both short and long term. This highlights the necessity for good forecasting and good planning while always keeping in mind the uncertainties linked to biological production.

Short term, moving from the bulk to the distribution of the vaccine, is no simple operation and it takes anywhere from 9 to 22 months (with the exception of the influenza vaccine) to manufacture and release a vaccine (Figure 15). This practically means that an inaccurate forecast, poor production planning, a batch failure, a change in recommendations by the health authorities, delays in batch releases, etc. will almost automatically translate into delays of several months to a year at market level.

Longer term, investing in new manufacturing equipment or facilities, is also no simple exercise and can take anywhere between 2 years for a new packaging line (studying, ordering, installing, validating) to 5 years for a new facility and 7 years for a new site, assuming no major complications (Figure 16). In practical terms for the vaccine manufacturer, this means having to take a major financial risk without knowing whether the development project will be successful and will yield an actual product. These time and cost elements have become even more critical given the fact that manufacturing capacities have been saturated for the last few years and therefore new investments have to be assessed on the basis of dedicated capacities, using the lowest market prices to establish the payback and the Net Present Value of the investments. The relevant resulting product costs then have to be computed on a “full-cost” basis, not

**Figure 16** Decision timeline for capacity increase.

just on marginal costs as could be the case when capacities were not saturated.

### C. The Supply Process

Having researched, developed, and manufactured vaccines, industry must supply them to the markets. Indeed, there is no such thing as a unified vaccine market, but rather several markets, each with their own specific features, as already mentioned: poor vs. developed countries; public vs. private markets; countries with different climates, epidemiologic patterns, infrastructure, etc.; and as a result, countries with different immunization schedules, vaccination coverage, and logistical requirements. Therefore supplying vaccines means being able to supply the right products with the appropriate presentation maintained in the cold chain—another vaccine specificity—in the right quantities and specifications, locally licensed and batch released, at a price.

Obviously, for the reasons already described above, there is no substitute to proper forecasting and planning to face an ever-increasing demand. Even in developed countries where normal market mechanisms operate, supplying the needs remains a challenge and often requires a real partnership between public authorities and industry. The challenge is even greater for less-developed countries, where the logistical infrastructure is often inadequate (whether for the physical distribution of the products or for an appropriate administration of the vaccination) and the buying power low.

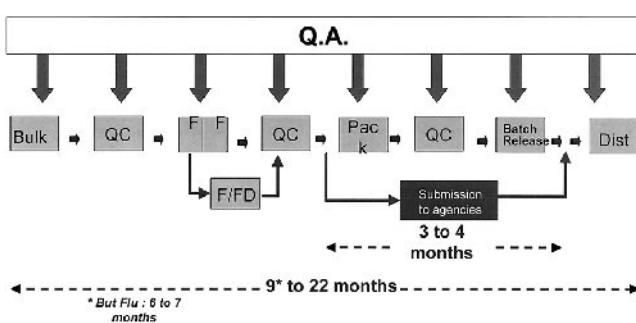

## V. SOCIETAL ISSUES

In a world where the “right to healthcare” is becoming an increasing concern, this situation raises issues of access, which some companies have addressed for a long time already, as well as issues of perception of vaccines [21].

### A. Access to Immunization

#### 1. Intellectual Property

Intellectual property (IP) is key to the survival of companies and to the pursuit of innovation [2,3,22]. It guarantees them an acceptable return on their research activities (which include both successful and unsuccessful projects). It trans-

**Figure 15** Main manufacturing steps.

lates into pricing policies that will provide such a return for a time. Now this may lead to the situation where vaccines—mostly recent ones—may prove too expensive for the health needs of less-developed countries.

This may be true in principle, albeit not necessarily in practice. All EPI vaccines except Hepatitis B have lost their patent protection a long time ago and these vaccines (including Hepatitis B) have been sold at very low prices to public buyers of less-developed countries. Still, quite often, supply is not sufficient because of the limited production capacity and the very low prices, not of patents.

The situation is obviously quite different for new patented products where the originating companies have to be guaranteed a fair return. Maintaining or even reinforcing patent laws is a must in developed countries. This has taken place to some extent with the extension of patent laws in some countries, for new indications and for orphan products, where the very limited size of the potential market is a strong deterrent to industry's interest.

At the same time, patents have also been weakened in a number of ways: the early introduction of generics (through such mechanisms as "Bolar" in the United States), the large number of countries still not enforcing patent laws, the threat of compulsory licensing, not only in less-developed countries but also in major markets such as the United States, linked to the bioterrorism scare. More generally, in the post-Seattle (antiglobalization movement), post-Pretoria (South African judicial ruling overriding patent), post-Doha circumstances, society at large has been applying strong pressures to make pharmaceuticals and vaccines more readily available to the poorest countries. Industry, while fully aware of these changes, needs to understand where this is taking such things as Intellectual Property protection, which remains the main stimulus to innovation. Creative thinking is needed at this time to develop new ideas to ensure compatibility between these apparently conflicting goals. It will probably take time and a mix of different steps from all parties to reach a satisfactory solution.

## 2. Technology Transfers

One of the ways to improve access for the less-developed countries has sometimes been seen in Transfers of Technology (ToTs). These transfers may look like an easy solution. This is certainly not the case. As previously discussed, setting up a state-of-the-art manufacturing facility is not an easy task. It requires money, adequately trained people, an adequate local environment (especially for controls), and support from other partners. It also requires a large-enough guaranteed market... and time.

As a result, a technology transfer can only succeed if it is very well planned, through a stepwise approach and a learning process. An ill-planned/ill-conceived ToT will only result in failure, frustration, and resentment. Also, such transfers will have to be financially successful. Obviously, if prices are too low, this will prove detrimental for local companies who need to heavily invest to catch up with their counterparts in developed countries.

Now with the emergence of significant local manufacturers in the major less-developed countries, such as China,

India, Indonesia, Brazil, etc., the developed countries' manufacturers also have to decide for themselves whether to delocalize some productions or enter in partnerships, joint ventures or outright ToTs, as an element of their long-term strategy. This has already taken place in a number of countries and will certainly further develop over the years.

## 3. Dual Track

Because of the vast needs and to the strong downward pressures on vaccine prices for the poorest countries, practical solutions have had to be identified to ensure supply. Overtime, this has developed into a situation where a "dual track" exists between developed and developing countries for many vaccines:

- Acellular pertussis vs. whole cell pertussis vaccines.
- Jeryl-Lynn-based measles/mumps/rubella (MMR) vs. Urabe-based MMR or monovalent measles.
- Inactivated polio vaccine (IPV) vs. oral polio vaccine (OPV).
- Combined vaccines vs. monovalent vaccines.
- Monodose vs. multidose vaccines.
- Thiomersal-free vs. thiomersal-containing vaccines.
- Wide access vs. limited access to new vaccines.

Obviously, dual-track has been closely related to dual pricing. Although ethically arguable in principle, such a situation is a pragmatic answer to a difficult situation. Taking a purely ideological stance would be counterproductive. What is probably a better answer is to make sure that any solution addresses epidemiological needs, is efficacious and safe, implemented with quality standards at the same level as for developed countries, and is price competitive.

## 4. Tiered Pricing

The practice of differential prices between affluent and poor countries has existed for a long time, especially for vaccines, and mostly for companies of European origin. This is linked to many factors, including Europe's historical relationship with these countries and different legal as well as cultural backgrounds between Europe and North America. This practice has been mostly applied to basic EPI vaccines for international tenders or local public markets (the most important ones) but much less for local private markets. Tiered pricing policies are only possible if limited to certain countries and if "normal" prices are implemented in developed markets, allowing not just paying for R&D, investments, margins, etc. but also—in a way—subsidizing these lower-priced markets. Such a strategy cannot be just the responsibility of industry [10,32]. Public authorities and international institutions and nongovernmental organizations (NGOs) also have to be involved, recognizing some basic rules and guaranteeing, among other things, that no reimportation will occur into developed markets, both for economical and technical reasons.

## 5. Access to New or Specific Vaccines

As already mentioned, one can readily understand that if achieving high coverage for EPI vaccines in the poorest countries is a challenge, introducing newer, more expensive

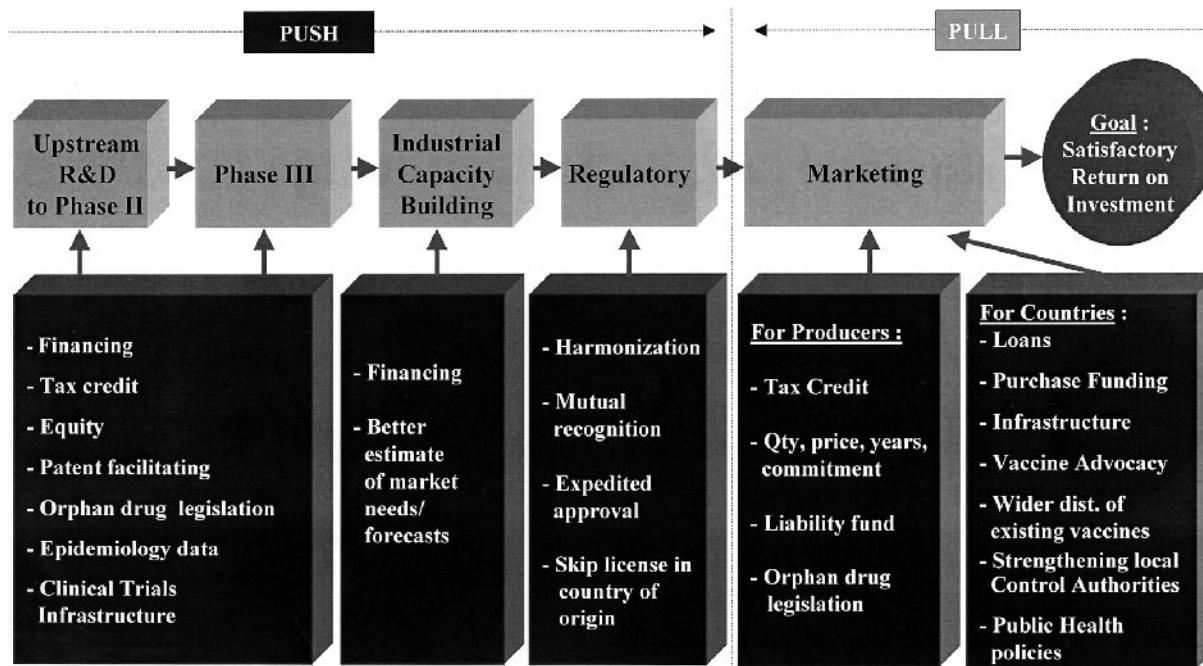

Figure 17 Typical Push/Pull mechanisms.

vaccines (not to mention future even higher-priced ones) is proving much more difficult. Pure market mechanisms have proved insufficient to tackle this situation. Only the joint effort of all stakeholders will have a chance to bring forward the beginning of a solution. As shown in Figure 7 above, the GAVI initiative has been the first such global approach with a chance of success. But sustaining initial results will require creativity and efforts on the part of all parties: countries, international institutions, nongovernmental organizations (NGOs), industry, etc. The priority will be to build local infrastructures able to implement consistent immunization strategies and to ensure long-term funding and ownership of these strategies. Focus will also certainly be a keyword. The creation of the Vaccine Fund is a clear step in this direction. Industry can and should be a full partner in this task. It should be encouraged to contribute, either through PUSH or PULL incentives (Figure 17) [33]. PUSH to help fund the development of vaccine solutions for the poorest countries; PULL to help create viable markets downstream.

## B. Perception of Vaccines

Along with ACCESS, PERCEPTION of vaccines is one of the other important issues facing immunization policies and policy makers. The paradox lies in the fact that it is simultaneously claimed that immunization is a “human right” but that getting immunized should result from an individual decision, thereby respecting “individual rights.” This is especially tricky for vaccines because only a high-enough coverage can ensure effective “herd immunity”, and, for some diseases, allow regional elimination or even global eradication (e.g., polio). At a time when vaccines have led to the

quasi disappearance of a number of diseases in many countries, the need to immunize is less strongly perceived and the side effects are more visible and more widely discussed.

Rare safety issues—sometimes based only on theory—can severely impact the success of immunization policies or campaigns in developed and less-developed countries [24]. In an era of instant and global communication [23], isolated incidents, pushed by strong antivaccine lobbies, can have devastating effects on public health. All parties, including industry, should accept that the paradigm has changed. Whereas in the past the producer used to call the shots, now the buyer and the regulator have assumed dominance and the power is now largely in the hands of the consumer and the media [23]. Also, recent developments such as the “principle of precaution” are here to stay, whether we like it or not. In such a situation, new attitudes need to be developed, accepting that all parties are accountable. We cannot just assume that vaccines are good for mankind and advocate their increased use. We also have to be more transparent, more informative, more open to challenge; we have to implement active “vaccine-vigilance” tools [24,34–36]. We have to anticipate, better coordinate efforts, and be prepared to stand by scientific data, while accepting that they may not always be the only answer to society’s concerns in today’s world.

### I. INTRODUCTION

Since the early 1960s, high-quality vaccines have been available to counter many of the most common infectious diseases that kill or severely harm children, such as measles, diphtheria, pertussis, polio, and tetanus [1]. Until as recently as 1975, however, less than 5% of the world's children had access to these vaccines, despite immunization being the most cost-effective of health interventions [2,3].

That extraordinary progress has been made in rectifying the gap in childhood immunization coverage between rich and poor countries is primarily the result of one of the largest and most successful public health initiatives ever—the Expanded Programme on Immunization (EPI). Through this program, a global network of national immunization services was developed, such that within 15 years, routine coverage of children had risen to nearly 75% worldwide [4], and world leaders were backing new and ambitious global immunization goals such as the eradication of poliomyelitis [5].

Although extraordinary progress has been made toward reaching all children with immunization services, as the last millennium closed on 31 December 1999, more than 25% of the children in the world were still not routinely receiving the basic childhood vaccines. Of more concern, in the first year of this new millennium nearly two million children died of vaccine-preventable diseases, with the majority of these deaths occurring in developing countries [6].

This chapter outlines the history and accomplishments of the global EPI effort and summarizes the challenges that must be overcome, particularly in developing countries, if every child is to be safely immunized with effective and appropriate vaccines as early as possible in life.

### II. 1974–1984: THE EPI IDEA AND THE EPI TOOLS

#### A. Origins

The success of the global smallpox eradication initiative was perhaps the most important stimulus for a World Health Organization (WHO) program to support the development of routine immunization services in developing countries [2]. By the end of 1973, smallpox had been restricted to only five countries in Asia and Africa [7], and it was widely agreed that the momentum of the Intensified Smallpox Eradication Programme should be exploited to control other vaccine-preventable diseases [8].

This consensus led WHO to establish the EPI in 1974, with the objective of raising childhood immunization coverage with an *expanded* number of antigens in an increasing number of countries [2]. While the Intensified Smallpox Eradication Programme remained WHO's highest immunization priority through the late 1970s, this period was used to develop the basic EPI principles such as the optimum vaccines and delivery strategies for developing countries.

Although the EPI initiative arose out of the smallpox program, many important elements were to differ substantially, perhaps none more so than the strategic approach.

\* Previous affiliation: World Health Organization, Geneva, Switzerland.

For example, by the mid-1970s the smallpox eradication program had demonstrated the utility of wide-scale mass immunization campaigns to control other important vaccine-preventable diseases in developing countries, such as measles [9]. Following a large EPI feasibility study begun in Ghana in 1976, however, the founders of EPI opted to promote the delivery of vaccines through routine immunization services rather than large-scale campaigns.

The original EPI vaccines were determined largely by the global relevance of the target disease and the cost-effectiveness of its control through immunization [10]. Initially, antigens against six diseases were included: BCG (against tuberculosis), DPT (against diphtheria, pertussis, tetanus), polio and measles for infants with tetanus toxoid for pregnant women to prevent neonatal tetanus (NT) (Table 1) [11]. Specific immunization schedules and policies, often quite different from those of industrialized countries (i.e., younger ages of administration), were established to optimize the uptake and impact of these vaccines in the developing country setting [12–14]. It was in 1977, the year of the last case of smallpox [7], that the World Health Assembly (WHA) formally declared the EPI goal of delivering these six antigens to the world's children by 1990 [15].

It is difficult to overstate the obstacles that existed in the late 1970s between the manufacture of a vaccine, usually in an industrialized country, and its safe administration under field conditions in a developing country, thousands of miles away [16]. Despite the tremendous diversity of the countries and cultures targeted by the EPI, in these early years a standardized approach to overcoming the huge operational and technical barriers to universal childhood immunization was to prove feasible. The first EPI operations manual was developed by 1977, with seminars conducted in most of the six WHO regions to introduce the program to senior public health officials [2]. These seminars established agreement on many critical issues including the standard EPI immunization schedule, a global EPI position on contraindications to specific vaccines, and the first standardized "global" reporting system for immunization.

## B. Equipment

Essential to moving from guidelines to actual immunization was the development and distribution of a range of cold-chain equipment that could maintain the potency of the EPI vaccines while withstanding the rigorous environment and

demanding conditions of developing-country use, particularly in rural tropical areas. Although the stability of the EPI-recommended vaccines varied depending on the antigen, the thermolability of OPV and the sensitivity to freezing of DTP dictated the parameters for the cold chain (originally set at 0° to 8°C, these were raised to 2° to 8°C in the year 2000 as newer more expensive and more freeze-sensitive vaccines were added) [17,18].

Because very little equipment was available that could guarantee these conditions amid the high ambient temperatures and unreliable electricity supply in many developing countries, by the late 1970s WHO's EPI had begun working with manufacturers to produce low-cost equipment for storing and transporting vaccines [19]. The technological solutions that were found included ice-lined refrigerators designed to protect vaccines against interruptions in the electricity supply and small, robust refrigerators for remote health centers operating on kerosene, gas, and solar energy [20,21] (Figure 1). By 1979, WHO had established a network of laboratories to evaluate new equipment and had published the first edition of the WHO/UNICEF Product Information Sheets (PIS), detailing the immunization equipment that met WHO specifications and could be recommended for use in developing countries. The PIS continues to be an essential resource for developing country immunization programs, covering a wide range of cold-chain, injection, disposal, and other equipment [22].

At the same time that this capacity to deliver potent vaccines to the field was being established it was also critical to minimize the risk of infectious complications due to unsterile EPI injections [23]. This has required the continuous development and evaluation of new injection, sterilization, and disposal equipment, and strategies [24,25]. In 1984, for example, the original glass syringes and open-boiling equipment of EPI were replaced with sterilizable plastic syringes and portable steam sterilizers, which had been developed specifically for WHO. As understanding of the risks posed by injections and injection equipment accumulated, EPI policy shifted toward the use of disposable injection equipment. To protect against the potential reuse of this equipment WHO facilitated the development of the "autodisable syringe" that could not be used more than once. This type of syringe, first used in mass vaccination campaigns, is now an essential component of a universal policy of WHO and UNICEF to use only autodestruct equipment for all immunizations by 2003 [26,27] (Figure 2).

## C. Implementation, Evaluation, and Oversight

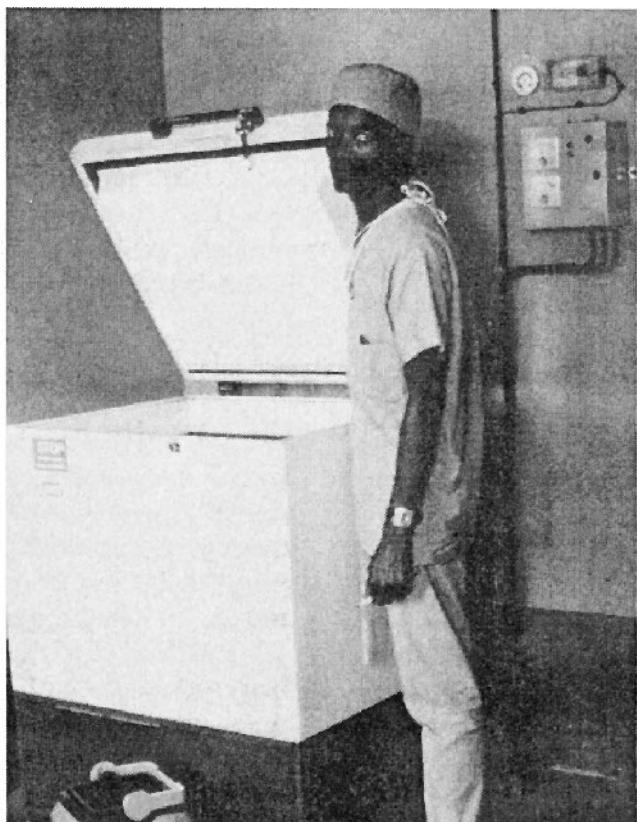

To extend immunization services beyond urban centers it was necessary to teach immunization techniques, injection safety, cold-chain maintenance, and program management from the national to village levels. By the end of 1977, the original EPI operations manual had been expanded into a training course for senior-level immunization program managers and the first course held in Kuala Lumpur, with participants from 19 countries. These materials were soon supplemented with training courses for cold chain and logistics (1978) and training and supervision (1979) [28]. By 1982, over 9500 people from 83 countries had been trained in one or more of these courses [2]. These standard

**Table 1** WHO-Recommended EPI Schedule<sup>a</sup>

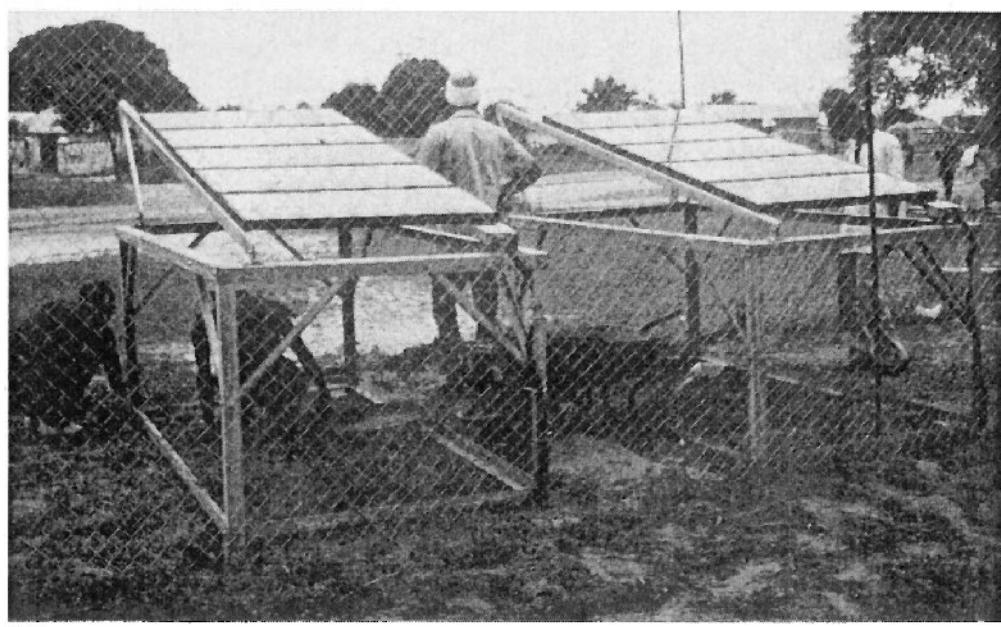

Contact	Age of child	Intervention
1	Birth	BCG, OPV, hepatitis B <sup>b</sup>
2	6 weeks	DPT, OPV, Hib, hepatitis B
3	10 weeks	DPT, OPV, Hib
4	14 weeks	DPT, OPV, Hib, hepatitis B
5	9 months	Measles, yellow fever, vitamin A

<sup>a</sup> The EPI also recommends that all pregnant women receive five appropriately spaced doses of tetanus toxoid for the prevention of neonatal tetanus.

<sup>b</sup> Alternatively, hepatitis B vaccine may be given at 6, 10, and 14 weeks of age in areas of low perinatal transmission.

**Figure 2** Selected equipment from the evolution of EPI injection equipment: steam sterilizers, plastic reusable syringes and needles, burn boxes, and autodisable syringes.

training materials have continuously been updated and expanded to include topics that now range from refrigerator repair to instruction on motorcycle maintenance.

The routine monitoring of global immunization performance by the WHO began in 1977. A central EPI information system was developed, with computer software for monitoring, at the national and regional levels, immunization coverage, surveillance data, and cold-chain equipment. The data generated permitted the first systematic estimates of developing country immunization coverage, thus facilitating the targeting of international technical and donor assistance. National immunization programs now annually report routine immunization coverage, surveillance, and other program data to WHO and UNICEF through a standardized reporting process [29].

In 1978, national EPI program reviews were introduced using a soon-to-be standardized methodology and joint national/international teams to evaluate all aspects of the im-

munization operations from the central to peripheral levels. Three hundred such reviews were conducted by 1994, often including a “30-Cluster EPI Coverage Survey” using the methodology that WHO had developed to corroborate reported immunization coverage [30,31]. These reviews played an important role in the development of national programs by motivating staff, identifying key areas for improvement, and raising political support by formally presenting the recommendations to national health authorities.

### III. 1985–2000: OPTIMIZING THE IMPACT OF EPI

#### A. Expanding Access

Although the necessary EPI policies, strategic approaches and equipment were largely in place by 1984, less than 50%

of the world's children were being "fully immunized" at that time [2]. Achieving the goal of universal childhood immunization (UCI) by 1990, defined as 80% coverage in the WHA Resolution of 1977, would require a massive acceleration of activities.

Recognizing this, the Rockefeller Foundation hosted a high-level meeting of potential EPI supporters and partners, cosponsored by WHO, UNICEF, the World Bank, and the United Nations Development Program (UNDP) in 1984 in Bellagio, Italy [32]. The 34 leaders in attendance—from developing countries, public health institutions, and international agencies—strongly endorsed the EPI concept and committed to its further expansion. To facilitate the coordination of international assistance to national immunization efforts, the cosponsors of the meeting established the Task Force for Child Survival and Development.

UNICEF played a particularly critical role in the acceleration of immunization activities. Its charismatic leader adopted the goal of universal childhood immunization and vigorously promoted it with national leaders [33]. UNICEF further helped support national immunization programs by operationalizing the EPI program through its regional and country offices. In addition to UNICEF's early role in the international procurement of WHO-approved vaccines and equipment, the organization also played a major role in the national social mobilization efforts that were to improve community awareness of, and demand for, routine immunization services.

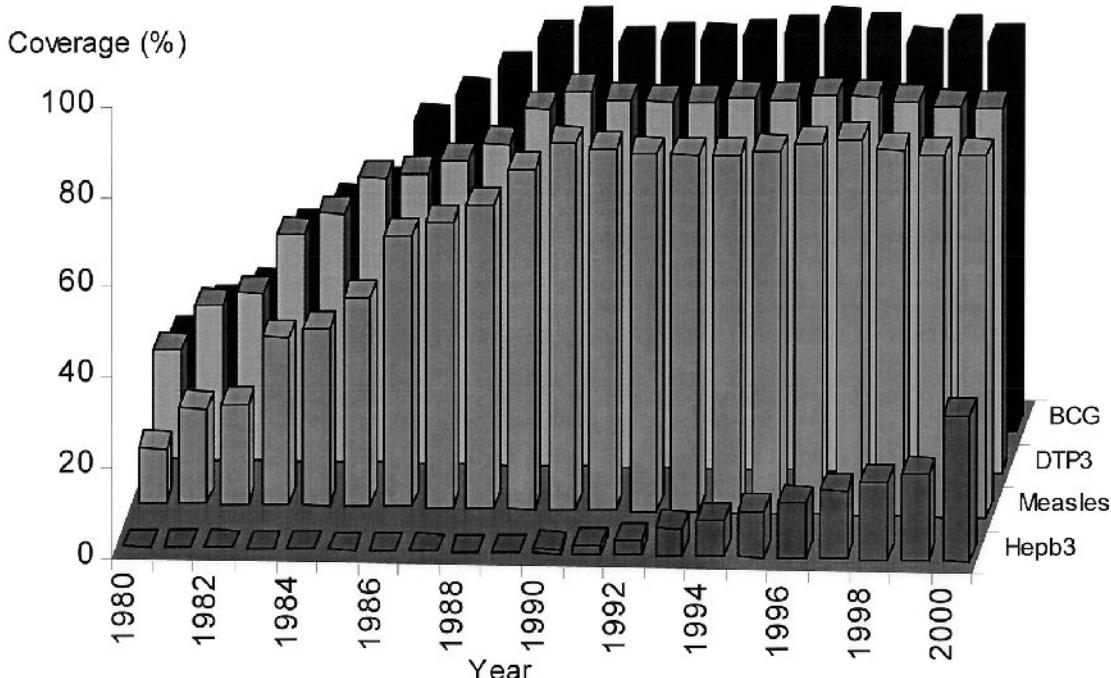

With the expansion of immunization activities, new technical issues arose and often threatened to undermine the optimal implementation of the programs. Ongoing operational and epidemiological research was essential to

resolve vaccine or immunization issues that were often unique to developing countries [2]. For example, although the epidemiology of the EPI target diseases was well understood in industrialized nations, the burden of disease due to poliomyelitis and neonatal tetanus was often grossly underestimated in developing countries, frequently holding up the introduction of one of those vaccines in a particular country. These hurdles were only overcome after the development and implementation of standardized lameness and neonatal mortality surveys, demonstrating the importance of these diseases in the developing country setting [34,35]. Similarly, specific policies were needed to counter misconceptions about contraindications to EPI vaccines and reflect the safety of their simultaneous administration [36–38].

As the technical, financial, political, and logistical challenges to reaching all children with the EPI vaccines were systematically addressed, the period 1985–1990 saw a tremendous rise in routine immunization activities worldwide. By 1990, vaccines were protecting nearly 75% of the world's children from measles, tetanus, polio, diphtheria, and pertussis (Figure 3).

### B. Accelerating Disease Control

As national immunization services were established or strengthened in developing countries, from the late 1980s onward WHO's technical oversight body for EPI turned its attention to the accelerated control of key EPI target diseases. In doing so, EPI was in fact returning to its original mandate in that "the primary concern of EPI is not immunization but disease control, using immunization as the strategy" [39]. This shift in emphasis was motivated by several

**Figure 3** Global immunization coverage of selected antigens based on official reports from countries to WHO, 1980–2000.

other factors, not the least of which was the need to maintain donor and political support for what had become a very successful public health program.

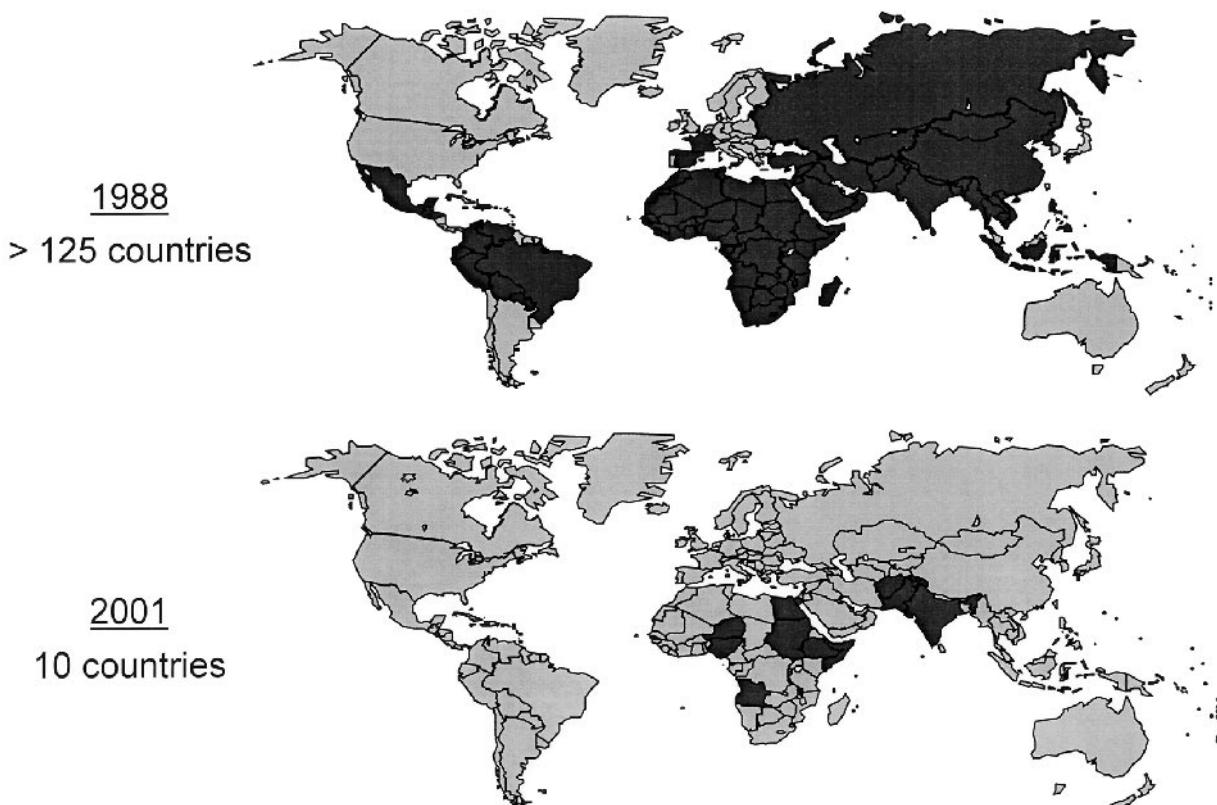

Consequently, in 1989 new EPI goals were established that went beyond the raising of routine immunization coverage to include the eradication of poliomyelitis, the elimination of neonatal tetanus and the reduction of measles mortality and morbidity by 90% and 95%, respectively [40]. The international political importance of these ambitious goals increased substantially in 1990 when they were endorsed at the World Summit for Children, the largest ever gathering of heads of states [5].

Despite this early attention, outside of the Americas there was limited progress toward any of these goals before the mid-1990s. The main reason for this was the widespread deterioration in the quality, coverage, and commitment to routine immunization that had begun in the early 1990s due to several factors [41]. Of particular importance, the rapid gains of the EPI expansion in the late 1980s appears to have fuelled among donors a false sense of the robustness of the program leading to a rapid contraction of international financial support, usually before other more sustainable funding had been secured [42–44]. Around the same time, structural adjustment programs began to markedly affect national budgets and staffing patterns in many developing countries. These problems were further compounded by health sector reform processes, which frequently led to a stagnation of EPI performance as the highly centralized EPI

structures were integrated with other child health services and/or critical functions and staff were devolved to the subnational level [45]. Even within the UN agencies, the growing demands of other priorities and programs limited the time, attention, and resources that staff of all levels could devote to immunization.

By 1995, however, efforts to achieve the specific disease-control goals of EPI had stimulated the development of new strategic approaches for reaching every child, including close collaboration with many new partners. In particular, the goal of global polio eradication had a massive impact as it grew into the largest public health initiative ever. Spearheaded by WHO, Rotary International, UNICEF, and the U.S. Centers for Disease Control and Prevention (CDC), the goal of polio eradication brought together a broad coalition of donor and technical partners to support national efforts to improve the reach of immunization services and establish effective surveillance. Through a combination of routine immunization, National Immunization Days, surveillance for acute flaccid paralysis (AFP), and house-to-house mop-up activities [46,47], polio fell from an estimated 350,000 cases (35,000 reported) in over 125 countries in 1988 to an estimated 550 cases (480 reported) in 10 countries at the end of 2001 [48] (Figure 4).

Substantial progress toward the measles control goals was first made in the Americas by building on the infrastructure and strategic approaches that had been established for polio eradication. In 1985, the WHO Region of the Americas

**Figure 4** Distribution of endemic poliomyelitis in 1988 and at the end of 2001.

went beyond the original goal, adopting a resolution to eliminate measles in all member states. By conducting massive “catch-up” campaigns, raising routine immunization coverage, introducing case-based measles surveillance, and establishing regular “follow-up” campaigns, indigenous measles was virtually eliminated from the region [49,50] (Figure 5). By the end of 2000, a global action plan for accelerated measles control had been developed, three WHO regions had established measles elimination goals and a wide variety of countries in all regions had implemented the Pan American Health Organization (PAHO) strategic approach [51].

Perhaps the most challenging of these goals was NT elimination, defined as < 1 case per 1000 live births in every district of every country. The disease had little visibility, as onset occurred very early in life and predominantly in rural areas among underprivileged populations. Furthermore, prevention required the immunization of women, rather than children, with multiple doses of tetanus toxoid during antenatal visits. Although NT deaths fell by 51% between 1990 and 1999, an estimated 200,000 NT deaths still occurred in 2000 [52]. Consequently, in November 2000 a new 5-year strategic plan was launched to achieve the goal by 2005, through routine and supplemental tetanus toxoid vaccination, strengthening of clean delivery services, and surveillance to detect and target areas and populations at high risk [53]. By the end of 2001, 20 of the 57 targeted countries had plans of action and 13 were already implementing activities.

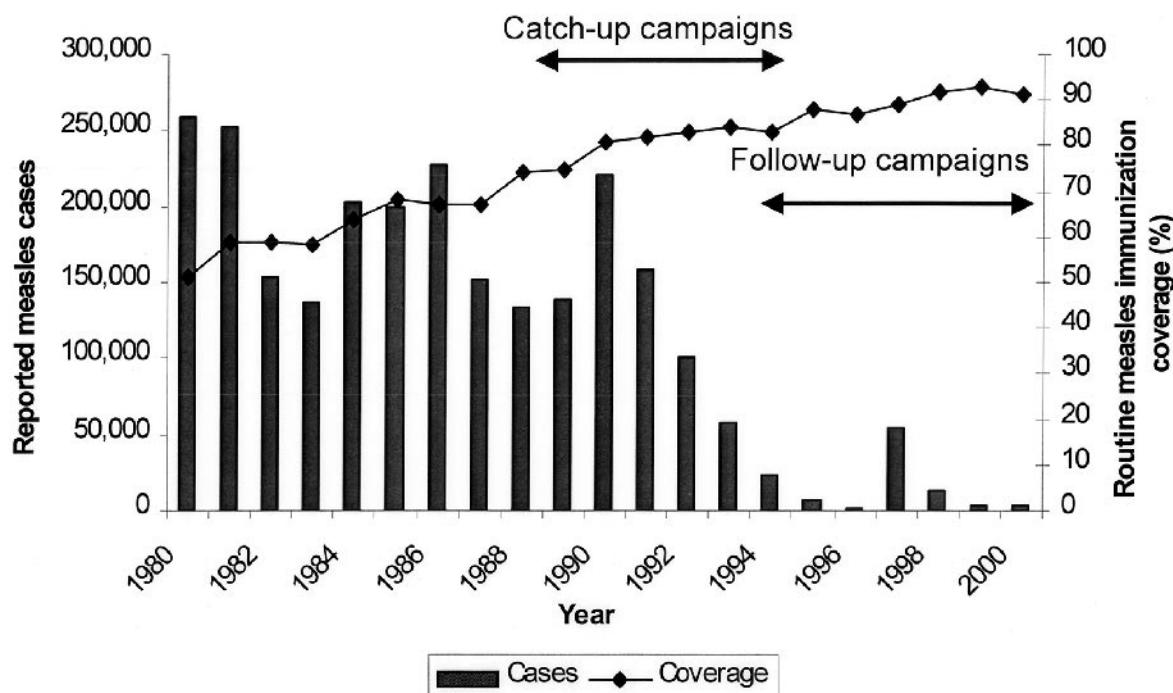

The pursuit of these accelerated disease control goals has helped raise the political visibility and attention to childhood immunization, particularly as national leaders personally launched the massive immunization campaigns.

These initiatives also greatly enhanced the international investment in global disease surveillance and developing country immunization programs. By the year 2000, for example, WHO alone had deployed over 3000 national and international personnel through the polio initiative to provide technical and administrative support to national immunization programs worldwide. New, efficient partnerships for immunization were also established through these initiatives, governed by cross-agency strategic plans and coordinated through national or regional level Interagency Coordinating Committees (ICCs). Perhaps most importantly, these efforts resulted in regular access to previously unreached geographic areas and populations, particularly through the strategic approaches and community engagement of the polio eradication initiative. In 2001 alone, an estimated 10 million health workers and volunteers immunized 575 million children with oral polio vaccine, even reaching areas affected by conflict [48].

### C. Introducing New Antigens and Interventions

As the expansion of the global EPI network significantly enhanced access to children worldwide in the late 1980s, increasing attention was given to the feasibility of systematically using the EPI infrastructure to deliver other antigens and, potentially, other health interventions (Table 2). Despite the logic and cost-effectiveness of many such proposals, it was not until 1999 that substantial progress was made in this regard.

The first additional antigen to be formally recommended for inclusion in EPI since 1974 was the yellow fever

**Figure 5** Measles immunization coverage and reported measles cases in the Americas, 1980–2000.

**Table 2** Current EPI Interventions, Year of Recommendation, and Principle Reasons for Recommendation

Intervention	Year of recommendation	Major considerations leading to recommendation
BCG, DPT, OPV, measles, tetanus toxoid vaccines	1974	Target diseases were global health problems. Effective vaccines were available. Immunization was feasible and cost-effective.
Vitamin A (micronutrient)	1987	Substantial impact on childhood mortality in vitamin A deficient areas. Compatible with EPI logistics.
Yellow fever vaccine <sup>a</sup>	1989	Resurgence of the disease in Africa in the late 1980s. Morbidity and mortality were highest in children.
Hepatitis B vaccine	1992	Universal childhood immunization is the most effective strategy. Lower cost permitted public sector use.
Hib vaccine <sup>b</sup>	1998	Major cause of bacterial meningitis and pneumonia in children. Safe and effective vaccine.

<sup>a</sup> Recommended for use in 33 African countries.

<sup>b</sup> As appropriate to national capacities and priorities.

vaccine in 1989. Recognizing the resurgence of yellow fever as a public health problem in Africa in the late 1980s, WHO's EPI technical oversight body in 1989 recommended that 33 countries on the African continent include this vaccine in their infant-immunization programs. By 1999, however, reported yellow fever vaccine coverage in these countries was only 19%, compared with 80% for measles, which is given at the same age (9 months). The reasons for this poor uptake varied by country, ranging from a lack of resources for vaccine purchase to a failure to appropriately modify or implement national immunization policies.

The first "new" vaccine to be included in EPI was the hepatitis B vaccine. Although licensed in 1981, its very high cost initially prohibited wide-scale use, even within industrialized countries. Even when the cost began to decline, however, there was limited support for universal childhood immunization against hepatitis B in some international health circles because the disease did not cause substantial childhood morbidity, even though it was a leading cause of liver cancer and early death among males in developing countries. By the late 1980s, the price of the vaccine began to decline as new producers emerged and the market expanded. In 1992, further declines in the vaccine price, combined with increasing cost-effectiveness data and the failure of targeted hepatitis B immunization strategies, warranted WHO's recommendation for universal childhood immunization [54,55]. By 1999, 117 countries, primarily high and middle income, had implemented the recommendation, but the vaccine remained unavailable in most of the poorest countries that harbored the highest burden of the disease [56].

Despite compelling data as to the appropriateness of including yellow fever and hepatitis B vaccines in EPI, it was only after 1999 that there was the opportunity to substantially improve the uptake of both vaccines in the world's poorest countries. In one of the most important developments in the history of EPI, the Global Alliance for Vaccines and Immunization (GAVI) was established in that year, bringing new cooperation, resources, and tools to the strengthening of routine immunization programs and introduction of new vaccines. GAVI has mobilized old and new

partners around a set of objectives and goals that ensures coordination of international and national immunization and vaccine research efforts. Among the most important of the tools available to GAVI is the Vaccine Fund, established with a \$750 million donation by the Bill and Melinda Gates Foundation and since augmented by other foundations and donor governments such that by the end of 2001 its assets had grown to over \$1.1 billion [57,58].

As of March 2002, the Vaccine Fund had already provided over 40 countries with the financing necessary to introduce hepatitis B into their routine immunization services and six countries had received support for yellow fever vaccine purchase [58]. The Fund had also facilitated the purchase of *Haemophilus influenzae* type b (Hib) vaccine for 11 countries. In addition to this support for new vaccines, the creation of the GAVI alliance has had an enormous impact on national and international efforts to revitalize immunization services through its high-level political advocacy, interagency coordination and, through the Vaccine Fund, routine immunization financing [57].

Of the nonvaccine interventions promoted for inclusion in routine immunization services, the most important has been vitamin A. Since the discovery in the 1970s and 1980s that regular supplementation with that micronutrient could reduce all-cause childhood mortality by as much as 23% [59], there has been substantial interest in administering it during routine immunization contacts, particularly with measles at 9 months of age [60]. Although the logistical implications of including vitamin A are relatively minor, as it is heat stable and administered by mouth, 10 years later only a limited number of countries had implemented the policy. In the late 1990s, however, the linking of vitamin A and immunization contacts took a major step forward when countries began including the micronutrient in polio National Immunization Days (NIDs) [61]. By 2000, there were compelling data to further promote the use of vitamin A during routine immunization contacts—inclusion of the micronutrient in polio NIDs in 61 countries in the period 1998–1999 had averted over 400,000 childhood deaths [62]. By the end of 2000, 49 of the 136 countries with known

vitamin A deficiency had begun distributing the micronutrient through routine immunization services.

Recognizing the opportunity that the EPI infrastructure provided, and building on the experience gained through the introduction of the yellow fever and hepatitis B vaccines and vitamin A, in the early 1990s WHO developed a framework to facilitate the introduction of new interventions [13]. This framework is intended to accelerate the evaluation of an intervention and, if necessary and feasible, modify its characteristics to streamline its integration into EPI programs.

#### IV. A NEW MILLENNIUM—NEW OPPORTUNITIES

In the year 2000, ambitious Millennium Development Goals were underwritten by all nations. These goals include a two-thirds reduction in child mortality by 2015. For this to be achieved, the full potential of the global EPI network must be exploited to prevent the three million vaccine-preventable deaths that continue to occur every year (Figure 6). Preventing these deaths requires extending the reach of immunization services to the more than 25% of the world's children who are yet to have regular access to immunization, the most cost-effective of health interventions. Particular attention must be given to increasing coverage among the world's poorest children who are disproportionately affected by vaccine-preventable and infectious diseases. That reaching all children with immunization is a feasible goal is abundantly evident in the progress achieved and experience gained over the past 25 years. The challenge will be to exploit the opportunities that exist to establish true equity in global childhood immunization.

One of the first challenges will be to ensure that there are accurate data with which to identify areas of low immunization coverage, particularly at the subnational level, so that corrective actions can be focused most effectively. During the last decade of the twentieth century, attention to coverage monitoring had declined as increased

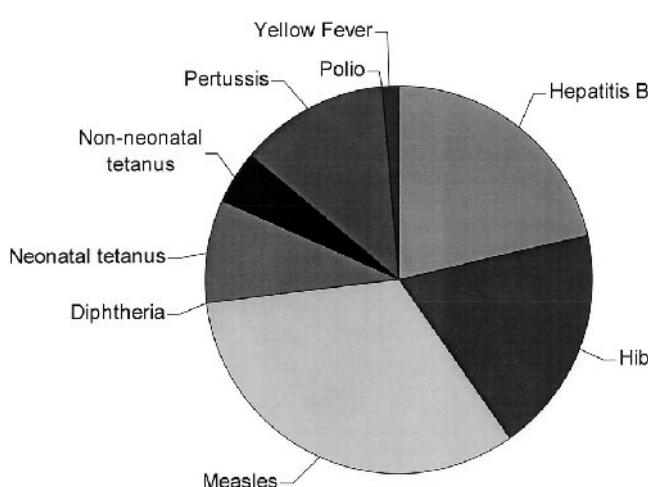

emphasis was placed on the use of disease surveillance data to monitor the impact of immunization. Consequently, an extensive review of national data from 1980 to 1999 found that immunization coverage levels were actually lower than had been reported. In fact, global DTP3 coverage at the time of the World Summit for Children in 1990 was estimated to have been only 73% rather than 80%, with little improvement throughout the 1990s [29,56]. Moreover, global coverage figures masked important differences between and within countries. Most importantly, in sub-Saharan Africa less than 50% of children born in 2000 were fully immunized [56].

Using accurate data, the capacity, tools and processes must be established to develop multiyear plans that address access constraints for countries and areas with coverage of less than 80%. Such plans must accurately identify and map currently unreached children or geographic areas, identify the underlying causes, and plan for their resolution. Particular attention will need to be given to separating those low coverage areas due to poor management of existing services (e.g., with high "drop-out rates") from those where services are just not present or poorly attended. Tackling the management problem requires a much overdue revision and implementation of the basic EPI immunization management guidelines to adapt them to the realities of the much changed, often decentralized health systems that have evolved since the mid-1980s [63].

The "access" problem will require reestablishing the outreach services and infrastructure that were so important to the immunization gains of the late 1980s. To ensure the sustainability of such services, however, they will need to be more closely integrated into the delivery of other health services and tailored to the size and needs of the communities that they are serving. Recognizing this, the United Nations Foundation has supported the work of WHO and UNICEF to pioneer and pilot-test an initiative known as Sustainable Outreach Services (SOS). The SOS approach draws heavily on the lessons learned from the polio NIDs, using periodic contacts to reach people with limited or no access to health services. The delivery of immunization is combined with other interventions such as impregnated bed nets and micronutrient supplementation. SOS is based heavily on community participation in selecting the interventions and facilitating their delivery [64].

To assist countries in these efforts, the UN agencies and immunization partners will need to provide technical and financial support at least equal to that which it has provided in the ongoing effort to eradicate polio. WHO and UNICEF have already detailed the major elements of the polio eradication infrastructure and begun planning the systematic transition of the institutional arrangements (e.g., ICCs, laboratory networks, technical oversight groups), physical infrastructure (e.g., cold chain, communications and transportation equipment) and human resources to support broader immunization goals. In 2001, UNICEF also established "Immunization-Plus" as one of its five health priorities, signaling its intention to substantially increase its support to national immunization services [65].

Insufficient financing remains a major barrier toward equity in immunization, and the search for sustainable EPI funding remains a chronic challenge for the world's poorest

**Figure 6** Distribution of the estimated three million annual deaths from diseases that are preventable by routine childhood vaccination, 2000.

countries. However, at no point in the history of EPI has there been as much attention to this area and as many promising initiatives [58,63]. For example, the Vaccine Fund of GAVI is requiring the development of national financial sustainability plans in countries receiving its resources. Meanwhile, most countries are expanding the scope of the Interagency Coordinating Committee that was established to coordinate polio eradication partner inputs, to encompass all immunization activities. Also at the country level, the decentralization of health services, with the devolution of planning functions and budget allocations, provides opportunities to improve coordination with other sectors and more effectively use resources to reach more children. Although the debt relief initiative for the highly indebted poor countries (HIPC) has yet to promote highly cost-effective health interventions such as immunization to the degree anticipated, this remains a potential mechanism for substantially enhancing financial support to immunization. At the international level, a GAVI Task Force is specifically addressing the issue of sustainable immunization financing with a particular emphasis on understanding and exploiting the many opportunities that exist. Finally, there is now concrete planning to extend the Vaccine Fund, which has become one of the most important new immunization financing instruments for poor countries, to beyond 2005.

In addition to the obvious logistical and managerial challenges to reach every child and ensure sustainable financing, the maturation of EPI has brought other extremely important although much less visible concerns. The importance of ensuring the safety of all immunizations led WHO to establish in 1999 a “priority project” in this area [66,67]. This has brought together the broad range of ongoing work in this area from ensuring “vaccines of assured quality” [including functioning national regulatory authorities (NRAs) worldwide], to improving injection safety and the monitoring and management of adverse events following immunization [68,69]. One of the most important developments in this project was the establishment of a WHO Vaccine Safety Advisory Committee to ensure the capacity to respond promptly, objectively, and with scientific rigor to vaccine safety issues anywhere in the world [70].

One of the more insidious threats to achieving and sustaining equity in global immunization is the growing challenge of “vaccine security.” Ironically, the growth in global immunization activity and coverage has recently been accompanied by a contraction in both the number of manufacturers producing vaccines for the developing country market and the amount of vaccine they produce [71]. The principal causes of this problem have been the consolidation of the pharmaceutical industry in the mid-1990s and the divergence of developing and industrialized country vaccine markets [71]. Although UNICEF procured vaccines for 40% of the world’s children in over 100 countries in 2001, it is operating in an increasingly challenging market where the gap between demand and supply has narrowed substantially. To manage this challenge and stabilize the market, UNICEF has substantially enhanced its long-term vaccine demand forecasting capacity in collaboration with WHO, increased its dialogue with manufacturers, and explored mechanisms to establish longer-term funding and contracts for vaccines.

## V. CONCLUSION

The last millennium closed with great achievements in the delivery of routine immunization services in developing countries. Within a 25-year period, global immunization coverage rose from less than 5% to nearly 75%. Early in that period a whole range of cold-chain and injection equipment was developed specifically for the tropical developing country setting and has now become the standard in most. A global network of national immunization programs was established, standardized approaches were developed, monitoring systems introduced, and legions of health workers trained.

As the reach of this global immunization network expanded, ambitious new disease control objectives have brought polio to the brink of eradication and demonstrated that the interruption of measles, one of the leading killers of children, is feasible. The pursuit of these goals has led to a massive expansion of the technical support provided by UN agencies to national immunization programs and demonstrated that with the appropriate mix of planning, partnerships, resources, and community engagement, all children everywhere can be regularly accessed with immunization services. The launch of GAVI in the year 2000 provided a mechanism to effectively tackle the financing gap that had become one of the greatest barriers to achieving equity in the introduction of new vaccines and expanding services to the hardest to reach children. Finally, the wide-scale delivery of vitamin A during immunization contacts has begun to demonstrate that the broader promise of the global EPI infrastructure to facilitate the delivery of other interventions can be realized.

Although a new millennium has brought new challenges for EPI, the commitment, concepts, and capacity needed to achieve equity in the delivery of childhood immunization services on a global scale has never been stronger. However, reaching all children with even the most basic of vaccines will require a level of sustained financing, national ownership, and international donor interest that has thus far proven elusive.

## ACKNOWLEDGMENTS

The authors are extremely grateful to Ms. Joan Hawe of the World Health Organization for her assistance with the references for this article, as well as Dr. Mark Kane of the Children’s Vaccine Programme, Dr. Jay Wenger of the World Health Organization, and Dr. Yves Bergevin, Dr. Okwo Bele, Ms. Maryanne Neill, and Ms. Shanelle Hall of UNICEF for their comments on specific sections of the manuscript.

## A Paradigm for International Cooperation: The Global Alliance for Vaccines and Immunization (GAVI) and the Vaccine Fund

**Lisa Jacobs and Tore Godal**

*GAVI Secretariat, Geneva, Switzerland*

**Jacques-François Martin**

*The Vaccine Fund, Lyon, France*

### I. BACKGROUND

For more than a century, scientists and public health leaders have known that preventing infectious diseases is the most efficient form of health intervention. During the twentieth century, medical research led to the development of vaccines that prevent several crippling, often fatal, childhood diseases.

In fact, vaccines helped to reduce the health gap between rich and poor countries. Up until the 1970s, outside of the world's richest countries most children were not vaccinated against even a single disease. Following the successful eradication of smallpox in 1977, public health advocates and experts around the world collaborated to help build systems in developing countries to routinely provide infants with vaccination against six diseases: measles, diphtheria, pertussis, tetanus, poliomyelitis, and tuberculosis (using BCG vaccine).

By 1990, 75% of the world's children received these "basic six" vaccines. In the history of international public health, there has been no other routine health intervention that has received such high coverage as vaccination.

However, as a new century begins, the world falls short of realizing the full benefit of childhood immunization. By the end of the 1990s, approximately 34 million children were born every year that would not become immunized. In sub-Saharan Africa, fewer than half of the children were being immunized. As a result, every year, approximately three million additional lives could be saved from easily prevented infectious diseases if vaccines could reach their target populations.

Moreover, vaccines such as those against hepatitis B and *Haemophilus influenzae* type b (Hib) have not been

introduced quickly enough in the poorest countries. New vaccines at late stages of development, such as those being created against pneumococcal pneumonia, meningococcal meningitis, and rotavirus diarrhea—diseases that kill millions of children every year in the developing world—are at risk of not reaching those who most need them. Finally, the search for vaccines against several of the most critical infectious disease threats of our time—HIV/AIDS, malaria, and tuberculosis—must be intensified, and effective health delivery systems must be strengthened to ensure that once these vaccines are successfully developed, all those in need can access them.

### II. THE GLOBAL ALLIANCE FOR VACCINES AND IMMUNIZATION COMES ON THE SCENE

The Global Alliance for Vaccines and Immunization (GAVI) was launched in 2000 as a coalition committed to reinvigorating and sustaining the promise of widespread immunization (see Table 1). A partnership that includes national governments, UNICEF, WHO, The World Bank Group, the Bill & Melinda Gates Foundation and other foundations, nongovernmental organizations (NGOs), the vaccine industry, and research and technical health institutions, GAVI exists as a mechanism for coordinating and revitalizing immunization programs at international, regional, and national levels.

By significantly expanding the reach and effectiveness of immunization programs country by country, the GAVI partners hope to decrease the burden of disease globally. GAVI reaffirms that immunization is a cornerstone for

**Table 1** GAVI Mission Statement

To save children's lives and protect people's health through the widespread use of vaccines.

*GAVI strategic objectives:*

- Improve access to sustainable immunization services.
- Expand the use of all existing, safe, and cost-effective vaccines where they address public health problems.
- Accelerate the development and introduction of new vaccines and technologies.
- Accelerate R&D efforts for vaccines needed primarily in developing countries.
- Make immunization coverage a centerpiece in international development efforts.
- Support national and international disease control targets for vaccine preventable diseases.

*GAVI milestones include:*

- By 2005, 80% of developing countries will have routine immunization coverage of at least 80% in all districts.
- By 2002, 80% of countries with adequate delivery system will introduce hepatitis B vaccine, and all countries by 2007.
- By 2005, 50% of the poorest countries with high burden of disease and adequate delivery systems will have introduced Hib vaccine.
- By 2005, the vaccine efficacy and burden-of-disease will be known for all regions for rotavirus and pneumococcal vaccines, and mechanisms identified to make the vaccines available to the poorest countries.

health, a key component of the broader framework of economic development and poverty reduction, and an essential step to protecting children's health and allowing each child to reach his or her greatest physical and intellectual potential.

#### A. The Vaccine Fund

The Vaccine Fund is a financing mechanism designed to help the GAVI alliance achieve its objectives by raising new resources and swiftly channeling them to developing countries. Because the partners of the Alliance provide direction and support in policy development and the processing of countries' proposals, administrative costs are kept low—almost all of Vaccine Fund resources go directly to countries.

The Vaccine Fund has received commitments from the governments of Norway, the United Kingdom, the United States, the Netherlands, Canada, Denmark, and Sweden and from the private sector, adding to its start-up grant from the Bill & Melinda Gates Foundation, pushing its total resources to above \$1 billion for 2001–2005.

Although initially conceived as primarily a commodity-based vaccine purchase fund, the GAVI partners quickly responded to the overwhelming demand for funds to help repair fragile and faltering immunization and health systems in developing countries. Thus, in addition to supporting countries to introduce vaccines against hepatitis B (hepB), Hib, and yellow fever into their routine systems, a performance-based grant system was developed to provide addi-

tional resources for countries to use to strengthen their immunization services based on their own national priorities and needs. In the future, Vaccine Fund resources may be used to accelerate the development and introduction of vaccines needed in the developing world.

Although the Vaccine Fund does not procure the six "traditional" vaccines for countries, Fund resources aimed at strengthening immunization systems ensure that more children receive those lifesaving vaccines as well.

Funding decisions are made based on proposals received from countries. Following are the main conditions that a country must meet to receive support:

- An Interagency Coordination Committee (ICC) must exist led by government and including representatives of local agencies involved with immunization. The ICC helps guide the application process and assists government with program management.
- A recent review (within 3 years) of immunization services must have been carried out.
- A multiyear plan outlining improvement and expansion of immunization services and mechanisms for sustainable financing must be available.

The GAVI partners designed the Vaccine Fund not to supplant other sources of funding but as a catalyst for additional funding. In fact, this has happened in many countries, with partners stepping in to provide needed support—from training to new refrigerators, and governments stepping in with more of their own budgets dedicated to immunization (Table 2).

#### 1. The Proposal Review Process

The country proposals for support from GAVI and The Vaccine Fund are reviewed by the Independent Review Committee (IRC), an independent committee of experts whose members have been selected by the Executive Secretary after consultation with the Working Group. Panel members are selected for their broad expertise in health with specific knowledge of vaccines and immunization, independence from the partners of GAVI, and integrity. Due regard is paid to the importance of selecting experts on as wide a geographic basis as possible. Primarily, these experts have been selected from low- and middle-income countries.

The proposals must be received at the Secretariat by specific dates set annually, about which the eligible countries are notified. Prior to their review, proposals are screened by the Secretariat for completeness and basic eligibility. Each proposal is then preassessed by a group of relevant experts from WHO and other GAVI partners. The group looks for consistency of information, validity of data provided, coordination with polio eradication, and injection safety efforts. Their feedback is provided in written form to the IRC for their use during deliberations on the proposals.

Proposals are reviewed by the IRC at the GAVI Secretariat in Geneva at set times throughout the year. The IRC reviews the proposals in accordance with the policies laid down by the GAVI Board, following the criteria for eligibility and assessment as expressed in the guidelines prepared by the Working Group.

**Table 2** Status of GAVI Support to Countries

At the World Health Assembly in May of 2000, the first call for proposals from GAVI and The Vaccine Fund was distributed to all eligible countries—the 74 countries with less than \$1000 per capita.
As of early 2002:
Sixty-six countries have submitted proposals and 54 have been approved for support.
More than \$800 million has been committed to these countries over the next 5 years.
The first cash support was disbursed in December 2000; vaccines started to reach countries in April 2001.
If countries achieve their plans, basic immunization rates in funded countries could increase by 17 percentage points and coverage of hepatitis B vaccine could increase from 18% to 65% by 2007, ultimately saving more than two million lives.

The recommendations of the IRC are communicated to the GAVI and Vaccine Fund Boards for final decision. Once the decisions are made, the GAVI Secretariat is responsible for communicating the decisions to the country ICCs, to partners at the regional and field levels, and to UNICEF Supply Division to trigger procurement of the necessary vaccines and supplies.

Committee members must sign a confidentiality and conflict of interest statement. Committee members who recently have been involved in any capacity in the immunization programmes in countries under review are not present during the deliberations of the review committee, and do not participate in the decisions for those countries.

## B. GAVI Governance and Structure (see Fig. 1)

### 1. The GAVI Board

Sets the policies and review progress of the Alliance.

The GAVI Board is comprised of the highest-level representation from the partners, there are four renewable members—WHO, UNICEF, The World Bank, and the Bill & Melinda Gates Foundation. Eleven additional, rotating members responsible for representing the collective expertise and perspective of their constituencies. The current (May 2002) rotating members are:

- Foundation: United Nations Foundation.
- Government—developing countries (two): India and Mali.
- Government—industrialized countries (three): Norway, the United Kingdom, the United States.
- Nongovernmental organization (NGO): Children's Vaccine Program at PATH.
- Pharmaceutical industry—industrialized country: Wyeth-Lederle Vaccines.
- Pharmaceutical industry—developing country: Center for Genetic Engineering and Biotechnology (Cuba).
- Research institute: Institut Pasteur (Paris).
- Technical health institute: U.S. Centers for Disease Control (CDC).

Carol Bellamy, Executive Director of UNICEF, started her 2-year term as GAVI Chair in July 2001, taking over from WHO Director-General Gro Harlem Brundtland who served as GAVI's first chair. The Board meets on average twice a year and schedules periodic teleconferences as needed to review progress and policies.

### 2. The Vaccine Fund Board and Staff

Responsible for raising the world's awareness about the GAVI immunization goals and securing the funds needed to support those goals.

The Board of the Vaccine Fund is composed of high-profile individuals with wide experience in philanthropy and business. Its first Chairman is former South African President Nelson Mandela.

### 3. The GAVI Working Group

Supports the Board in policy development and implementation.

Composed of managers in the GAVI partner institutions, these staff are able to translate GAVI priorities into their respective agency work plans. The Working Group currently includes 10 members, representing WHO; UNICEF; the World Bank; the GAVI Secretariat; the Vaccine Fund; the Children's Vaccine Program at PATH, the Government of Tanzania, the University of Maryland School of Medicine, USAID; and GlaxoSmithkline Biologicals.

### 4. The GAVI Secretariat

Facilitates coordination between the partners and manages the review of country proposals to the Vaccine Fund.

The Secretariat is small—five professional staff and three administrative staff, housed in the European regional office of UNICEF in Geneva. The Secretariat's budget is financed by membership fees paid by the GAVI Board members and the Executive Secretary reports to the GAVI Board.

### 5. Task Forces

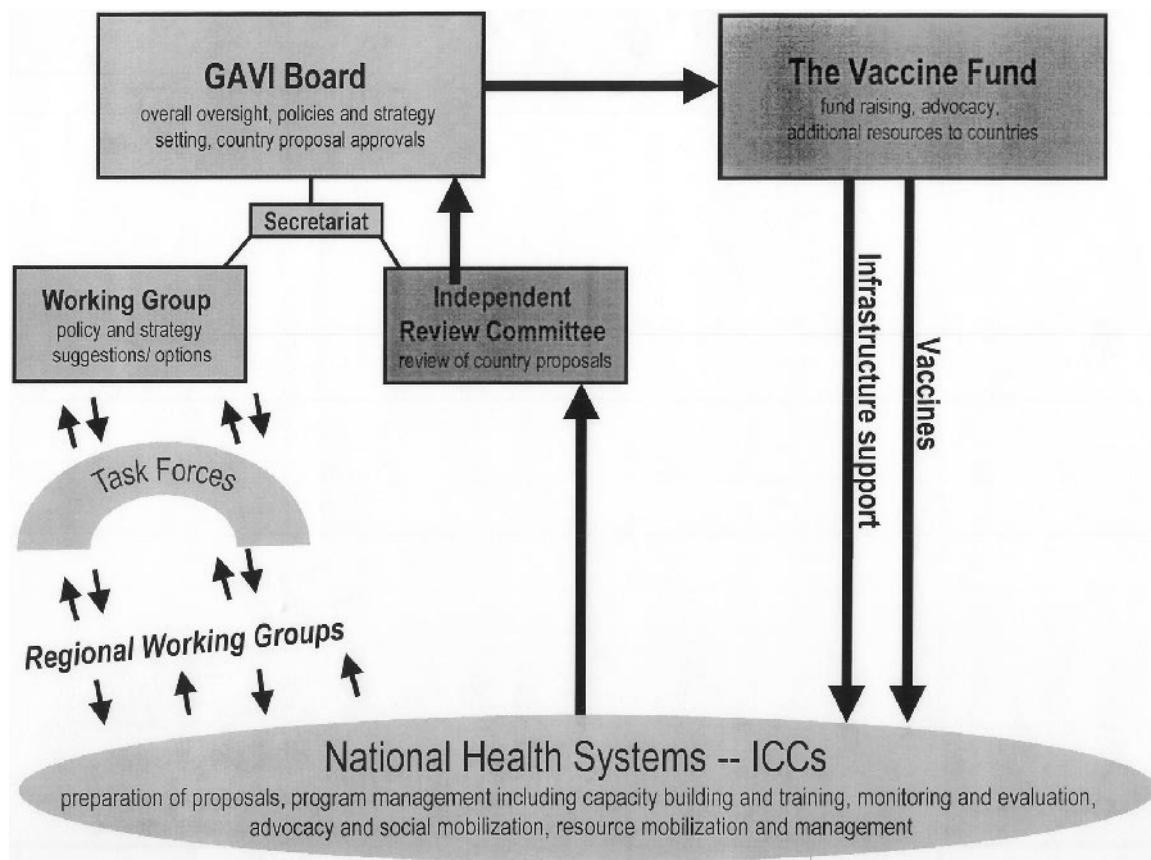

Established to address specific issues of concern to the Board.

Task forces are managed by their respective lead agencies, and include representatives of the relevant partner agencies. The Advocacy Task Force is chaired by UNICEF; the Task Force for Country Coordination is chaired by WHO; the Financing Task Force is co-chaired by the World Bank and USAID; and the Research and Development Task Force is co-chaired by WHO, the University of Maryland, and Chiron Vaccines.

### 6. Regional Working Groups

Coordinate technical support and information sharing between the national and international levels.

The regional working groups (RWGs) were established by partners with a technical presence at the regional level—in most cases WHO and UNICEF—in response to the need to more quickly identify and address the technical assistance requirements of countries, improve communication, and streamline efforts, in support of the GAVI and Vaccine Fund processes.

**Figure 1** GAVI organogram.

## 7. National International Agency Committees

Critical to the GAVI partnership.

National ICCs represent the leadership and commitment of the national governments and analogous in their operations to the GAVI Board, i.e., enhancing partner roles through coordinated action. ICC decisions do not overrule governance of partners.

The roles and functions of ICCs vary considerably from country to country, depending on size, strength of the government, and the presence of other health system coordinating groups such as sector-wide groups.

ICCs increasingly are composed of both external donors and agencies and national/internal partners involved in local action. Thus, coordination does not only encompass technical and financial support for government action, but also coordination of implementers—such as NGOs—that may bring their own international or national resources.

## III. R&D IN THE CONTEXT OF THE GAVI ALLIANCE

The global vaccine research community includes many diverse players, each contributing in different ways with vastly heterogeneous resources and distinct agendas. Much can be gained by coordinating agendas and goals to render

efforts complementary, avoid duplication, and maximize the use of limited resources.

The many partners involved in vaccine research and development activities and epidemiological studies in both industrialized and developing countries are represented in the Alliance in a truly synergistic effort. Partners include governmental research institutes, academic research programs, large vaccine manufacturers, biotechnology companies, units within Ministries of Health, etc. There are also partners that are not primarily engaged in research but who, as implementers of immunization, will provide critical input to researchers to advise them on what is needed, feasible, and desired at the front lines of primary care, and in contrast, what cannot be readily incorporated into primary care regimens.

With all of the current activity in vaccine R&D, it is important that in the context of GAVI, efforts focus on identifying those gaps where an alliance can have a strategic advantage. Thus, while the GAVI partners recognize that a high priority lies in HIV/AIDS and malaria, given the massive global effort to these projects worldwide, the Alliance decided to prioritize other vaccines that are receiving less attention.

In addition, even if these vaccines become available, many of the poorest countries lack the infrastructure to put these vaccines into public health use efficiently. Therefore,

initially, GAVI partners decided to initially place their R&D focus on vaccines that have a lower technical risk and a greater potential for more near-term development and introduction.

In order to identify these priority vaccines, members of the GAVI Task Force on Research and Development (R&D TF) conducted wide consultation with the R&D community to develop consensus.

The criteria for choosing the disease specific projects was based upon several considerations:

Either no currently registered vaccine or for which the existing vaccines have notable drawbacks that severely limit their public health usefulness (e.g., the existing vaccines are not immunogenic in infants, yet that age group is an epidemiological target for vaccination).

High potential impact in terms of disease mortality rate and disability-adjusted life years (DALYs).

Nonavailability of alternative solutions to managing the disease.

Good potential for changing/improving the immunization system for the future in terms of capacity building and promoting behavioral or system change.

High degree of feasibility with available tools and infrastructure; political commitment.

The consultation process led to a consensus that the three vaccines that should receive high priority in the context of GAVI are *Streptococcus pneumoniae*, rotavirus, and *Neisseria meningitidis* group A (which may be approached either as a monovalent group A, a bivalent group A/C, or a quadrivalent group A/C/Y/W135 vaccine). Success with these vaccines will alleviate the burden of important diseases in developing countries but will also build the infrastructures for efficient testing and delivery of vaccines that will come later, such as HIV, TB, and malaria.

GAVI partners are also focused on seeking out and developing new technologies that will improve safety, effectiveness, utility, or performance of immunization systems in developing countries. The same broad criteria for evaluating vaccine candidates were used for new technologies, and priority areas were identified to be the following:

Decreased dependence upon and streamlining of the cold chain.

Improved tools to measure immunization services performance.

Reducing infectious wastes and ultimately eliminating the use of sharps (needles and syringes).

Preference will be given to research and development on new technologies being conducted in developing countries.

#### IV. LOOKING TO THE FUTURE: ISSUES AND CHALLENGES

##### A. Safety and Waste Management

Worldwide, each year, the overuse of injections and unsafe injection practices combine to cause an estimated 22.5

million hepatitis B virus infections, 2.7 million hepatitis C virus infections, and 98,000 HIV infections. Although injections given as a part of immunization programs account for a very limited proportion (approximately 5%) of the injections delivered and are widely considered the safest of all delivered, there is a growing body of data demonstrating the safety of immunization programs throughout the world need to be improved.

Based on the principle of “do no harm,” the GAVI partners acknowledge the importance of improving the safety of immunization programs and have focused special attention on safety in relation to the other elements of immunization programs.

Appropriate disposal of medical waste is an important element of efforts to improve the safety of national immunization programs and should be based on the principle that the “polluter pays.” Although at present there are very limited environmentally sound options for safely eliminating waste, the Alliance is committed to supporting countries in their immediate action, using the best practices available to minimize the risk of exposure to medical wastes for staff and the community. GAVI partners encourage further investment in the development of new environmentally sound, reasonably priced methods for disposing of medical wastes.

##### B. Vaccine Supply

The relatively small size of the developing country vaccine market has resulted in reduced private sector investment in relevant vaccines and thus reduced production capacity. GAVI, with private sector involvement and a 5-year perspective, lends a much-needed stability to delivery systems, demand creation, and vaccine supply. GAVI partners believe that if the public sector can work to help make the developing country vaccine market more attractive to vaccine manufacturers, children living in the poorest countries will live healthier lives by having access to better and more effective vaccines.

##### C. Sustainability

Financial sustainability is crucial to the success of immunization programs in countries and will be the measure of GAVI’s success in the long term. However, the challenge of creating systems that are sustainable beyond the initial time of investment is one of the most critical issues facing all areas of development—not just GAVI.

To clarify the aim of strategies developed to enhance the sustainability of programs, the GAVI Board adopted a new definition of financial sustainability: “Although self-sufficiency is the ultimate goal, in the nearer term sustainable financing is the ability of a country to mobilize and efficiently use domestic and supplementary external resources on a reliable basis to achieve target levels of immunization performance.”

In this way GAVI partners recognize that for the foreseeable future, maintaining high-quality immunization programs in the health systems of the poorest countries will require continued external support—from donor governments, NGOs, the private sector, and individuals—

support that has flagged in too many countries in recent years.

#### D. The Vaccine Fund: Future Needs

The Vaccine Fund was created to provide resources to countries to fill critical gaps in funding for immunization services. The GAVI Board identified that the most critical gaps at present are the weak health service infrastructure in many countries, the delay in introducing new life-saving vaccines as they become available, and the need to improve safety of immunization programs.

As the country programs progress, new gaps are likely to become apparent, and new vaccines now on the horizon will need to be introduced into routine immunization systems. Therefore, the Vaccine Fund will need to continually attract new resources.

#### E. Maintaining a Robust Learning Curve

It is important to retain the perspective of GAVI as an experiment. By joining in this public-private alliance the GAVI partners have committed to working together in new ways. As new hurdles arise, the Alliance has been able to reexamine and revise its policies and directions. For exam-

ple, The Vaccine Fund expanded its early focus on vaccines to include support for health system infrastructure. The critical issue of immunization safety has emerged so the GAVI Board adopted a new policy so that The Vaccine Fund now provides countries with safe injection devices for all routine immunizations.

Much of the early work of the Alliance has been dedicated to the development of policies and the proposal process for The Vaccine Fund, and providing the eligible countries the technical support they need to apply for support. Now that nearly all eligible countries have applied to The Vaccine Fund, with many of them approved, the GAVI partners are shifting emphasis to supporting implementation of improved immunization programs and issues of sustainability. Looking ahead, GAVI partners will need to continually monitor their impact to assess whether their efforts, and support from The Vaccine Fund, have in fact helped countries meet their targets.

The role of the partners—most of which have worked in immunization long before GAVI came together—cannot be stressed enough. With so much attention focused on GAVI and The Vaccine Fund as new contributors to the global immunization community, it must be remembered that all of the progress logged over the past 2 years has resulted from partner commitments—staff, resources, and financial support—in countries, regions, and at the global levels.

## Economic Analyses of Vaccines and Vaccination Programs

**Benjamin Schwartz and Ismael Ortega-Sanchez**

*Centers for Disease Control and Prevention, Atlanta, Georgia, U.S.A.*

### I. INTRODUCTION

Economic analysis has been used to assess a wide range of issues related to vaccines and vaccination programs. Vaccine development priorities for the United States have been assessed by the Institute of Medicine (IOM), categorizing prospective vaccines based on their development and implementation costs compared with the projected health benefits achieved by their use [1]. Manufacturers may use economic analyses to determine allocation of resources among candidate vaccines and to establish vaccine price. After a vaccine is licensed in the United States, cost effectiveness is one of the factors considered by the U.S. Advisory Committee on Immunization Practices in making recommendations for its use [2]. Once a vaccine is recommended, economic analysis may, in part, provide the basis for modifications, recommending new settings or populations in which the vaccine should be used. Economic evaluation of programmatic issues, such as approaches to increasing vaccination coverage, have also been assessed. Although balancing the economic value of immunization against other health programs has not been a key issue in some industrialized countries, for the developing world, the cost of vaccines and the economic analyses of immunization compared with other programs have been important [3].

In the industrialized world, vaccination programs have been characterized by rapid change. Advances in immunology, molecular biology, and technology have markedly accelerated the rate of new vaccine development. Between 1985 and 2000, new vaccines recommended in the United States have included DTaP, enhanced potency inactivated polio vaccine (IPV), *Haemophilus influenzae* type b (Hib) conjugate, hepatitis A and B, varicella, Lyme disease, rotavirus, and pneumococcal conjugate vaccines. Combination vaccines have been developed; however, as their development and licensure have lagged behind other new vaccines, as many as five injections at a single visit are now required to fully vaccinate an infant under the U.S. schedule. Vaccination costs have increased disproportionately to the number of antigens administered. In 1990, the cost of fully vaccinat-

ing a child through 5 years of age in the United States was \$243.90 which provided protection against nine diseases; in 2000, the cost of recommended vaccines was \$605.85 to protect against 11 diseases, or \$665.31 to protect against 12 diseases, in some geographic areas. Finally, the types and severity of outcomes prevented by vaccination may also be changing. New vaccines to prevent varicella, hepatitis A, Lyme disease, rotavirus, and pneumococcal infections prevent few deaths in industrialized countries compared with older products. Each of these changes—the increasing number of vaccines and injections, the increasing costs, and the lesser severity of the diseases being prevented—has resulted in greater scrutiny of recommendations for new vaccines and greater importance of the economic rationale for their use.

In the developing world, the Global Alliance for Vaccines and Immunizations and the increased availability of funding have catalyzed changes in vaccination programs. Virtually all countries have received increased support for program infrastructure and the introduction of new vaccines. Although external funding has overcome many barriers, the expectation that countries will assume a greater share of the burden over time makes economic analysis increasingly important for decision makers throughout the world.

The purpose of this chapter is to describe the types of economic analysis commonly used, their components, and the advantages, disadvantages, and controversies that exist with each approach. In addition, some of the limitations and inconsistencies of vaccine economic analyses published in the medical literature will be highlighted, emphasizing the importance of critical analyses of this body of work.

### II. TYPES OF ECONOMIC ANALYSES

#### A. Cost-Benefit Analyses

Three types of analyses are commonly used to assess the economic rationale for immunization or other health-related programs: cost-benefit, cost-effectiveness, and cost-utility

analyses (Table 1) [4]. *Cost–benefit analyses* (CBAs) compare the monetary benefits from implementation of a health program with its monetary costs. All inputs in a CBA, including health outcomes, are converted to monetary units, resulting in an outcome that is expressed as money saved or spent. The results of a CBA are typically presented either as the *net present value* (NPV) of the program or the *cost–benefit (CB) ratio*. NPV is defined as the difference between the discounted benefits and the discounted costs of the intervention, or  $NPV = \sum_{t=0}^N \delta^t (B_t - C_t)$ , where  $\delta^t = 1/(1+r)^t$ ,  $r$  = the discount rate as a decimal, and  $t$  = number of years analyzed (between  $t = 0$  and  $N$ ). Equivalently, results of the analysis can be expressed by the CB ratio, which is the ratio between the discounted costs and the benefits of the intervention, or

$$CB = \frac{\sum_{t=0}^N \delta^t C_t}{\sum_{t=0}^N \delta^t B_t}.$$

For new vaccines, where the price per dose has not yet been set, a “break-even” price can be calculated, where the net costs and benefits are equal ( $NPV = 0$ ).

The CBA is useful to compare the economic value to society of programs with different impacts such as a health program with another (nonhealth) type of program. The NPV of an immunization program can be compared with the NPV of an early childhood education program or a program to encourage aquaculture. Another advantage of this approach is that the results are expressed in a way that is easily understood by policymakers and the public.

An important shortcoming of CBA is the need to quantify all the impacts of a program in monetary terms. Assigning a monetary value to health outcomes for a disability or death is problematic. While one approach is to assign a monetary value based on the net present value of the expected future earnings lost [4], this results in the ethical dilemma of valuing life differently based on country or, possibly, by gender or ethnic group within a country. While a number of different methods have been proposed to estimate the economic value of a life, no method is accepted universally. It is also difficult to assign a monetary value to the pain and suffering that occurs with an illness. The *willingness-to-pay* (WTP) or *contingent valuation* method has become a common strategy to define these values. WTP measures the

value placed on avoiding an outcome. Several approaches may be used to define WTP. One common approach involves surveying a population for the maximum they would spend to avert or decrease the risk of a specific hypothetical outcome [4]. Drawbacks with this approach include results being sensitive to how the outcome is presented; differences in valuation between those with different socioeconomic status or levels of education; difficulties setting values for very rare events such as severe adverse events following vaccination; and disparities between what people say and what they do. An alternative method taken, in part, from product development and marketing is *conjoint analysis*. Using this method, preferences are expressed for programs or products that have a range of defined attributes jointly as a “product profile” [5]. Although this approach has not been used for analyses of vaccines or vaccination programs, it may be a useful strategy to better value a product or program.

## B. Cost-Effectiveness Analyses

*Cost-effectiveness analysis* (CEA) assesses the value of a program by calculating the expenditure per health outcome achieved (net cost/net health effect). Some common examples include cost per case prevented and cost per death averted. Average cost effectiveness (ACE) is used to describe costs and outcomes for an independent program,  $ACE = C_A/E_A$ , where  $A$  is a program or strategy. Incremental cost effectiveness (ICE) describes the ratio between costs and outcomes for programs that are being compared,  $ICE = (C_A - C_B)/(E_A - E_B)$ , where  $A$  and  $B$  are competing programs or strategies. Finally, marginal cost effectiveness (MCE) describes the costs and outcomes within a single program to show cost of expanding,  $MCE = (C_{A^1} - C_A)/(E_{A^1} - E_A)$ , where  $A^1$  is an extension of  $A$ .

Because the denominator is a specific health event, CEA is used to choose between alternative interventions that are aimed at achieving a similar outcome. For example, CEA has been used to determine whether cholera vaccination in conjunction with rehydration therapy in refugee settings is cost-effective in preventing morbidity and mortality compared with rehydration therapy alone [6]. An advantage of CEA compared with CBA is that by comparing similar outcomes, it is unnecessary to convert health outcomes into monetary values.

A limitation of this approach, however, is that CEA can be used only if the interventions being compared share a

**Table 1** Comparison of Characteristics of Cost–Benefit, Cost-Effectiveness, and Cost–Utility Analyses

	Cost–benefit analyses	Cost-effectiveness analyses	Cost–utility analyses
Outcome measure	Net present value	Cost per health outcome averted (or gained) Net costs Net benefits	Cost per health utility (e.g., QALY) gained Net costs Health utilities gained
Calculation of outcome measure	Benefits–costs	Health program A vs. health program B (with same health outcome)	Health program A vs. health program B (with different health outcome)
Useful for comparing	Health programs vs. nonhealth programs		

common outcome measure. For many new vaccines in the United States, where the impact on morbidity far outweighs that on mortality, CEA is of little use in comparing value (e.g., for prevention of varicella, rotavirus gastroenteritis, and pneumococcal otitis media). In addition, the results of CEA are more difficult to apply in policymaking. For example, infant pneumococcal conjugate vaccination at a cost of \$58 per dose would cost society \$160 per episode of otitis media prevented, and \$3200 per episode of pneumonia prevented [7]. Is the cost reasonable to achieve the specified health outcomes? Although one could compare directly the costs of preventing otitis media or pneumonia with those of treatment, such an approach would ignore the benefit of prevention compared with cure.

### C. Cost–Utility Analyses

*Cost–utility analysis* (CUA) is a subset of cost-effectiveness analysis where a common outcome measure is developed to take into account different types of health impacts. The calculation of cost and impact in CUA is identical to that for CEA except that the denominator is expressed as health utilities gained. The CUA is most useful in three settings: (1) when comparing health programs that have different disease impacts; (2) when summarizing the overall impact of a program that affects both morbidity and mortality outcomes; and (3) when comparing a program that primarily affects mortality with one that primarily affects morbidity. Because results of CUA are expressed as cost per health benefit, this method could not be used to compare a health program with a nonhealth program.

One strength of CUA is that as with CEA, outcomes are expressed as cost per change in health status; thus, health outcomes do not need to be converted into monetary equivalents. However, a common metric does need to be established that allows comparison of qualitatively different health outcomes. *Years of potential life lost* (YPLL), *quality-adjusted life years* (QALYs), and *disability-adjusted life years* (DALYs) are examples of widely used utilities [4,8–11].

One common utility used in CUA, the QALY, provides a method to compare health outcomes, where both the quality and the duration of life are affected by a disease. QALYs represent the sum of each year of life multiplied by the quality of each of those years. Quality is expressed on a scale ranging from 1 (perfect health) to 0 (death). Several approaches have been used to establish quality values for morbid conditions. Using the *standard gamble* approach, respondents are asked to state a preference between living with a disability and an alternative that includes a risk of death ( $p$ ) or of perfect health ( $1-p$ ). The probability at which the respondent considers the two options equivalent represents the health utility. With the *time trade-off* method, respondents are asked how much perfect life they would trade to avoid life with a defined health condition [4]. Several utility scales are available, and recommended methods to derive health utilities have been published by the Panel on Cost Effectiveness in Health and Medicine, established by the Public Health Service [12].

Although CUA has been used more frequently in recent years to evaluate and compare health programs, there are

several limitations of this method. Most importantly, the results of a CUA depend on the utilities assigned to acute and chronic morbid states. Preferences expressed using standard gamble or time trade-off methods are affected by the description of the health condition and the characteristics of the respondents. Generally, those who suffer a chronic condition score their health-related quality of life differently than the general population [4]. Developing health utilities may also be more difficult for acute conditions or when the respondent is not the one who would suffer the illness. For example, to derive health utilities for influenza vaccination of children one approach would be to interview parents to determine how much of their healthy life they would choose to trade in order to decrease the probability that their child develops influenza during a given year. By contrast, assessing health utilities would be easier when considering the potential value of therapeutic vaccines for chronic illnesses. For policymakers, understanding the meaning of a health utility is more difficult than evaluating a positive or negative value in a CBA or a cost per health outcome in a CEA. Therefore, presenting a comparison between programs or developing a scale to define what is a “good buy” for a QALY or other health utility may be important for those interpreting CUA results.

### D. Examples of Economic Analysis Used to Evaluate Vaccines and Vaccination Programs

Each type of economic analysis has been used in assessing vaccines and vaccination programs. CUA has been used to compare and determine priorities among clinical preventive services. Eight studies of vaccination, including 33 cost-utility ratios published between 1976 and 1997, were evaluated along with 42 studies assessing other preventive services (e.g., chemoprophylaxis, screening tests, and counseling). Overall, vaccines were the most “cost-effective” interventions with a median cost per QALY of \$1500 and a range from being cost saving to a cost of \$140,000 per QALY [13]. Moreover, among 30 preventive services recommended by the U.S. Preventive Services Task Force, childhood vaccination was valued as the highest, based on the clinically preventable burden and the cost per QALY saved [14]. CUA was also used by the IOM to compare vaccine development priorities with priority categories defined by the cost per QALY saved [1]. By contrast, CEA and CBA have been employed more often to assess the impact of a new vaccine or a change in the vaccination schedule [7,15–17]. Programmatic issues, such as the use of reminder-recall or other interventions to increase vaccination coverage, have been assessed by CEA with the outcome measured as cost per person vaccinated [18]. Willingness-to-pay methods have been used to define preferences for safer or combination vaccines [19,20].

## III. COMPONENTS OF ECONOMIC ANALYSES

Whatever economic analysis method is used, the quality of the analysis depends on including all important costs and benefits—as appropriate to the method selected and the

perspective being taken (see Section 3.5. Distribution of Costs and Benefits)—and on being able to obtain accurate estimates for each of the components of the model. While it is often difficult to predict the health effects of a program, an economic analysis must also identify direct and indirect costs associated with program inputs and impacts. In instances where the accuracy of cost or impact data is unclear, sensitivity analyses that vary the uncertain components are a useful method to determine which parameters in the model are driving the results of the analysis.

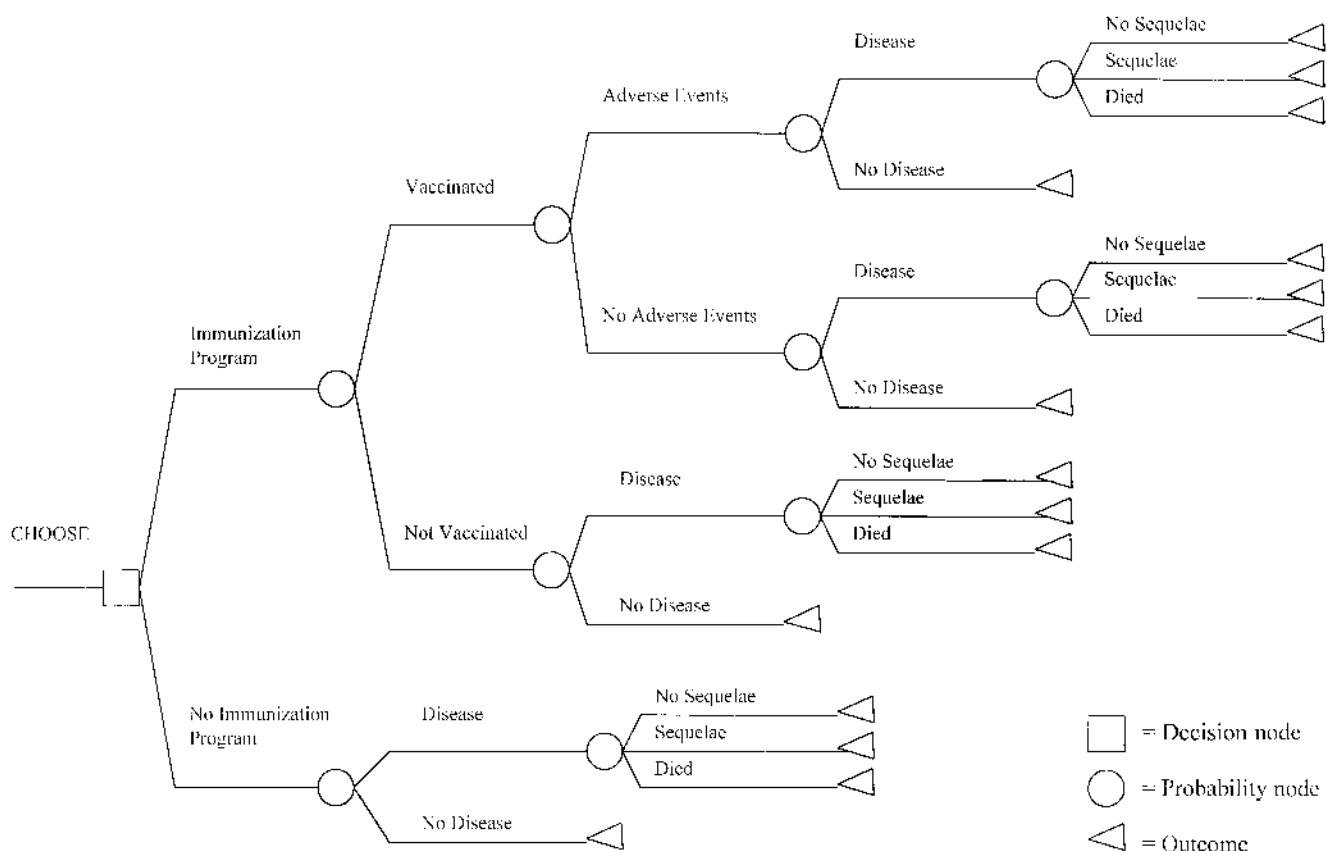

### A. Developing the Model

The evaluation of a vaccine or vaccination program using CBA, CEA, or CUA begins with creating a conceptual model indicating expected costs and health impacts. A decision tree (Fig. 1) is a useful way to present the different program impacts and their estimated probability of occurrence. Many of the computer software programs for conducting economic analyses begin with the creation of a decision tree; however, this graphical representation is not required to conduct an economic analysis and many investigators prefer to use spreadsheet software. The key to an economic analysis, regardless of the software used, is to develop a comprehensive model that includes as many of the expected impacts and costs as possible.

In a decision tree, the range of possible outcomes and the probability that the outcome will occur are represented graphically. Typically, a decision tree begins with a “decision node” (presented as a box), where the alternative interventions are distinguished from one another (e.g., implement or not implement an immunization program). The next levels of the decision tree describe the consequence of the previous decision and its probability. Examples include vaccinated/not vaccinated, adverse event/no adverse event, and disease/no disease. The probability of each of these events is represented by a “probability node” (presented as a circle). Probability nodes may have several different possible outcomes. However, the alternative outcomes of a probability node must be mutually exclusive and exhaustive; consequently, the sum of the probabilities of a probability node will always equal 1. The final level of the decision tree, called the “outcome node” (presented as a triangle), represents the ultimate health outcome of the sequence of events along a branch of the decision tree. Different adverse events and types of disease should be specified separately along with the consequences of each (e.g., no sequelae, sequelae, or death).

### B. Estimating Impacts

Determining the impacts of a new vaccine and the probabilities of their occurrence is not easy. Although disease out-

**Figure 1** Example of a decision tree.

comes prevented can be defined simply as the product of the disease burden times the vaccine efficacy, accurately defining these parameters may be complex. An infection may result in several disease outcomes; some of these (e.g., pneumonia or otitis media) may seldom be etiologically diagnosed and disease burden may vary by age, population group, and by year. Health outcomes of an illness are also likely to differ by age and may change over time with the development of new therapies; the long-term impact of sequelae may be poorly defined. Results of randomized vaccine efficacy trials pre-licensure, where enrollees generally are healthy and vaccine is administered in controlled settings, may differ from those obtained when a vaccine is used broadly in the population. In addition, some impacts of vaccines cannot be determined until the vaccine is in widespread use. Herd immunity can substantially increase the benefits of vaccination, but cannot be measured from clinical trials in which the unit of randomization is the individual subject. Uncommon adverse events will also not be detected until after a vaccine is recommended and widely used.

### C. Estimating Costs

Direct and indirect costs typically are considered in economic analyses of vaccination programs (Table 2). Direct costs include the costs related to health events that would occur with and without the program and the costs of the vaccination program itself. The direct costs of health events include costs of medical care visits, diagnosis and of acute and long-term treatment. The costs of transportation to the doctor's office or hospital and of housekeeping or childcare services during a period of illness are also direct costs. The direct costs of the vaccination program include the cost of vaccine, the administration, and the medical care visit including travel costs. Other program costs that may be less obvious include the costs of storing and transporting vaccine, of maintaining the cold chain, and of training health care workers to administer the new vaccine. The impact of these costs will be minimal and often is not included in analyses of vaccines delivered in industrialized countries; however, it may be important for vaccines administered through the public sector in developing countries where the incremental costs would be more substantial. Treatment of adverse events following immunization must be added to costs although for most vaccines, the magnitude of these costs will be small relative to other components of the model. Other costs may be considered in certain settings, depending on the purpose of the analysis. Vaccine development costs may be relevant if the analysis focuses on priorities for developing new vaccines. For a new vaccine to be used in developing countries, it may be reasonable to consider foreign exchange costs, discounting costs borne in local currency.

The largest category of indirect costs is typically described as losses in productivity due to time away from work, disability, or premature death as a consequence of the illness. Some analyses also include the costs of pain and suffering from illness, of adverse events, or an additional injection as indirect costs, with data derived using methods such as willingness to pay. For many recently recommended

**Table 2** Examples of Direct and Indirect Costs Often Considered in Economic Analyses of an Immunization Program

<i>Direct costs</i>
Medical care costs associated with disease
Inpatient services
Outpatient services
Long-term care (e.g., home health services, rehabilitation, equipment)
Diagnostic tests and procedures
Medications
Other therapy
Vaccination program costs
Vaccine
Vaccine administration
Medical care visit(s) for vaccination
Medical care visit(s) for adverse events (inpatient/outpatient)
Medication for therapy of adverse events
Transportation to and from medical services
Child care
Housekeeping
Vaccine research and development
<i>Indirect costs</i>
Change in productivity from illness or vaccine adverse event
Time lost from death and illness
Time lost for medical care visits
Decreased productivity while at work due to illness or sequelae
Time lost while caring for an ill family member
Foregone leisure time while ill or caring for an ill family member
Intangible costs (e.g., pain and suffering)

*Source:* Ref. 4.

Specific costs included will depend on the type of economic analysis and the perspective taken.

vaccines in the United States, inclusion of indirect costs has a substantial impact on the results of the analysis; this impact often is highlighted when the value of a new vaccine is described from the health care payer's perspective, where only direct costs are considered, as compared with the societal perspective, where both direct and indirect costs are included. For example, the break-even cost of vaccine in the United States for an infant rotavirus vaccination program was estimated at \$9 from the health care payer's perspective compared with \$51 from the societal perspective [16]. For vaccination of infants with pneumococcal conjugate vaccine, the costs were estimated at \$18 and \$46, respectively [7]. Routine varicella vaccination of U.S. children has been estimated to save \$5 for every dollar invested from a societal perspective, but, from the payer's perspective, would cost about \$2 for each case of chickenpox prevented [15]. Although indirect costs are routinely included in economic analyses and are recommended to be used by the Panel on Cost Effectiveness in Health and Medicine [12], there is no solid evidence supporting the assumption that in the absence of illness, national productivity would increase by

the magnitude estimated. If workers use vacation or sick leave days when ill or when caring for a sick child, if they trade work shifts with a coworker when they make a medical care visit, or if industries would cut their workforce rather than increase output if worker absences were eliminated, then it would be incorrect to assume that societal productivity would increase if illness were prevented. Some economists respond to this by equating the value of “productivity” and leisure time, suggesting that lost leisure when ill or caring for a sick child has the same societal value.

Once decisions have been made regarding what costs to include in an economic analysis, the next step is to assign monetary values. For medical care and treatment, the use of costs, rather than price or charge, is recommended because the cost more closely reflects the true value placed on that service. Several databases, including Medicare payments or the payments made by large managed care organizations, are available to estimate costs of medical care. Charge data can be converted to costs by using published cost-to-charge ratios [4].

Indirect costs generally have been calculated from the number of days lost due to illness multiplied by the value of a work day. Approaches to valuing work differ: Some studies perform separate calculations for men and women; some consider the proportion who are employed full time, part time, or are unemployed; some distinguish between work days and weekends; and some assign a monetary value to “housekeeping” for persons not in the workforce. I am aware of no studies that assign lower indirect costs when the population affected by a disease is disproportionately in a lower socioeconomic group.

Because indirect costs of recently licensed vaccines have outweighed direct costs and because methods for defining indirect costs vary, public health personnel and policy-makers must scrutinize the methods in economic evaluations and understand the choices made and estimates used. In four recent analyses of influenza vaccine [21–24], the number of work-loss days estimated for an ill adult ranged from 0.52 to 2 and the value of a work day ranged from \$93.40 to \$120 per day. In addition, one study [21] estimated the cost of influenza vaccine and its administration at \$4 based on data published five years previously.

Estimates of the value of human life also vary between studies and may account for some of the variability in results. The human capital approach values life in a manner similar to capital equipment, whose productive output is lost or diminished due to premature death or disability. The value of the death is equivalent to the net present value of his/her expected future earnings. This approach is consistent with methods for calculating indirect (productivity) costs and often is used in CEA and CUA. Critiques of this approach are that it undervalues persons who are older or not in the workforce and that the value of life will differ between countries so that international comparisons of health states would tend to favor conditions that affect the populations of industrialized countries. Values obtained using the willingness-to-pay approach tend to be higher than using the human capital approach and may vary considerably between studies [25]. For diseases where mortality is a common

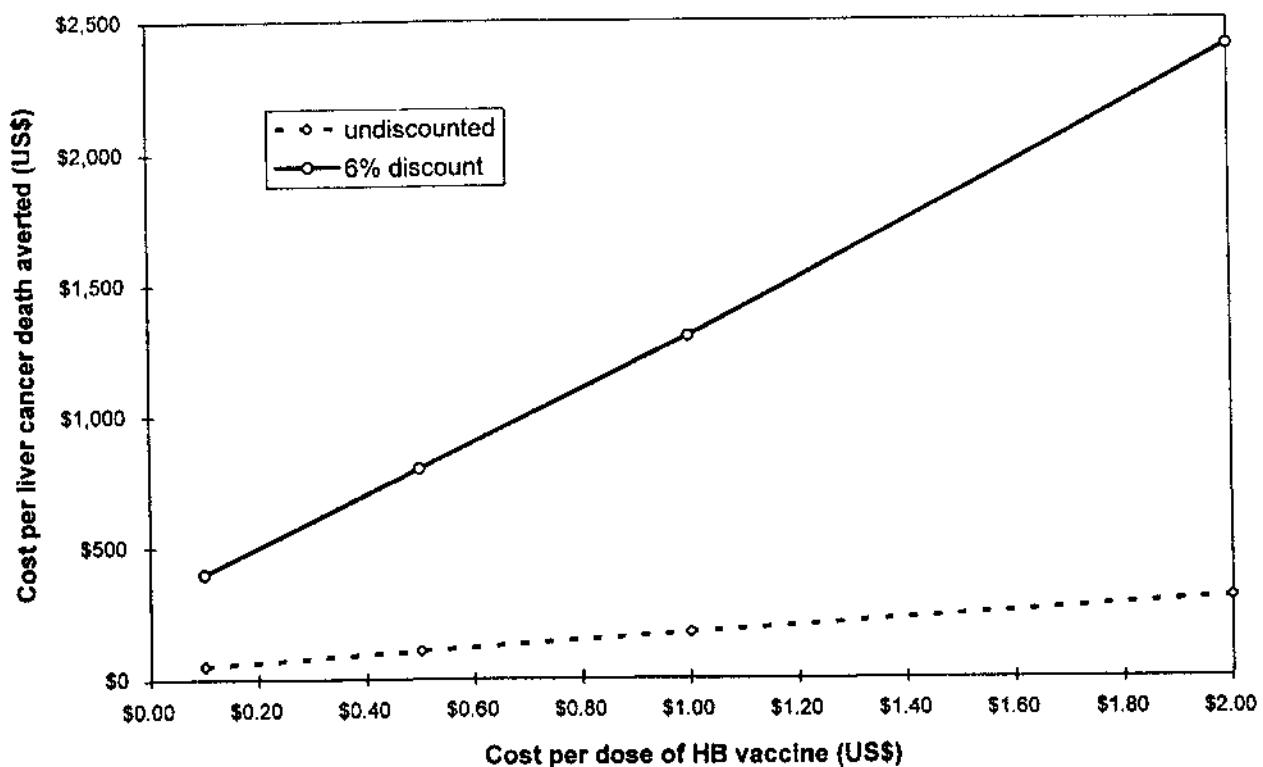

outcome, these differences may be important to the overall results of the analysis.

#### D. Discounting Costs and Health Effects

Quite often, the costs and benefits of a vaccination program accrue at some point in the future, long after the vaccination itself. Because society values accruing benefits early and delaying costs until later, a method called *discounting* is used to adjust all costs and benefits to their present value. It is important to note that discounting is not strictly an attempt to adjust for inflation because even with no inflation, individuals will prefer benefits that occur now compared with sometime in the future. Although no single discount rate is used universally, the Panel on Cost Effectiveness in Health and Medicine recommends using a rate of 3% [12]. Other rates may be chosen to facilitate comparison with other studies and in sensitivity analyses. The importance of discounting will vary for a vaccine, where the impact is acute and long-term consequences of infection are rare (e.g., influenza), and one where the health impacts occur long after the vaccine was administered (e.g., hepatitis B). A cost-effectiveness analysis for the use of hepatitis B vaccine in the Gambia provides an example of the impact of the discount rate used on results of the analysis (Fig. 2) [26]. In this CEA, the authors assume that the vaccine will be used as a routine infant immunization and that the efficacy is 85%. Because the costs for the vaccination program accrue now but the benefits associated with the prevention of hepatocellular carcinoma occur a median of 35 years in the future, discounting those future costs and benefits has a substantial impact on the results, demonstrated by the eightfold difference in cost per liver cancer death averted, depending on whether discounting is included. Note that use of a 3% discount rate would decrease the magnitude of this difference.

#### E. Distribution of Costs and Benefits

Economic analyses may assess costs and benefits using a family, a health care payer, or a societal perspective. Although vaccination recommendations in the United States have relied primarily on societal-level analyses, the decisions that are made may not be considered optimal at other analysis levels. For example, U.S. recommendations for routine childhood use of varicella, rotavirus, and pneumococcal conjugate vaccines are cost-neutral or cost-saving to society at current vaccine prices, but represent a net cost to health care payers, who do not benefit from the productivity cost savings accruing to society. Even when only direct costs are considered, the benefits of vaccination may not accrue to the party bearing the costs. For example, because of the high annual turnover in the client population of a managed care organization, the costs of a prevention program for hepatitis B or invasive pneumococcal disease among older adults may be borne by one organization, while another reaps the benefits of disease prevented years into the future. In many developing countries, the Ministry of Health bears the majority of the burden for the direct costs of a vaccination

**Figure 2** Impact of discounting on cost effectiveness of hepatitis B vaccination in The Gambia. (From Ref. 26.)

program, while the benefits of indirect costs averted are distributed throughout the population.

#### IV. SENSITIVITY ANALYSES

Parameter estimates in economic analyses are inherently uncertain, in part, because data on disease and its prevention are limited by the populations studied and because future events (e.g., the rate of inflation) cannot be known. Because of the uncertainty surrounding many of the estimates in economic models, sensitivity analyses are important to assess whether the results are robust—that is, the conclusions are valid across the range of reasonable estimates—or whether little confidence can be placed in the overall result and more data need to be collected to better quantify key parameters. In conducting a sensitivity analysis, one approach is for the investigator to define a plausible range across which the true value of each parameter may vary. The impact of changing each parameter between plausible extremes can be determined one by one in univariate sensitivity analyses. This type of analysis is useful in identifying the parameter(s) to which the overall result is most sensitive [7]. However, a univariate sensitivity analysis cannot determine the true range in possible outcomes or a confidence interval around the baseline result. Bivariate analyses or best-case and worst-case analyses that select extreme values for each parameter are also of limited value. Several statistical modeling techniques are available and are included in

standard cost-effectiveness software [12]. Multiple simulations, using Markov or Monte Carlo analyses, randomly varying the parameters across the reasonable range according to an assumed distribution, can approximate a confidence interval for a cost-effectiveness ratio [24].

#### V. INTERPRETING AND COMPARING ECONOMIC ANALYSES

As the results of economic analyses are more often being used to support recommendations for use of new vaccines, the importance of their results to vaccine manufacturers and health officials increases. Manufacturer support or disease prevention goals of academic and public health scientists may exert subtle influences on analytic methods and results. While neither manufacturer support nor disease prevention goals invalidate the results of a well-done study, it is important to assess economic analyses with careful attention to the methods used and a cautious (perhaps even skeptical) perspective when assessing the results. Key elements that should be included in a published economic analysis are shown in Table 3 [12]. Special care should be taken in evaluating the parameters to which the model is most sensitive. For example, when considering disease burden, what data are available (including, perhaps, data not presented in the manuscript) and are they generalizable? If data from multiple studies were available, how were they summarized and a base-case estimate selected? For a disease

**Table 3** Key Items to Include in a Published Report of an Economic Analysis

(1)	Approach
	General design of the analysis
	Target population for intervention
	Program description (e.g., case setting, model of delivery, timing of intervention)
	Description of comparison program
	Time horizon
	Perspective of the analysis
(2)	Data and methods
	Identification of outcomes of interest
	Definition of outcome measures
	Description of model
	Modeling assumptions
	Diagram of event pathway or model
	Software used
	Sources for and data on model parameters (e.g., disease burden, program effectiveness, cost data)
	Strategy for summarizing data to develop base-case estimates when multiple data points are available
	Statement of methods for obtaining expert opinion, where it is used to estimate parameters
	Method to define preferences and preference weights
	Critique of data quality
	Statement of year of costs
	Statement of method used to adjust costs for inflation
	Statement of type of currency
	Statement of discount rate
(3)	Results
	Results of model validation
	Aggregate cost and impact of the program
	Results of base-case analysis
	Results of sensitivity analysis
	Statistical estimates describing uncertainty, if possible
	Graphical representation of results and sensitivity analysis
(4)	Discussion
	Summary of results
	Summary of sensitivity of results to assumptions and uncertainties in the analysis
	Robustness of the analysis
	Limitations of the study
	Relevance of the results to specific policy questions or decisions
	Results of related economic analyses

Source: Ref. 12.

Specific items included may differ based on the type of economic analysis undertaken.

that results in significant morbidity but in little mortality, what data are used to determine rates of work loss among adult caretakers of sick children and what economic values are assigned to their productivity? Based on the results of the sensitivity analysis, can the results of the study be considered robust across the range of plausible inputs or should the analysis be deemed noncontributory to decision making? Finally, as additional studies are done or as a vaccine is used postlicensure, are new data that result in changes in the assumptions or parameters available? In conducting economic analyses, adhering to standards rec-

ommended by the Panel on Cost Effectiveness in Health and Medicine may help eliminate potential biases and improve uniformity and, therefore, comparability between studies.

## VI. SUMMARY

Economic analyses are an important element in setting priorities for health interventions, vaccine development, and vaccine recommendation. Results can provide the economic rationale for the use of scarce health resources on vaccines and vaccination programs and can provide guidance on the most effective ways to implement new and current vaccines. The type of economic analysis performed and the components included in the analysis will differ based on the questions addressed. Attention to the issues outlined in this chapter can help to provide the basis for well-designed economic analyses that will be useful to decision makers faced with many alternative health interventions, but limited economic resources.

### I. INTRODUCTION

This chapter will provide a detailed overview of the roles and responsibilities of the Food and Drug Administration (FDA) in testing and licensing of vaccines. Moreover, this chapter will describe the FDA's role in the clinical evaluation of preventive vaccines, with a focus on the Investigational New Drug (IND) application process, the Biologics License Application (BLA) review and approval process, and postlicensure requirements. Finally, some of the regulatory and scientific challenges of newer vaccines using advanced genomic techniques will be addressed.

The Center for Biologics Evaluation and Research (CBER), Office of Vaccines Research and Review (OVRR) of the FDA is responsible for regulating vaccines produced by manufacturers licensed in the United States. Current authority for the regulation of vaccines resides in Section 351 of the Public Health Service Act (PHS Act) and specific sections of the Food, Drug, and Cosmetic Act (FD&C Act) [1]. A single set of basic regulatory approval criteria apply to vaccines, regardless of the technology used to produce the vaccine. In the United States, vaccines are regulated as biological products. The regulations used in implementing these Acts are contained in Title 21 of the Code of Federal Regulations (21CFR). The regulations in the CFR cover general requirements such as current good manufacturing practices, labeling, licensing procedures, and conduct of clinical trials. The CFR also covers methods to be used in, and the facilities or controls to be used for the manufacture, testing, processing, packaging, and holding of vaccines to assure that these products meet the requirements of the FD&C Act as to safety, strength, and purity.

The regulations detail the minimum requirements for the preparation of vaccines (Figure 1). It is worth noting

that certain regulations have been changed or eliminated as a result of the FDA's constant challenge to develop standards for assessing the safety and efficacy of vaccines using more state-of-the-art technologies. For example, 21 CFR 620, Additional Standards for Bacterial Products, and 21 CFR 630, Additional Standards for Viral Vaccines, were revoked in August 1996. Instead of incorporating new standards into the regulations, the BLA itself contains all the appropriate testing methods for in-process and release testing for each specific new vaccine. This approach allows for flexibility in responding to scientific advances and new technologies as they emerge in vaccine development. The FDA also publishes guidances and other regulatory documents on specific topics to assist manufacturers and clinical investigators in developing new products (Table 1).

Prior to discussing the procedures for the regulation of vaccines, it would be useful to review certain definitions codified in the regulations. As further defined in 21 CFR Part 600, safety is "the relative freedom from harmful effect to persons affected, directly or indirectly, by a product when prudently administered, taking into consideration the characteristics of the product in relation to the condition of the recipient at the time." Purity is the "relative freedom from extraneous matter in the finished product, whether or not harmful to the recipient or deleterious to the product." Potency is "the specific ability or capacity of the product, as indicated by appropriate laboratory tests or by adequately controlled clinical data obtained through the administration of the product in the manner intended, to effect a given result." Simply put, to be licensed, a vaccine must be a preparation of known characterization and purity that has been demonstrated to be safe and effective. The exact standards required to meet these criteria for a particular vaccine are

- 21 CFR 25 Environmental impact considerations
- 21 CFR 50 Protection of human subjects
- 21 CFR 56 Institutional Review Boards
- 21 CFR 58 Good laboratory practice for nonclinical laboratory studies
- 21 CFR 201 Labeling
- 21 CFR 202 Prescription drug advertising (promotional labeling)
- 21 CFR 210 Current good manufacturing practice in manufacturing, processing, packing, or holding of drugs; general
- 21 CFR 211 Current good manufacturing practice for finished pharmaceuticals
- 21 CFR 312 Investigational new drug application (IND)
- 21 CFR 314.126 Adequate and well-controlled trials
- 21 CFR 600 Biological products: general
- 21 CFR 601 Licensing
- 21 CFR 610 General biological products standards

**Figure 1** Food and Drug Administration regulations relevant to the manufacture, product quality, and clinical testing of vaccines. Regulations covering the Food and Drug Administration are located in Title 21 of the Code of Federation Regulations (CFR). The CFR can be accessed on-line and directly searched from <http://www.access.gpo.gov/nara/cfr/>. These may also be directly obtained from the Government Printing Office, Washington, D.C., 20402-9328.

dependent on the specific vaccine and the technology used to produce it.

Regulatory issues should be considered as early in the development process as possible, because ultimately, regulatory compliance is an essential basis for licensure, regardless of the quality of the safety and efficacy data. The first

regulatory requirements that must be considered are purity and preclinical safety, the two prerequisites to move a vaccine from the laboratory to the clinic. Both must be demonstrated prior to beginning clinical trials. In addition to requirements for product quality, the quality of data generated in clinical studies is of the utmost importance because

Points to consider in the characterization of cell lines to produce biologics (1993)
ICH guidance on quality of biotechnological/biological products: derivation and characterization of cell substrates used for production of biotechnological/biological products, Q5D (1998)
Points to consider in the manufacture and testing of monoclonal antibody products for human use (1997)
ICH guidance on viral safety evaluation of biotechnology products derived from cell lines of human or animal origin, Q5A (1995)
Points to consider on plasmid DNA vaccines for preventive infectious disease indications (1996)
Guidance for industry for the evaluation of combination vaccines for preventable diseases: production, testing, and clinical studies (1997)
Content and format of chemistry, manufacturing, and controls (CMC) information and establishment description information for a vaccine or related product (1999)
Guidance to industry on considerations for reprotoxicity studies for preventive vaccines for infectious disease indications (2000)
Guidance for industry—formal meetings with sponsors and applicants for PDUFA products (2000)
IND meetings for human drugs and biologics—chemistry, manufacturing, and controls information (2001)

safety and efficacy data from studies that do not or cannot meet regulatory requirements for adequate, well-controlled studies cannot lead to approval.

## II. GENERAL CONSIDERATIONS FOR VACCINE TESTING

### A. Vaccine Testing

The requirements for testing of licensed products are described in 21 CFR. Some of these requirements are generally applicable to all products, whereas others are tailored to the specific vaccine. Examples of tests that are generally applicable to all products include those for bacterial and fungal sterility, general safety, purity, identity, suitability of constituent materials, and potency [2]. Additional product-specific tests designed to provide additional assurance of safety or purity may be required; for example, testing of viral seeds and cell cultures for extraneous viruses is especially relevant for live viral vaccines. Although not all necessary tests for assessing safety, purity, and manufacturing consistency are prescribed in the regulations or guidance documents developed by the FDA, all production steps, as well as control and lot release testing must be described in the IND and in greater detail in the manufacturer's biologics license application. Once the product is licensed, testing is conducted according to the exact specifications in the manufacturer's license application.

When considering the issue of release testing, a general rule is that testing should be performed at the latest manufacturing step compatible with adequate assay performance. Specifically, the CFR provides a list of tests that should be completed on product that is in final container (e.g., identity, sterility, and general safety). In contrast, other release testing may be performed upstream prior to final fill of the product. Potency testing is an example where the test may be performed on either the product in final container or formulated bulk products; however, characteristics associated with potency (protein to polysaccharide ratio for conjugate vaccines) may be measured at earlier steps in the manufacturing process [3]. Consideration of such approaches should be discussed early on with the FDA and be based on sound scientific rationale. Although final container testing requirements are specified in the CFR, the importance of adequate in-process tests should not be minimized. The inclusion of critical in-process tests and specification may provide valuable information regarding consistency of manufacture and provide a mechanism for detection of early manufacturing or product deviations.

With regard to the required testing for licensed biologic products, the FDA is reevaluating the appropriateness of selected requirements and/or the test method cited in the CFR. For example, the general safety test is required by the FDA for all products, including vaccines. The general safety test, performed using guinea pigs and mice, is for the detection of extraneous toxic contaminants that may have been introduced during the manufacture or filling process. However, in the case of certain vaccine types, the relevance of the general safety test has been questioned. For example, the

relevance of evaluating an orally delivered vaccine by intra-peritoneal injection of animals is questionable. In addition, the question of the utility of such a test for a product with inherent toxicity that interferes with the interpretation of the test, e.g., live bacterial vaccines, has been raised. Currently, the FDA is discussing whether to eliminate the requirement for the general safety test. Another example of where the FDA is revisiting the CFR requirements is in regard to the testing for pyrogenic substances by intravenous injection into rabbits. Because of the variability of in vivo tests such as the rabbit pyrogenicity test, consideration is given to alternative methods such as the limulus amoebocyte lysate (LAL) assay for endotoxins. Following discussions with the FDA, the LAL assay may be substituted for the rabbit pyrogenicity test and may provide a more quantitative assessment of endotoxin content in a product. The ability to assess endotoxin levels in vaccine lots may also provide a measure of manufacturing and process control from lot to lot.

Although guidelines exist for the general principles in developing and testing biologics, additional standards of purity, potency, and preclinical safety are most often developed for each specific product. The importance of additional in-process and manufacturing consistency controls should not be minimized. For example, additional controls are applied to characterizing purified antigen products and biotechnology products compared to those tests applied to relatively crude, killed, whole-cell bacterial vaccines. In the latter case, the manufacturing process applied to killed whole-cell bacterial vaccines should strive to eliminate cell-associated impurities. Control assays must demonstrate the absence of such impurities, to the highest degree of sensitivity that is possible. For these vaccines, demonstration of the absence of toxicity becomes a critical purity parameter and validation studies to demonstrate the safety of the final preparations become the cornerstone in safety and manufacturing control testing.

As touched upon earlier, well-defined manufacturing methods and controls are critical components in assessing the safety and purity of biologics. These parameters are also important in demonstrating consistency of manufacture from lot to lot. One important step in manufacturing consistency is the demonstration of process validation, which includes the appropriate selection of potency, purity, and identity tests to assure control over the manufacturing process. These tests should be identified early in the product development to ensure that the product is of defined quality and consistency and allows for "bridging" of products and the respective clinical responses induced during all phases of clinical evaluation. Further, all steps taken toward the adoption of a testing procedure, including the rationale, scope, and specifications, should be documented in the BLA.

In general, the manufacturer or sponsor develops manufacturing and control tests; however, there may be involvement of the regulatory agency as well. The CBER is particularly likely to become involved if the product is new or represents a novel problem in testing. As the product moves toward licensure, the sponsor develops the testing program in greater detail. The final testing methods must be established prior to conducting any major clinical trials that are designed to demonstrate efficacy and safety, as well as

before production of manufacturing consistency lots. During the prelicensing phase, assay performance is evaluated to determine whether a test under development will be appropriate for lot release of every batch of product.

## B. Good Manufacturing Practices

When a potential candidate vaccine is ready to move toward the licensing pathway, two parallel activities take place. The process for manufacturing the vaccine at a research scale must be developed into a process that is appropriate for the manufacture of large-scale clinical material. For example, purification procedures used in the manufacture must be amenable to scale-up and to regulatory approval. Modification of facilities may also be required to accommodate scale-up changes. In addition, facility and process validation must meet the needs of the clinical program and ultimately, the requirements for licensure. Manufacturing, quality (assurance and control), and regulatory input should be incorporated early in the development process to facilitate a more seamless transition from pilot to full-scale production.

To facilitate the transition beyond research scale, one should consult the requirements for current Good Manufacturing Practices (GMP), 21 CFR 211. Good Manufacturing Practices are regulations, guidelines, or advice published by a recognized body (governmental or nongovernmental) outlining minimum manufacturing, quality control, and quality assurance requirements for the preparation of a drug or biological for commercial distribution. Further, they address the manufacturing methods, facilities, controls, packaging, storage, and installations for pharmaceutical operations. Good Manufacturing Practice is that part of Quality Assurance which ensures that products are consistently produced and controlled to the quality standards appropriate to their intended use and as required by marketing authorization. Good Manufacturing Practice encompasses both production and quality control.

Quality Assurance (QA) encompasses all activities necessary to assure and verify confidence in the quality of a process used to manufacture a finished drug or biologic. Quality Assurance is a wide-ranging concept, which covers all matters that individually or collectively influence the quality of a product. It is the sum total of the organized “arrangements” made with the object of ensuring that medicinal products are of the quality required for their intended use. Therefore quality assurance incorporates Good Manufacturing Practice.

Quality Control (QC) involves test and inspection activities employed to determine the level of conformance of an item to its specification. Quality Control is that part of Good Manufacturing Practice which is concerned with sampling, specifications, and testing, and with the organization, documentation and release procedures which ensure that the necessary and relevant tests are actually carried out and that materials are not released for use, nor product released for sale or supply, until their quality has been judged to be satisfactory.

The basic concepts of QA, QC, and GMP are interrelated. Production operations must follow clearly defined procedures. They must comply with the principles of GMP

to obtain products of requisite quality. Quality Control is not confined to laboratory operations, but must be involved in all decisions that may concern the quality of the product. The independence of QC from production is considered fundamental to the satisfactory operation of QC.

## III. CLINICAL TESTING (INVESTIGATIONAL NEW DRUG PROCESS)

### A. Overview of Clinical Evaluation

The clinical development of vaccines is carried out in four phases, as is the case for any drug or biologic (note that the FDA uses Arabic numerals in referring to the different phases). Initial Phase 1 studies are intended to evaluate safety; Phase 2 studies usually include dose-ranging studies that may provide an early indication of efficacy. Phase 1 and 2 studies provide clinical research information that directs the development of the final formulation and dosing schedule to be used in Phase 3. Phase 3 studies provide the pivotal efficacy and safety data that are required for licensure, and are generally large trials conducted in populations that represent the target population for the marketed product. The FDA strongly recommends that clinical trials designed to evaluate the safety, immunogenicity, and efficacy of vaccines be randomized and well controlled, especially in Phase 2 and 3 of clinical development. Choices of control groups and study design, as well as information on “adequate and well-controlled studies” can be found in 21 CFR 314.126. Phase 4 studies are generally large-scale postmarketing studies conducted to obtain additional data on adverse events focusing primarily on events that may occur at a very low frequency.

The clinical development of a product usually starts with a sponsor approaching the FDA for permission to conduct a clinical study with an investigational product through submission of an IND application. The FDA has a maximum of 30 days to review the IND application and determine whether study participants will be exposed to any unacceptable risks. To assist in the assessment of risk to subjects in the clinical study, the IND application must include information on the composition, source, and method of manufacture of the product; the methods used in testing the product’s safety, purity, and potency; preclinical studies demonstrating safety and activity; and previous human experience. The focus in this section will be on Phase 1, 2, and 3 clinical trials for vaccines. If the clinical data support the safety and effectiveness of the new vaccine, these results may be submitted in a BLA to support approval for marketing the vaccine in the United States.

### B. Phases of Clinical Development

#### 1. Phase 1

Phase 1 vaccine trials are primarily intended to provide a preliminary evaluation of safety and immunogenicity. Initial Phase 1 trials for new vaccines are typically conducted in a small number, e.g., 20, of closely monitored healthy adult volunteers who are at low risk for infection. Additional Phase

1 studies are conducted, as necessary, to provide safety data for evaluating the vaccine in additional populations. Depending on the vaccine and the initial clinical data obtained, pediatric trials may begin after an initial Phase 1 trial in adults. Early clinical development in infants will often have a stepwise progression from older to younger age groups.

The Phase 1 study may include the evaluation of more than one vaccine dose, usually in a stepwise fashion of increasing dose by group. Dose-ranging groups may be studied concurrently or sequentially, depending on factors such as the reactogenicity detected in preclinical models or clinical studies of similar products.

## 2. Phase 2

Differentiation between a Phase 1 and Phase 2 vaccine trial is not always clear. The objectives of Phase 1 and 2 studies tend to merge together, with the distinction often being the size of the study. Phase 2 trials enroll more subjects, e.g., up to hundreds, and are often randomized and controlled. Evaluation of dose and schedule in a target population may begin in Phase 1 and continue into Phase 2. In general, the objective of Phase 2 vaccine trials is to determine the optimum dose and schedule required to maximize the immune response generated. Moreover, Phase 2 clinical development includes trials designed to provide more definitive immunogenicity data (i.e., more precise estimates of effect) regarding vaccine formulation, dose, schedule, and route of administration. In some cases, Phase 2 data may also provide information regarding specific adverse events that should be more carefully evaluated in a larger Phase 3 trial(s).

When designing the Phase 2 study, there are several considerations that should be incorporated into the study plan to allow for gathering optimal information in preparation of a pivotal Phase 3 study. These considerations include: (1) the evaluation of immune responses in the context of simultaneous administration of the investigational vaccine and already licensed vaccines that would likely be administered concurrently (e.g., during infancy or to travelers); (2) the concurrent administration of vaccines with other products normally expected to be administered simultaneously, e.g., immune globulins and drugs; (3) the development of laboratory assays that may be used for the case definition for an efficacy trial (e.g., serological tests used to distinguish the immune response in study participants elicited by vaccination from that elicited by wild-type infection); (4) immunogenicity (and efficacy) differences between populations that may result from differences in factors such as genetics, nutritional status, background infections, and prior exposure of vaccinees to the infectious agent; (5) background epidemiological data for the disease or infection under study, including seroincidence data; and (6) the determination of geographic strain specificity where appropriate, so that the vaccine will include antigen(s) that will be relevant to the infectious organisms occurring in the intended efficacy trial population.

## 3. Phase 3

Phase 3 studies enroll large numbers of individuals, and in most cases, include the pivotal efficacy trials as well as expanded safety studies. The FDA highly recommends that

plans for Phase 3 studies be discussed with the Agency after Phase 2 data have been obtained and prior to initiation of the Phase 3 study to ensure that studies are adequately designed to meet intended goals, including support of product licensure.

The size and duration of a Phase 3 efficacy trial are determined by many factors, including the incidence of the infectious disease that the study vaccine is intended to prevent and the plans to assess the duration of protection afforded by the study vaccine. A small Phase 3 study may involve hundreds to several thousand participants; a large trial may involve tens of thousands of participants. By the start of Phase 3, there should be data from hundreds of vaccinees for whom detailed observations have been made and rates determined for common, nonserious events. Therefore for subsequent larger trials, a simplified design may be acceptable in which only a subset of subjects in each group is assessed in detail for the more common events while the focus on expanded safety data incorporates active monitoring of all participants to capture less frequent and serious adverse events. Extended follow-up of participants, e.g., following completion of an efficacy trial, may be required as part of a postmarketing commitment and, therefore, advanced planning for such follow-up should be considered.

Phase 3 efficacy studies should be carefully designed to allow a valid estimate of efficacy, and the 95% confidence limits on the efficacy estimate should be considered in calculating sample size [4,5]. In a trial where multiple immunizations may be necessary to attain optimal immune responses, maximum efficacy might not be attained until after the final immunization. Thus the sample size calculation should be adjusted to account for study participants who are lost to follow-up or incompletely immunized. Most efficacy trials employ a double-blind, randomized, and controlled study design. Factors that should be considered in the selection of a control include: (1) no vaccine is licensed for the indication being sought by the study vaccine and thus the use of a placebo is not precluded; (2) no vaccine is licensed for the indication being sought by the study vaccine but another vaccine appropriate for the study population could be used as the control (individuals randomized to the placebo group would receive the benefit of the vaccine utilized as the control); or (3) a vaccine licensed for the indication being sought by the study vaccine exists and should be used in comparison with the experimental vaccine. The FDA has published a guidance to industry that discusses the type of efficacy evidence needed to support licensure [6].

Study designs without a randomized control group, such as case-control studies, have been proposed; however, these designs pose many potential problems with regard to issues such as the comparability of study groups. Historical rather than concurrent randomized controls have also been considered. However, because of the many possible variations in subject baseline characteristics, changing standards of healthcare, and altering epidemiology of disease, historical controls have not usually been acceptable for establishing vaccine efficacy for licensure. Nonrandomized studies have significant limitations for interpreting safety data as well.

A vaccine efficacy trial should have a formally established independent Data Monitoring Committee (DMC) [7].

[The term Data and Safety Monitoring Board (DSMB) is also used to describe this type of committee.] Data Monitoring Committee members should have relevant multidisciplinary representation (e.g., clinicians and biostatisticians with relevant training and experience, bioethicists) and be independent of the sponsor and investigators. If the DMC will conduct a review of the interim data, the following information should be prospectively provided in the protocol: the conditions (e.g., specific schedule, number of events, etc.) that must be met before performing the interim analysis; the criteria for early termination of the study; and a list of the individuals who will have access to the interim data. A statistical plan for any interim analysis should be included with the original submission of the protocol. Any unmasked review of the data, including any review of the data by treatment group (regardless of whether the identity of the treatment is revealed) would be considered an interim analysis [8–13].

### C. Use of Serological Endpoints to Support Efficacy

Evidence of safety and efficacy must be available prior to the licensing of any product. For new vaccines, efficacy is usually assessed in trials designed to demonstrate prevention of the targeted infectious disease, as discussed above. However, serological endpoints may be adequate to substantiate effectiveness for the purpose of licensure when a previously accepted correlation between such serological endpoints and clinical effectiveness already exists [see discussion in 21 CFR 601.25(d)(2)]. A serological correlate of protection for vaccine efficacy may be identified from a prior successful clinical efficacy trial with clinical disease endpoints, or may be inferred from sources such as population-based studies of immunized persons. Detailed information about each assay intended to assess immune response should be provided to the IND *in advance* of using the assay.

Evaluation of the validity of serological endpoints for a particular setting frequently includes assessments of both functional antibody levels and quantitative antibody levels, often by enzyme-linked immunosorbent assay (ELISA). The relevance of the ELISA antibody levels may depend on correlation with the functional antibody levels, especially for situations in which the strongest link to efficacy is the functional antibody levels. In some instances, such a serological correlate of protection may provide adequate efficacy data to support licensure of a new vaccine, e.g., a new tetanus and diphtheria vaccine. Serological endpoints have also been used to provide the efficacy data for new combination vaccines with components consisting of previously licensed products and/or antigens with efficacy already demonstrated in clinical trials. Extensive discussions of the clinical studies used to support licensure of combination vaccines are available [4,5,14].

## IV. LICENSING REQUIREMENTS (REVIEW AND APPROVAL PROCESS)

Once all three phases of clinical development are successfully completed, a biologics license application (BLA) may be

submitted to the FDA for review. To be considered, the license application must provide the multidisciplinary FDA reviewer team (medical officers, microbiologists, chemists, biostatisticians, etc.) with complete manufacturing and testing information, as well as efficacy and safety data. This information is necessary to make a risk/benefit assessment that results in a determination to recommend or reject the licensure of a vaccine. The CBER has published a guidance document for vaccine manufacturers that provides an overview of the chemistry, manufacturing, and control information that should be submitted in a BLA [15]. Vaccine approval also requires the provision of adequate product labeling to allow healthcare providers to understand the vaccine's proper use and indications, including its potential benefits and risks, to communicate with patients and parents, and to safely deliver the vaccine to the public. In addition, the proposed manufacturing facility undergoes a prelicensing inspection by CBER product and facility experts. During this inspection, the entire production process is reviewed in detail along with a review of all production equipment, utility systems, personnel, and batch records.

### A. FDA Advisory Committee Deliberations

Prior to licensure of a new vaccine or the approval of a significant new indication for a currently licensed vaccine, the FDA will often request manufacturers to present their data to the Vaccines and Related Biological Products Advisory Committee (VRBPAC). This expert committee, which consists of non-FDA scientists, physicians, biostatisticians, and a consumer representative, provides advice to the Agency regarding the production, testing, safety, and efficacy of the vaccine for a proposed indication.

The FDA staff formulates relevant questions for the Committee and may also make presentations at the meeting. Consultation by the VRBPAC or other appropriate FDA advisory committees is not limited to the immediate prelicensure stage; clinical data and questions, as well as related preclinical issues, may be referred to an FDA advisory committees *at any time* during drug development. Review of transcripts from previous related advisory committee meetings may be informative to sponsors, and can be obtained from the CBER Freedom of Information (FOI) staff. Recent committee transcripts and documents may also be available on CBER's WWW site. Sponsors should review CBER guidance with regard to submitting materials for advisory committee meetings, especially with regard to due dates [16].

### B. Postlicensure Activities

The FDA continues to oversee the production and performance of vaccines after licensure to ensure continuing safety and efficacy of the vaccine. After licensure, monitoring of the product and of production activities, including periodic facility inspections, continues as long as the manufacturer holds a license for the product. If requested by the FDA, manufacturers are required to submit to the FDA the results of their own tests for potency, safety, and purity for each vaccine lot. They may also be required to submit samples of each vaccine lot to the FDA for testing. However, if the sponsor requests an alternative procedure that provides

continued assurance of safety, purity, and potency, the CBER may determine that routine submission of lot release protocols (showing results of applicable tests) and samples is not necessary.

Until a vaccine is given to a large population, all potential adverse events cannot be anticipated and therefore, CBER uses both active and passive methods for assessing safety. One method for expanding safety information is by conducting Phase 4 studies, i.e., formal studies on a vaccine once it is on the market. For any new approval (BLA or BLA supplement), manufacturers may be asked to perform specific postmarketing studies, for example, to provide additional assessments of less common or rare adverse events or to further assess the duration of vaccine-induced protection. The CBER's Office of Vaccines Research and Review usually requests that such protocol(s) be provided for FDA review and comment prior to application approval. As required by 506B of the FDAMA, in 2001, regulations went into effect that add requirements to submit status reports for certain postmarketing studies, i.e., studies in the areas of clinical safety, efficacy, and pharmacokinetic and nonclinical toxicology [17].

## V. REGULATORY CHALLENGES WITH NEW VACCINE APPROACHES

The framework and guidances provided for regulation of vaccines are often "challenged" with the development of novel vaccine approaches. The following select examples of novel technologies will underscore the challenges facing vaccine developers and regulators alike in establishing testing methods that achieve the goals of demonstrating purity, potency, and safety.

### A. Vectored Vaccines

The advances in molecular biology and the genomic revolution in organism sequencing has allowed for the generation of highly targeted vaccine approaches using a number of delivery mechanisms. Use of live replicating bacterial organisms such as *Bacillus Calmette-Guerin* (BCG) or *Salmonella* to express foreign genes has been the focus of much effort over the past few years [18]. The approach of using vectored vaccines to deliver antigens is of interest because this approach may allow for expression of antigens that could stimulate mucosal immunity or allow for a more persistent gene expression. The advances in genomics and immunology have allowed for the identification of gene sequences that may be important in providing protection from disease and critical elements involved in mounting both humoral and cellular responses.

When considering such an approach, early discussion with the FDA regarding manufacturing and testing, as well as clinical development, is recommended. For example, if the vectored vaccine contains sequences for generating a cell-mediated immune (CMI) response, the development of an appropriate potency test for the vectored vaccine should include an evaluation of the ability of the vaccine to induce such a response. Also, the sophistication of molecular biol-

ogy allows for creating vaccines expressing multiple antigens in the form of polypeptide sequences for generating cytotoxic lymphocyte responses or for generating responses to multiple serotypes/subgroups of the organisms. In this case, the product development and testing will need to address the control and release testing for detection of each of these epitopes. Of note, the preclinical safety testing of vectored vaccines eliciting humoral and/or CMI responses should be carefully addressed to ensure that the toxicity study is adequate to evaluate the possible direct and indirect toxicity of constitutive expression of transgenes and the possible generation of tissue cross-reactive immune responses. Additional testing to evaluate the persistence of the vectored vaccine and stability of the construct expression should also be addressed using an appropriate animal model. The choice of the animal model and design of such studies will require frequent and detailed discussions with the FDA.

Vectored vaccines may also pose a challenge with regard to the clinical development path. The example of a BCG-vectored HIV vaccine expressing neutralizing antibody and cell-mediated immune response epitopes illustrates several of the challenges facing this vaccine approach. Several aspects of developing such a vaccine were discussed at a World Health Organization (WHO) workshop [18]. One major area of concern identified was the need to establish appropriate assay methodologies to measure the immune response to both the humoral and cellular components of the vaccine. The clinical development path should include early discussions and efforts in establishing appropriate assays for measuring immune responses generated during the clinical study. Robust assays to measure clinical parameters that could reflect protection were viewed as essential prior to Phase 3 field trials.

Vectored vaccines can also present challenges as to the determination of an appropriate study design and illustrate the complexity of evaluating these vaccines clinically. For example, the BCG-vectored HIV vaccine may be viewed as a combination vaccine where the vaccine may impact disease conditions caused by more than one organism. In this case, the combination vaccine may include a preventive vaccine for tuberculosis and HIV. Guidance on the regulatory framework for evaluating combination vaccines [4–6,19] should be considered. Using a vaccine with proven efficacy or previously licensed as a vector poses a challenge to regulatory agencies. In the case of a recombinant BCG product, the issue of how to design a study to demonstrate that there is no negative effect on the efficacy of the BCG component may be difficult to address. The demonstration of bridging efficacy of the recombinant BCG back to the parental strain will require extensive discussions with the FDA. As with many combination vaccines, critical issues in clinical development are the ability to demonstrate no adverse effects on safety, immunogenicity, or efficacy of the parental individual vaccine components [19,20].

### B. Plant-Based Vaccine Development

Another exciting new approach is plant-based vaccines. Recent advances in plant technology have allowed for the expression and correct processing of viral epitopes and bacterial toxin subunit proteins [21,22]. Plant-based

approaches take advantage of the recent advances in genomics and understanding of plant biology, and offer the advantages of being relatively inexpensive to produce and store, easy to scale-up for mass production and allows for versatility of delivery [22,23]. Plant-based technology can be either the use of the plant as a “bioreactor” for the production and subsequent purification of proteins or as a production or “delivery” system. In this latter case, the vaccine is usually delivered as an edible product. The focus of this section will be on edible vaccines and the complexity of product development.

The use of plant-based technologies poses a challenge to the appropriate application of the regulatory framework for assessing vaccine safety, purity, and potency. With regard to manufacturing and testing, the questions of how to determine potency and consistency of manufacture are difficult to answer. Depending on the plant delivery system used, the purification of the expressed protein from the plant may be possible and allow for an assessment of potency based on quantity of gene expression extracted from a fixed amount of starting material [23]. Even if this approach is used, it is still difficult to assess the consistency of expression from plant to plant. The evaluation of gene expression on an individual plant basis is difficult and therefore also makes the determination of manufacturing consistency difficult to demonstrate. Also, agricultural facilities that produce plant-derived biologics provoke interesting discussions as to the requirements for manufacturing under conditions consistent with cGMP. A number of issues relative to the plant propagation should be considered and addressed as early as possible with the FDA. For example, discussion such as the containment of the transgenic plants to prevent possible spread of the transgenes to other plants; the use of pesticides/herbicides in the growth and as contaminants in the product; the water and soil conditions used in the propagation of the plant; and the evaluation of contaminating organisms or toxins in the product are critical to address early on with FDA and may require additional consults with other Federal agencies such as the United States Department of Agriculture (USDA) or the Environmental Protection Agency (EPA).

As with “traditional” vaccine production, the product developer using this approach should devise ways to establish and characterize master and working seed stocks and address the storage and stability of the seed stocks to be maintained over time in storage. As a part of characterization of the seed stocks, the genetic and product stability should be examined.

The use of plant-based technologies also involves additional safety concerns that are unique to this novel approach. For example, the use of plant-derived materials raises the concern that plant toxins may be present. The absence of such toxins should be determined as part of the characterization and selection of seed stocks and expression systems. In addition, the oral delivery of vaccines in plants raises the issue of whether such a delivery system would result in the generation of immune tolerance. If possible, these unique concerns should be addressed using appropriate animal models, if available, and be carefully examined in the clinical setting as part of clinical safety monitoring or follow-up.

In summary, the expanded application of molecular biology and genomics in vaccine technology has raised the possibility of creating novel genetically engineered organisms and plants whose mode of delivery involve novel routes of administration and immune stimulation mechanisms. With these advances in science come the challenges of how to best manufacture, test, and regulate these novel products. As these approaches move forward, it is essential that vaccine developers and the FDA enter into frequent discussions on the appropriateness of product and clinical testing.

## ACKNOWLEDGMENTS

The authors wish to thank Ms. Linda Rosendorf and Karen Chaitkin for their thoughtful review of the manuscript. We would also like to thank Dr. Karen Goldenthal for her contributions to the clinical section of this manuscript.

This chapter reflects the authors' assessment of the approach to clinical trials and product development for preventive vaccines and is not intended to represent the official position of the FDA or the NIH.

### I. INTRODUCTION

The tremendous benefits of immunization in reducing the morbidity and mortality of infectious diseases are well recognized, both from a public health perspective as well as from an individual perspective. Widespread use of vaccines in the past century has led to improved control of many infectious diseases including diphtheria, pertussis, and measles, and eradication or near eradication of diseases, i.e., smallpox and polio [1]. However, this public health triumph comes with the implicit understanding that effective health interventions such as immunizations are not completely free of risk. Vaccines are held to the highest standards of safety because they are usually given to healthy individuals (often children) to prevent an infectious disease to which they might be exposed in the future rather than treat an established disease or condition. Yet vaccines, like all pharmaceutical products, can have adverse effects ranging from transient common local reactions to rare but serious and irreversible events. Successful immunization strategies incorporate rigorous scientific assessments to ensure the safety of vaccines both pre- and postlicensure, and effectively communicate the benefits and risks to the public.

In this chapter, which will primarily focus on preventive vaccines for infectious disease indications, we present a practical approach for planning the safety evaluation of new vaccines by offering a framework for integrating safety into vaccine development. We develop the rationale for this framework by reviewing lessons learned from historical events and recent controversies, examining scientific methods for evaluating the safety of vaccines, and applying principles of risk management and risk communication to immunization safety.

### II. EVOLUTION OF THE VACCINE SAFETY SYSTEM IN THE UNITED STATES

#### A. Past Experiences

Concerns over the safety of vaccines can affect public acceptance of immunizations, with consequent increases in rates of infectious diseases, as has been described in countries where whole-cell pertussis-containing vaccines were abandoned because of the alleged association with encephalopathy [2]. While vaccine safety controversies have sometimes garnered public and media attention on the basis of limited scientific information, significant advances have resulted from lessons learned when real vaccine safety problems emerged.

#### 1. Immunization Against Smallpox: Variolation and Vaccination

The recognition that immunizations can cause adverse effects dates back several centuries, to the practice of “variolation,” or the controlled inoculation of healthy individu-

\* Sir Graham Wilson. *The Hazards of Immunization*. The Athlone Press, London; 1967.

The views represented here are those of the authors and not intended to represent those of their respective organizations.

als with infectious material obtained from individuals suffering from smallpox (*Variola major*) or previously inoculated with smallpox (Figure 1). When this practice was introduced in England from the Orient during the eighteenth century, it was observed that those inoculated occasionally developed disseminated lesions and even fatal smallpox infections. Mortality of variolated individuals was reported at rates of 1 in 50 during the earlier years of the practice to 1 in 2800 during the 1760s [3].

Jenner's smallpox vaccine, developed in 1796 from cowpox (*Vaccinia virus*) lesions, was associated with fewer serious reactions. Despite the improved safety profile, opposition to vaccination arose shortly thereafter, coalescing into organized resistance after an 1867 British law mandated smallpox vaccination [4]. Similar political opposition was seen in the United States when a compulsory vaccination program was initiated in response to a smallpox epidemic in 1901–1903 in Boston [5]. Those opposed to vaccination questioned the safety and efficacy of smallpox vaccination, and argued for individual liberty, i.e., the right to decide whether to be vaccinated. The debate against mandatory vaccination in Boston resulted in a landmark case, *Jacobson*

*v. Massachusetts*, decided by the U.S. Supreme Court in 1905, which ruled that the state could pass laws mandating vaccination to protect the public from dangerous communicable diseases [5]. This intersection of individual rights with public health policy has resurfaced in subsequent immunization debates such as state mandates for routine childhood immunizations [6].

## 2. Bacterial Contamination of Biological Products

Several unfortunate episodes documented the critical importance of quality control, both in the manufacturing of vaccines and in their handling at the time of administration. As demand increased for vaccines and antitoxins, new processes were needed to increase the supply. The recognition that person-to-person inoculation as described above could transmit infectious diseases such as syphilis provided impetus for the commercial production of smallpox vaccine on “vaccine farms” where *Vaccinia virus* was propagated on the skin of cows [7]. But the production of biological products remained unregulated, and the lack of adequate quality control measures led to inevitable mishaps. In St.

**Figure 1** “The Cow Pock—or—the Wonderful Effects of the New Inoculation!” (From the Publications of the Anti-Vaccine Society/J. Gillray, 1802.)

Louis in 1901, 20 children became ill and 14 died following receipt of an equine diphtheria antitoxin contaminated with tetanus toxin. This event led to the passage of the Biologics Control Act of 1902 (The Virus, Serum, and Toxin Law), which contained several notable provisions, including license requirements for biological products and their manufacturing facilities, authority to conduct unannounced inspections, the requirement for accurate product labels, and penalties for noncompliance including revocation of license [8]. In 1928, 12 children died of staphylococcal sepsis in Queensland, Australia, following contamination of a multidose container of diphtheria toxin–antitoxin mixture, prompting the investigating committee to recommend that biological products should not be formulated in containers for multiple use unless a sufficient concentration of antiseptic was added to inhibit microbial growth [9].

### 3. Viral Contamination of Yellow Fever Vaccine

The need for careful quality control of all materials used in the manufacturing process was demonstrated when an investigational yellow fever vaccine was implicated as the cause of an estimated 50,000 cases of jaundice observed in 2 to 2.5 million U.S. soldiers immunized in 1942, with a case fatality rate of 2–3 per 1000. Investigation at the time pinpointed the cause as contamination of the human serum used as a stabilizing agent; serological testing decades later confirmed the etiology as hepatitis B [10–12]. Removing human serum from the manufacture of yellow fever vaccine halted the outbreak.

### 4. The Cutter Incident

Perhaps one of the most widely publicized problems with quality control was the so-called “Cutter Incident.” Rapid scale-up of inactivated polio vaccine (IPV) production was required to meet projected demand for IPV during the initial U.S. polio immunization campaign, following public announcement of the results of the Francis Field Trial in 1955. Following observations of a temporal association between receipt of IPV and cases of paralytic polio, a meticulous epidemiological evaluation traced the source to certain lots of the Cutter vaccine in which scaled-up production resulted in aggregates of poliovirus incompletely inactivated by formalin. Affected lots were associated with 60 cases of paralytic polio in vaccine recipients, and 89 cases in family contacts [13]. This incident highlighted the importance of quality control for every change in the manufacturing process and careful epidemiological assessment to evaluate the association between a vaccine and an adverse event.

### 5. Vaccine-Associated Paralytic Polio

The critical role of epidemiological evaluation of very rare adverse events was further highlighted in the painstaking investigation that connected oral polio vaccine with the rare occurrence of paralytic poliomyelitis. In 1964, the Public Health Service commissioned a special advisory committee that met at the Communicable Diseases Center, now known as the Centers for Disease Control and Prevention (CDC), to evaluate whether a small number of cases of paralytic polio

observed in vaccinated individuals living in nonepidemic areas could be attributed to receipt of oral polio vaccine (OPV). Because no laboratory techniques were available at that time to distinguish vaccine from wild-type polio strains, the committee relied on epidemiological surveillance data between 1962 and 1964. While the committee acknowledged that the current state of the art of virology was unable to determine whether any individual case of paralysis could be directly attributed to the vaccine, they concluded that epidemiological evidence pointed to a causal link with OPV for at least some of the 57 cases deemed “compatible” or possibly because of vaccination [14]. The committee estimated the incidence of vaccine-associated paralytic polio to be 1 in 6 million doses for type 1, 1 in 2.5 million doses for type 3, and 1 in 50 million doses for type 2, but concluded that the benefits of routine immunization with OPV relative to the risks of naturally occurring disease outweighed the potential rare risk of paralytic polio following OPV [14]. That the committee’s epidemiological assessment has been supported by subsequent laboratory data linking vaccine-associated cases with OPV strains [15] underscores the value of integrating surveillance data, clinical information, and scientific methods in the evaluation of adverse events.

### 6. Formalin-Inactivated Respiratory Syncytial Virus and Measles Vaccines

Adverse events following immunization have occurred in unpredictable ways. Examples include an enhanced lower respiratory illness observed in naive infant recipients of an investigational formalin-inactivated respiratory syncytial virus (RSV) vaccine following exposure to natural RSV disease [16,17]; and an atypical and often more severe clinical presentation of measles in individuals who had received a licensed inactivated measles vaccine and were subsequently exposed to wild measles virus, sometimes many years following immunization [18–20]. The condition of atypical measles has all but disappeared in the United States following the elimination of endemic measles disease and reliance on the live attenuated measles vaccine. However, the early experience with formalin-inactivated RSV vaccine has continued to hamper RSV vaccine development, due, at least in part, to limited understanding of enhanced RSV disease pathogenesis [21]. These experiences reinforced the need for improved laboratory methods evaluating adverse event immunopathology, careful monitoring for adverse events during clinical studies, the importance of maintaining an index of suspicion for events that may occur years following immunization, and introduced the potential for “enhanced” disease as an adverse event following vaccination.

### 7. Expert Panel Reviews of Vaccine Efficacy and Safety

In 1972, responsibility for regulating biological products in the United States was transferred from the National Institutes of Health (NIH) to the Food and Drug Administration (FDA). At that time, many biological products had been licensed and in widespread use for decades; however, some products lacked adequate documentation of efficacy and safety, in light of evolving standards for quality control

and clinical trial design. In 1973, the FDA commissioned a series of panels consisting of outside experts to evaluate available data on safety and efficacy of licensed vaccines. For example, the panel review of bacterial vaccines and toxoids did not find evidence that any licensed vaccines were unsafe, but did find that several products lacked sufficient evidence to make a determination [22]. Many products so classified had not been produced or marketed in decades. Faced with having to provide additional data on manufacturing processes or from clinical trials, several manufacturers requested their licenses be voluntarily revoked [22]. While this review did result in a winnowing of the number vaccine manufacturers and vaccines licensed in the United States, the net effect was to ensure that all U.S. licensed vaccines met applicable standards at the time of review for quality control of manufacturing and clinical demonstration of safety and efficacy.

## 8. Pertussis Vaccine Controversy and the National Childhood Vaccine Injury Act

The political leverage of advocacy groups has affected a wide range of immunization activities, from vaccine research and development to immunization delivery, yet has been most profound regarding issues of vaccine safety, highlighting the fragile interrelationship among vaccine supply, coverage rates, and public confidence and acceptance of vaccines. This became vividly apparent during the 1970s and 1980s, when concerns were raised over a possible association between diphtheria and tetanus toxoids and whole-cell pertussis vaccines (DTP) with encephalopathy, first in Japan and Europe and later in the United States [23,24]. A consumer advocacy group, Dissatisfied Parents Together (DPT), was established in the United States [25], spurring public debate on this issue. Increased litigation against vaccine manufacturers led some to withdraw from the marketplace, further reducing the number of manufacturers, and prompting the CDC to stockpile vaccines in the event of critical shortages.

In response, a coalition of health professional organizations, consumer advocacy groups, and others pressed for the passage of the National Childhood Vaccine Injury Act of 1986 [26, as amended 1989]. The Act created the Vaccine Injury Compensation Program (VICP) and called for a unified national reporting system for vaccine-associated adverse events leading to the creation of the Vaccine Adverse Event Reporting System (VAERS), mandated comprehensive reviews of vaccine-related adverse events by the Institute of Medicine (IOM), provided for improved record keeping of vaccine administration, and mandated the development and distribution of vaccine information materials. Responding to the legislative mandate under the Act for comprehensive reviews of vaccine safety, the IOM performed extensive reviews in 1991 (pertussis and rubella vaccines) [24] and 1994 (diphtheria and tetanus toxoids, measles and mumps, polio, hepatitis B, and *Haemophilus influenzae* type b vaccines) [27]. Of note, the IOM concluded that there was either no evidence or there is insufficient evidence to establish a causal relationship for approximately two-thirds of the conditions studied, highlighting areas needing further research.

## 9. Shift in Benefit–Risk Assessment

The U.S. whole-cell pertussis vaccine controversy of the 1980s also focused attention and resources on development and use of vaccines with improved safety profiles, such as the acellular pertussis and enhanced inactivated polio vaccines. The widespread use of vaccines has led to dramatic decline in the incidence of infectious diseases and simultaneously dimmed the public's collective memory of the contagiousness, severity, and long-term sequelae of many infections that were once common in childhood. Consequently, a shift has occurred in the benefit-to-risk ratio of vaccines, both actual (i.e., the true risk of an individual experiencing a vaccine-preventable disease has declined) and perceived (i.e., the individual no longer views the disease as a threat), resulting in diminished acceptance of adverse effects, even those rarely occurring. Recognition of the improved local and systemic reactogenicity profile of acellular pertussis vaccines led U.S. immunization advisory bodies to replace whole-cell pertussis vaccines in the recommended schedule [28,29]. Similarly, the occurrence of eight to nine cases a year of paralytic polio in the United States associated with use of OPV, coupled with certification of polio eradication in the western hemisphere by the World Health Organization (WHO) in 1994, prompted the ACIP to recommend first a sequential IPV/OPV schedule [30], and later an IPV-only schedule [29].

## B. Recent Events

### 1. Rhesus Rotavirus Vaccine and Intussusception

The recent experience with RRV in the U.S. illustrates the methodological difficulties in detecting rare adverse events and the public policy dilemma of balancing a vaccine's benefits with an infrequent but potentially life-threatening risk. Intussusception, or telescoping of the bowel causing acute obstruction, is a rare condition often of unknown etiology that occurs in infants. This condition was observed during licensure clinical studies in 5 of 10,054 infants receiving RRV (0.05%) and 1 of 4633 receiving placebo (0.02%), with the difference in RRV recipients versus controls not statistically significant ( $P > 0.45$ ) [31]. Analysis of surveillance data did not suggest an association between wild-type rotavirus vaccine and this adverse event, and thus did not provide support for a biological mechanism [30]. However, the finding of intussusception in RRV recipients during licensure studies was noted in the product label, without attributing causality to the vaccine. Following U.S. licensure, reports to VAERS of intussusception following RRV led to the temporary suspension of vaccine use [32] and triggered epidemiological investigations including case-control/case-series [33] and retrospective cohort [34] studies. Analyses of these studies showed the association between RRV and intussusception to be strong, temporal, and specific, with the attributable risk estimated to be approximately 1 in 11,000 vaccine recipients [34].

Given strong evidence of an association (albeit rare), the potentially life-threatening nature of intussusception, and limited mortality due to rotavirus disease in the United States, the ACIP rescinded its recommendation for RRV

in October 1999, and the manufacturer withdrew the vaccine from the market and ceased production [35]. The benefit-risk assessment for rotavirus vaccines is considerably different in developing countries, where the incidence of rotavirus infection is comparable to the United States but results in significantly higher morbidity and mortality. However, the U.S. risk management decision regarding RRV has had worldwide ramifications, with other countries reluctant to use a product withdrawn from the U.S. market [36]. Developers of new candidate rotavirus vaccines already in clinical studies have had to carefully consider what level of clinical safety data would be required for licensure, in light of the rarity of intussusception and the lack of an animal model to aid preclinical testing. As a consequence, clinical trials designed for a more robust assessment of rare adverse events are likely to be substantially larger and more costly than the prelicensure trials of RRV.

## 2. Immunization and Chronic Conditions

Alleged links between immunizations and chronic conditions such as MMR (measles, mumps, and rubella) vaccine and autism [37,38], thimerosal (used as a preservative in some vaccines) and various neurodevelopmental disorders including autism [39], the OspA Lyme vaccine and rheumatoid arthritis [40], immunizations and insulin-dependent diabetes [41], hepatitis B vaccine and multiple sclerosis [42], and the “antigen overload” hypothesis [43] have provided additional challenges in assessing the safety of vaccines. Assessment of a causal association between immunization and chronic conditions is complicated by the multifactorial etiology of many of these illnesses, the often imprecise onset of symptoms, and the difficulty of proving a negative (i.e., that the adverse event is not caused by the vaccine). However, such vaccine safety concerns may have an impact on vaccine acceptance and use, as illustrated by declines in MMR uptake in Great Britain [44] and the decision by the manufacturer of the U.S. licensed Lyme vaccine to cease production and distribution [45]. The complexity of these issues points to the need for a comprehensive and systematic approach to evaluate data on vaccine safety, which is to be discussed later in this chapter.

## 3. Vaccine Supply, Quality Control, and Liability

Recent vaccine shortages in the United States have highlighted the precarious interrelationship between vaccine supply, quality control requirements, and liability concerns. Inadequate supplies to meet the high demand for influenza, tetanus and diphtheria toxoid, pneumococcal conjugate, MMR, and other vaccines have forced immunization advisory bodies such as the ACIP and the American Academy of Pediatrics (AAP) Committee on Infectious Diseases to develop interim recommendations for a number of vaccines in response to shortages [46–50]. No single explanation appears to explain the insufficient supply of multiple vaccines from different manufacturers, but vaccine safety issues may play a role. Frequently cited reasons for the reluctance of pharmaceutical manufacturers to develop and market vaccines include the complexity of vaccine manufacturing procedures, liability concerns due to vaccine adverse events, and

small profit margins for vaccines compared with other pharmaceutical products [51]. As previously cited examples have illustrated, controlling manufacturing processes is an essential element of vaccine production. The need to overhaul production facilities to meet current good manufacturing practices (cGMP) and the difficulty in predicting demand for newly licensed vaccines, which depends in part on perceived safety, are additional factors mentioned for shortages of some vaccines [51]. The net result is little redundancy in vaccine supply, so a shortage of one product can have a ripple effect on the entire U.S. immunization program.

## 4. Vaccines and Biological Terrorism

The benefit-risk assessment for immunizations is not a fixed entity, as has been demonstrated by renewed interest in smallpox and anthrax vaccines generated by terrorist attacks on September 11, 2001, and the mailing of letters containing anthrax spores to public officials and media representatives [52]. Routine smallpox vaccination ended in the United States in 1972 when the pending global eradication of smallpox had essentially reduced the threat of smallpox in the United States to zero. In this setting, the risks of the vaccine—rare serious reactions such as encephalitis and eczema vaccinatum, which caused approximately seven to nine deaths per year—greatly outweighed the risks of the disease [53,54]. In recent years, a mandatory anthrax vaccination program by the U.S. military met with resistance by some military members concerned with the safety of the vaccine [55]. However, a thorough review of anthrax vaccine’s safety profile [56], coupled with recognition of the benefits of immunization that have become more visible in light of recent terrorist activities, may shift perceptions and acceptance of this vaccine. At the same time, there are renewed efforts to develop new and safer vaccines against smallpox, anthrax, and other potential threats of bioterrorism [57,58].

## III. SCIENTIFIC METHODOLOGY FOR DETERMINING VACCINE SAFETY

Establishing the safety of a particular vaccine requires a multiprong approach: preclinical research and testing, clinical studies, and postlicensure assessments including epidemiologic evaluations. Responsibility for evaluating vaccine safety begins with vaccine researchers and/or manufacturers, and later extends to regulatory authorities, other government and international agencies, immunization advisory bodies, and others. Much attention has been devoted to immunization safety efforts in the last decade in the United States and worldwide. The WHO with its vital role in worldwide immunization programs has made immunization safety, from quality control to vaccine delivery and effective response to vaccine safety concerns, a global priority [59,60]. The International Conference on Harmonization (ICH), a collaborative effort of regulatory authorities and pharmaceutical companies in Europe, Japan, and the United States, to harmonize requirements for registering pharmaceutical products, has developed recommendations on a range of preclinical, clinical, and postlicensure safety evaluations [61]. The role of the FDA for vaccine development is discussed

elsewhere in this volume [Baylor, Falk, Midthun, this volume]. This section will review the scientific methodology underlying vaccine development as it pertains to safety.

In evaluating a vaccine's safety, it is important to recognize that safety is not an "all or nothing" phenomenon. This is acknowledged in the FDA definition of safety; that is, "the relative freedom from harmful effect to persons affected directly or indirectly by a product when prudently administered, taking into consideration the character of the product in relation to the condition of the recipient at the time [62]." Thus the property of safety is *relative* and *relational*; it depends upon the benefit–risk assessment at a particular point in time, the specific indication, and the intended recipient or population.

## A. Laboratory Methods

The diversity of biological products necessitates some individualization of the preclinical evaluation; however, certain general principles should be kept in mind. Prior to introduction of an investigational vaccine in human volunteers, the investigator should provide evidence supporting the scientific rationale for a vaccine candidate (e.g., immunogenicity), data demonstrating the quality of the product, and preclinical safety information on the vaccine.

The development of appropriate animal models may be useful in evaluating disease pathogenesis, immune response, toxicity, and in some cases, efficacy against challenge with the infectious disease that the vaccine is intended to prevent. Product quality is assessed by evaluating the manufacturing process, the materials used during production, and the final product. Specific descriptions of the manufacturing process, documentation of the source and quality of the materials used in manufacture, and in-process testing help to characterize the safety of the product [63]. In addition, ICH has developed a wide range of guidance documents on quality assurance and in vitro and in vivo preclinical studies [61]. Recent concerns about transmissible spongiform encephalopathies have highlighted the need to document the sources of bovine-derived materials and have led the United States to exclude materials for vaccine manufacture from countries in which Bovine Spongiform Encephalopathy (BSE) or BSE risk exists [64–66].

Careful attention should be given to the design of pre-clinical toxicity studies, particularly when the investigational product consists of components not previously studied in humans such as new antigen delivery systems and novel adjuvants [67]. Vaccines intended for administration to pregnant women or women of childbearing potential should be evaluated for developmental toxicity; the specific timing of these studies in relation to the vaccine clinical development process depends on the population in such trials [68].

Additional laboratory testing of vaccines may be warranted depending on the particular product, e.g., adventitious agent testing for vaccines produced in animal or human cell substrates [69], preclinical studies evaluating the potential for integration of plasmid DNA into the host genome for DNA vaccines [70,71], and demonstration of adequate attenuation for live attenuated vaccines [72]. Attention

should be devoted to developing tests for sterility, general safety, identity, potency, and demonstrating purity of the vaccine, as these elements will be required for licensure [73]. Continued vigilance is necessary, particularly for novel vaccine technologies that require the development and standardization of new quality control measures. Laboratory evaluation of vaccine safety does not end when clinical studies begin or when a vaccine is licensed. Changes in the manufacturing process or components, the development of enhanced testing techniques, as well as new safety concerns identified in clinical studies or in postmarketing surveillance of a vaccine or one closely related, should prompt the investigator and/or manufacturer to consider whether re-evaluation of the product's preclinical safety is warranted.

## B. Clinical Studies

### 1. Vaccine Clinical Studies and Human Subject Protections

Intrinsic to the design and conduct of clinical studies is compliance with accepted ethical principles guiding human participation in clinical trials, such as informed consent, equitable selection of subjects, and appropriate scientific and ethical review of the proposed study. Evolutions in thought regarding elements of ethical research, as well as the use of new vaccine technologies with uncertain risks, present new challenges for ensuring participant safety in clinical trials. Human subject protections are guided by ethical principles formalized in consensus documents such as the Belmont Report [74], various iterations of the Declaration of Helsinki [75], and the International Ethical Guidelines for Biomedical Research Involving Human Subjects [76]. Similar concepts are codified in Department of Health and Human Services (DHHS) Regulations as the "Common Rule" [77] adopted by 17 federal agencies that support or conduct research with human subjects, and FDA regulations that govern drug, biological, and device research [78].

### 2. Phases of Clinical Studies

The stages of human clinical studies are divided into *phases* for regulatory purposes [79]. In the United States, when a new vaccine is first tested in humans, a sponsor (a vaccine manufacturer, academic investigator, government agency, or other individual or organization) must first submit an Investigational New Drug (IND) application to the FDA [80]. During each phase, clinical studies should be designed and conducted under conditions that optimize human subject protections and provide sufficient data to proceed to the next phase.

*Phase I.* Phase I studies represent initial testing in humans. These studies are designed to evaluate safety and typically enroll small numbers of subjects, generally between 10 and 100. Because of the small sample size, these studies can identify only very common adverse effects and are descriptive in nature. These studies may also include a limited dose-ranging design to provide preliminary information on immune responses and the corresponding safety profile at particular doses. The recording of adverse events

is facilitated by case report forms designed to capture expected adverse events, based on previous experience with the investigational product or one closely related, as well as the route of administration. For example, for a vaccine that is intramuscularly administered, investigators should monitor local reactions such as redness, swelling, and pain, and systemic complaints such as fever, accompanied by a grading scale to quantify severity. The case report form should also collect information on unanticipated adverse events.

Appropriate duration of active follow up will depend on the investigational product, generally a minimum of 3 days postvaccination for killed or subunit vaccines, and 2–3 weeks postvaccination or until the vaccine strain is no longer detectable for live attenuated products. In addition, further active follow up of all vaccines at the time of blood draw for serology, e.g., at 1 month postimmunization, is appropriate. Collection of data on local and systemic events can make use of diary cards, clinic visits, or telephone calls. The use of clinical criteria defined *a priori* for halting further administration to subjects (i.e., “stopping rules”) may be an important safety feature to consider for products being tested in humans for the first time, especially when indicated by preclinical testing, or when the properties inherent to the vaccine suggest the potential for serious adverse effects (e.g., live attenuated vaccines). If the intended population is infants and no previous studies have been conducted in infants with the vaccine under study or one closely related, a stepwise approach is often used with initial studies conducted in adults before use in children.

**Phase II.** Phase II studies may include up to several hundred individuals and are designed to evaluate the general safety profile of the vaccine, including local reactions such as redness and swelling at the injection site as well as general side effects such as fever and malaise. These studies also include immunogenicity evaluations and often include dose ranging. The design of Phase II studies may be more elaborate and include blinding, randomization, and placebo controls. During Phase II, the safety of a vaccine may be assessed with other immunizations routinely administered at the same time to evaluate for the possibility of altered immune responses. These studies, although larger than in Phase I, will still be able to evaluate only the most common types of adverse events.

**Phase III.** Phase III studies are designed to gather additional information regarding efficacy and safety that is needed to assess the overall benefit–risk relationship of the vaccine for licensure. In this regard, they are sometimes referred to as “pivotal” studies because they are designed to include adequate data in the target population and proposed schedule of administration to support the intended use. Such studies are generally randomized and controlled.

For *Phase III* studies, the sample size is usually determined by the number required to establish efficacy of the new vaccine, and may range from a few hundred to tens of thousands of subjects. For some new vaccines, e.g., combination vaccines with components having well-accepted immune correlates of protection, it may be possible to provide evidence for efficacy based on immunogenicity rather than clinical efficacy endpoints; the sample sizes of such pivotal

immunogenicity studies may be significantly less than that required to demonstrate clinical efficacy. In such cases, the sample sizes of pivotal safety studies should be adequate to evaluate less-common adverse events, such as those occurring at rates of 1 in 100, with careful consideration of the relevant adverse events to be monitored and the expected background incidence in the target population. Phase III vaccine studies usually have limited ability to detect rare adverse events (Table 1). To detect a doubling of less-common adverse events, such as those occurring at background rates of 1 in 100, requires approximately 5000 subjects. Clinical trials involving 50,000 individuals would be needed to detect doubling of an adverse event with a background incidence of 1/1000 [81,82].

**Phase IV.** Phase IV or *postmarketing* studies are usually conducted postlicensure to further investigate rare events. Some have advocated the use of expanded “simple” trials prelicensure to provide more precise data on risks of uncommon adverse events (see discussion below) [82].

The use of automated databases, such as those administered by health maintenance organizations, in Phase III studies may facilitate collection of data on less-common adverse events. Detailed information on common local and systemic adverse events may be collected in a subset of individuals enrolled in these studies using diary cards or via telephone or clinic follow-up. If data at any stage of clinical development raise significant concerns regarding the safety of the product, the FDA may request additional information or may halt ongoing or planned studies through a “clinical hold” [83].

Independent scrutiny with respect to the safety of human subjects during clinical trials is afforded by institutional review boards (IRBs), committees designated by institutions to approve the initiation and conduct of clinical studies. The IRB review and approval of clinical studies of new vaccines is required both by FDA and DHHS regulations. In designing clinical studies, investigators or sponsors should consider the use of Data Monitoring Committees (DMCs), also known as Data and Safety Monitoring Boards (DSMBs). Data Monitoring Committees consist of individuals with relevant expertise who provide ongoing review of data accumulated

**Table 1** Sample Sizes Needed to Detect Increased Rates of Rare Adverse Events After Immunization

Rates (%)	Sample size <sup>a</sup>	Number of potentially affected individuals per million vaccine recipients
1.0 vs. 2.0	5,000	10,000
1.0 vs. 3.0	1,750	20,000
0.1 vs. 0.2	50,000	1,000
0.1 vs. 0.3	17,500	2,000
0.05 vs. 0.1	100,000	500
0.01 vs. 0.02	500,000	100
0.01 vs. 0.03	175,000	200

<sup>a</sup> Two-arm trial, power = 80%, alpha (2-sided) = 5%.

during clinical studies. The role of the DMC is to advise the sponsor on the safety of current study participants and the continuing validity and scientific merit of the study [84]. Draft guidance is available from the FDA to help determine when a DMC is needed and how such committees should operate [84].

Ethical and practical issues facing investigators with respect to pivotal studies include the choice of research design, including the use of placebo controls when evaluating the efficacy of a vaccine against a disease for which a licensed vaccine already exists [85,86]. This issue is particularly relevant for clinical studies conducted in developing countries. Conducting clinical studies in international settings presents additional challenges such as ensuring adequate local review and oversight, the need for studies to be relevant to the health needs of the host country, and the sustaining newly introduced health interventions once the trial is completed [87–89]. Challenge studies of vaccine efficacy, i.e., inducing infection in subjects to study the efficacy of an experimental vaccine, can present issues for subject safety [90]. When planning challenge studies, investigators should carefully consider the reversibility of the infectious disease and its sequelae. Demonstrating efficacy when field efficacy trials or human challenge studies are not feasible or are unethical, e.g., vaccines against agents of bioterrorism, presents another potential hurdle. For products that reduce or prevent serious or life-threatening conditions where the product is expected to provide meaningful benefit over existing approaches, the FDA has recently finalized a new regulation describing how animal efficacy data can be used to support licensure [91]. In this setting, human clinical data on safety and immunogenicity would still be required.

### 3. Limitations of Prelicensure Vaccine Safety Assessments

The process outlined above for the development of vaccines prior to licensure and marketing has resulted in very safe vaccines. Regulations mandate strong controls on manufacturing processes, a staged approach to clinical development to systematically assess the benefits and risks of a vaccine, and rigorous controlled studies, usually randomized and blinded, to limit the effect of confounding and bias on outcome and thereby increase the likelihood of valid conclusions about safety and efficacy. However, prelicensure testing of vaccine safety cannot address all issues of concern. First, incomplete understanding of the immunopathophysiology of vaccine adverse effects has generally precluded the design of safer vaccines from “first principles,” e.g., deleting a short peptide chain from a vaccine antigen to prevent the possibility of autoimmunity due to molecular mimicry. Second, in many instances, the safety database prior to licensure may include a relatively small number of vaccine recipients (~10,000) compared with the number who might ultimately receive the vaccine (e.g. ~4,000,000 infants in U.S. birth cohort per year for a routinely recommended childhood vaccine), so adverse effects occurring at a rate of 1/1000 or lower are unlikely to be distinguishable from expected background. Third, clinical trials often exclude subgroups of the general population such as the immunocompromised,

preterm infants, and individuals with chronic or self-limited illnesses, and may have limited data from different racial or ethnic groups or geographic locations. Thus prelicensure clinical studies may not address the variation in susceptibility to adverse effects that exists in the general population.

### 4. Vaccine Licensure

If efficacy and safety are demonstrated during preclinical and clinical development, a license application can then be submitted to regulatory authorities for evaluation, including data on the benefits and risks of the new product. In the United States, the sponsor and the FDA present their findings to the Vaccines and Related Biological Products Advisory Committee (VRBPAC), an external committee of experts, in an open public meeting for comment and advice on interpretation of the submitted data and other issues related to the acceptability of the new vaccine. The approval process also entails the provision of adequate information to health-care providers and the public in the form of a product label that describes the vaccine’s proper use, including its potential benefits and risks, and any contraindications.

## C. Postlicensure Assessment of Vaccine Safety

The above mentioned limitations of clinical trials and the need to understand if observed adverse events are due to vaccines have led to the use of other approaches to detect and evaluate the causal connection between vaccines and rare adverse events after the vaccine has been licensed. These include additional clinical studies agreed to by the sponsor as a condition of licensure (sometimes called Phase IV studies), active and passive surveillance for unexpected adverse events after licensure, and targeted clinical, epidemiological, and laboratory studies to evaluate safety concerns that arise after the vaccine is in widespread use.

### 1. Phase IV Studies

Phase IV studies generally are designed to focus on issues that might have arisen during prelicensure testing, as well as to identify unexpected adverse events not observed prelicensure. These studies typically take place in the first few years after licensure with information expected to be presented in a timely fashion to regulatory agencies and immunization advisory groups. One example of how safety concerns arising during prelicensure development might necessitate Phase IV studies is provided by the theoretical association between arthritis and Lyme vaccine. During the development of Lyme vaccine, licensed in the United States in 1998, laboratory findings suggested that treatment-resistant Lyme arthritis might be caused by molecular mimicry between outer surface protein A (OspA) of *Borrelia burgdorferi* and the human protein LFA-1, in people with certain Human Leukocyte Antigen (HLA) genes [92]. Because the Lyme vaccine antigen consists of OspA, there was a theoretical concern that the vaccine might cause arthritis in susceptible individuals. Although increased risk of arthritis was not observed in approximately 5000 vaccine recipients in a randomized, blinded, placebo-controlled prelicensure trial

[93], a much larger Phase IV study was initiated to evaluate the risk of inflammatory arthritis in the general population. To date, no evidence of increased risk has been identified in this study [Chan, personal communication]. Nevertheless, the manufacturer withdrew the vaccine from the market in 2002, citing poor sales [95].

## 2. Vaccine Safety Surveillance

In addition to Phase IV studies planned prior to licensure, postmarketing monitoring of vaccine safety also involves identification of possible adverse effects of vaccination through surveillance of spontaneous adverse event reports made to vaccine manufacturers or directly to the FDA, followed by evaluation of these “signals” for a possible causal link to the vaccine.

*Vaccine Adverse Event Reporting System.* In the United States, systematic surveillance of adverse events after vaccination is undertaken using the Vaccine Adverse Event Surveillance System, jointly managed by the FDA and CDC [94,95]. The VAERS receives between 10,000 and 15,000 adverse event reports annually; approximately 10–15% are reported as serious (defined as life-threatening, hospitalization or prolongation of hospitalization, a persistent or significant disability/incapacity or a congenital anomaly/birth defect, or a medical event that may require intervention to prevent one of the above situations [96]). Information on VAERS and vaccine safety including the VAERS database, the VAERS form, and access to on-line reporting, is available on the internet ([www.vaers.org](http://www.vaers.org); [www.fda.gov/cber/vaers/vaers.htm](http://www.fda.gov/cber/vaers/vaers.htm); or [www.cdc.gov/nip](http://www.cdc.gov/nip)).

*Utility of Passive Surveillance Systems.* Passive surveillance systems such as VAERS do not actively track adverse events after vaccination, but rely on reports from healthcare providers, patients and their parents, and other interested parties. The VAERS is useful for detecting unrecognized adverse events, monitoring known reactions, identifying possible risk factors, and vaccine lot surveillance [94,95,97]. Priorities in analyzing VAERS data include adverse events reported after recently licensed vaccines, issues that have been identified to be of particular concern to the public, and rare adverse events not likely to be identified in clinical trials or controlled postmarketing safety studies (e.g., alopecia [98], and Stevens Johnson Syndrome [99]). Other priorities for VAERS analysis include those adverse events causally linked with immunization, to describe the range of clinical signs and symptoms, investigate potential risk factors, and pathophysiology (e.g., thrombocytopenia [100], syncope [101], and hypotonic–hyporesponsive episodes in infants (HHE) [102]). In addition, all reports of serious adverse events and death following vaccination are reviewed by FDA medical officers as they are received. Periodically, vaccine-specific surveillance summaries are prepared to describe reported adverse events and to look for unexpected patterns in clinical conditions that might suggest a causal link between the vaccine and the clinical condition [103–111].

*Limitations of Passive Surveillance Systems.* Limitations of surveillance systems dependent on spontaneously

reported adverse events include lack of verification of reported diagnoses, lack of consistent diagnostic criteria for all cases with a given diagnosis, wide range in data quality, underreporting, inadequate denominator data, and lack of an unvaccinated control group [94,95,112,113]. The validity of reported diagnoses and completeness of information in VAERS reports has only been formally studied for a few conditions. In one study evaluating reports of encephalopathy, encephalitis, and multiple sclerosis [114], between 26% and 51% of reports for these conditions lacked sufficient information to make a diagnosis. Enhanced follow-up is sometimes conducted to systematically collect information as the first stage in the signal evaluation process [99,100,102].

*Standardized Case Definitions.* The absence of consistent definitions for adverse events has hampered analysis of VAERS data. Application of case definitions for HHE [115], encephalopathy, encephalitis, and multiple sclerosis [114] to VAERS reports has shown the value of case definition development. The Brighton Collaboration is an international effort to extend these efforts by developing standardized case definitions of adverse events following vaccination for additional conditions [116]. These definitions might be used as guidelines for reporting adverse events to VAERS or applied to prelicensure trials.

*Passive Surveillance and Assessing Causality.* The limitations of passive surveillance systems mean that it is usually not possible to assess whether a vaccine caused the reported adverse event. Individual case causality assessment has been employed to evaluate reports using Bayesian probability [117] and a standardized algorithm in Canada [118]. This latter method was adapted by the Anthrax Vaccine Expert Committee to evaluate reports of adverse events following anthrax vaccine for the Department of Defense [119]. This approach involves systematic review of individual cases to make a diagnosis, search for known etiologies, and assess the biological plausibility of the adverse event’s being caused by the vaccine using expert opinion. Similar approaches have been considered for use in drug adverse event causality assessment, but their use has remained controversial when applied to unexpected adverse events [120–122]. As a result of the limitations of VAERS and individual case causality assessment, analysis of VAERS data focuses on describing clinical and demographic characteristics of reports and looking for patterns to detect “signals” of adverse events plausibly linked to a vaccine, thereby helping to define a hypothesis that can subsequently be examined in proper epidemiological studies. Even this limited and structured approach to analysis of VAERS data has proven controversial [123,124].

In addition to the approach described above combining descriptive epidemiology with medical judgment, several quantitative approaches have been proposed. These approaches all involve trying to identify conditions that are more commonly reported after a certain vaccine or combination of vaccines than after others. These methods are often collectively referred to as “data mining” and include older approaches such as proportional reporting ratios [125] as well as newer techniques [126,127]. Signals generated

through such quantitative analysis are usually subject to clinical and descriptive epidemiological analysis to focus on the most interesting findings. These semiautomated approaches should help to improve the efficiency of screening tens of thousands of adverse events reported annually [128], although their utility in replacing traditional case series evaluations remains to be seen [129].

*International Surveillance Systems.* The vaccine safety efforts of the World Health Organization (WHO) include the development of national systems to deal with adverse events [130]. The WHO has also established a Global Advisory Committee on Vaccine Safety to make independent assessments of vaccine safety issues [59]. Many countries have surveillance systems and these data are aggregated by the WHO Collaborating Center for International Drug Monitoring at Uppsala, Sweden, including some data from vaccine adverse event surveillance systems. This center has developed a data mining technique for routine monitoring of this database and routinely publicizes possible signals. The United Kingdom's Medicine Control Agency (MCA) enhances their surveillance for new products with the "yellow card" system. New products are distributed with a reporting form (the "yellow card") to highlight the need for clinicians and pharmacists to be alert for and report adverse events. If an adverse event occurs, the reporter sends the form to the MCA and Committee on Safety of Medicine so that the adverse event can be evaluated.

### 3. Targeted Evaluations of Vaccine Safety Signals

Evaluation of signals usually requires epidemiological methods, sometimes combined with clinical and laboratory analysis. The CDC established the Vaccine Safety Datalink (VSD) as a resource for conducting cohort studies using large administrative databases maintained by health maintenance organizations to evaluate specific hypotheses [131,132]. Studies from the VSD have found increased risk of intussusception after rotavirus vaccine [34], and febrile but not nonfebrile seizures after DTP or MMR vaccines [133]. Analyses of VSD data have also produced important negative studies. For example, no difference was found in adverse events by brand of hepatitis B vaccine [134] and no association was found between rubella vaccine and chronic arthropathy in women [135], childhood vaccination and type 1 diabetes [136], and measles-containing vaccines and inflammatory bowel disease [137].

Other countries have also used population-based databases to study vaccine safety concerns. Among the best known is the General Practice Research Database (GPRD) in the United Kingdom [138]. Recent examples of the use of the GPRD include studies showing no association between MMR vaccine and increased incidence of autism [139] and oral polio vaccine and intussusception [140].

Ad hoc studies are sometimes needed to study rare adverse events if the vaccine or adverse event of concern is not sufficiently represented in even large databases such as the VSD, or if confirmation of a study outcome is sought in a different population. Such an approach was used to demonstrate that there was not an increased risk of multiple sclerosis or exacerbation of multiple sclerosis following

hepatitis B vaccine using the Nurses Health Study database and the European Database for Multiple Sclerosis [141–143]. An ad hoc case-control study was conducted to demonstrate an association between intussusception and the rhesus rotavirus vaccine (RRV) [33]. Similarly, a special study was conducted to estimate an excess risk of 1 case of Guillain–Barre syndrome (GBS) per million people administered flu vaccine in the 1992–1993 and 1993–1994 flu seasons [144].

The small relative and attributable risks identified by epidemiological investigations, such as the influenza vaccine—the GBS study mentioned above, push the limits of current population-based observational cohort methods in evaluating associations between vaccines and adverse events. Structured clinical and laboratory evaluations of individual cases as part of case-control studies of rare adverse events are needed to fill the gap between surveillance and population-based cohort studies. To provide a systematic resource for case-based evaluations, the CDC has organized the Centers for Immunization Safety Assessment (CISA) [47]. These centers will serve as referral sites for clinical vaccine safety questions; develop clinical protocols for the evaluation and management of adverse events possibly related to immunization; systematically evaluate patients with similar adverse events to identify mechanisms of action and risk factors; and develop and test protocols for revaccination of people who have experienced adverse events, as has been recently carried out in Australia [145].

One area of investigation that might be particularly fruitful for case-based approaches is evaluation of the hypothesis that genetic variability is a source of increased risk for rare adverse events. At present, only a few small studies have attempted to address this issue, primarily focusing on HLA genes. One study found higher frequencies of HLA-DR2 and DR5 in women who developed joint symptoms following rubella vaccination as compared to placebo recipients with joint symptoms [146]. Another study found an increased frequency of HLA-DR9 (DRB1\*0901) and HLA-DR17 (DRB1\*0301) in Thai patients who developed autoimmune encephalomyelitis following Semple rabies vaccine [147]. Studies evaluating polymorphisms in other genes influencing immune and inflammatory responses, such as T cell receptors [147] and cytokines [148,149], might also prove to be a productive approach. Additional research in this area may help determine if certain individuals should be excluded from receiving selected immunizations or if vaccines could be designed to reduce the risk of rare adverse effects based on knowledge of genetic susceptibility.

## IV. COMPREHENSIVE ASSESSMENT, RISK MANAGEMENT, AND COMMUNICATION OF VACCINE SAFETY CONCERN

Because data on vaccine safety come from many different sources, making an overall assessment, developing a risk management plan, and communicating the plan to healthcare professionals and the public should be carried out as part of an integrated process involving vaccine developers, government agencies, regulatory authorities, and immunization recommending bodies. Systematic methods for

approaching this stage of the vaccine safety process are presented in this section.

### A. Causality Assessment

Evaluating the causal link between a vaccine and an adverse event often requires integration of different levels of information because conclusive biological evidence or data from sufficiently powered and properly conducted clinical trials are usually not available. Several general considerations, patterned after those proposed by Hill in 1965 [150] and adapted by others [151], have been generally accepted in the field of epidemiology for causal inference. The IOM used the following criteria for assessing whether evidence indicates the presence of an association between an adverse event and vaccine exposure [24].

**Strength of Association**—The strength of an association refers to the magnitude of the measure of effect of an exposure, usually the relative risk or odds ratio, in a study comparing an exposed and an unexposed group. The larger the magnitude of the effect, the less likely any observed effect is due to chance, bias, or confounding. In general, in observational studies, relative risks of 2 or less are considered to be evidence of a weak association, because the likelihood the effect is due to chance, bias, or confounding is greater than if the effect is larger [152,153]. Ecological studies alone are not generally accepted as strong evidence of causality, because they do not link individual exposure to individual outcome, and can be subject to confounding by unknown or uncontrollable factors.

**Dose–Response Relation**—A dose–response relation is defined as an increased strength of association with increased magnitude of exposure. The existence of a dose–response relation strengthens an inference that an association is causal.

**Temporally Correct Association**—Exposure must precede the event by at least the duration of disease induction. This consideration may be limited by the fact that knowledge of the pathogenesis and natural history of an adverse event may be insufficient.

**Consistency of Association**—This consideration requires that an association be found regularly in a variety of studies, using different study populations and study methods.

**Specificity of an Association**—Uniqueness of an association between an exposure and an outcome provides a stronger justification for a causal interpretation than when the association is nonspecific. However, perfect specificity between an exposure and an effect cannot be expected in all cases because of the multifactorial etiology of many disorders.

**Biological Plausibility**—The existence of a possible mechanism of action that fits existing biological or medical knowledge is thought to increase the likelihood that an association is causal. Because little is known about the details of immunopathological effects of vaccination, it is easy to generate a

theory as to how a vaccine might cause an effect. Moreover, unexpected adverse effects are unexpected because they do not have a biological explanation for their occurrence. For these reasons, biological plausibility is often considered to be a major factor only if it favors causality.

Hill also included “experimental evidence,” “analogy,” and “coherence” as additional considerations in his original discussion of causal inference [150,151]. As noted earlier, experimental evidence from clinical trials is seldom available for very rare adverse events. “Analogy” has not been accepted as strong evidence of causality because analogies between exposure and a particular condition often can be drawn, even when causal relationships do not exist. Coherence “implies that a cause and effect interpretation for an association does not conflict with what is known of the natural history and biology of the disease [151].” This guideline has been interpreted as being similar to biological plausibility, but it might also be relevant to the process of balancing among the strength of the considerations supporting a causal interpretation against the strength of alternative explanations.

### B. Risk Assessment

A complementary approach to evaluating vaccine safety concerns is the use of formal risk assessment methods, patterned after methods used for environmental exposures. The National Academy of Sciences approach involves hazard identification, dose–response analysis, exposure assessment, and risk characterization [154]. Hazard identification refers to the qualitative identification of the adverse effects in animals or humans. Dose–response analysis seeks to establish the relationship between the magnitude of the exposure and the incidence of the adverse event. Exposure assessment determines the magnitude, time, duration, and route of exposure. Risk characterization integrates the three prior steps into an assessment of causality and when adequate data are available, a quantitative estimate of risk.

Risk assessment has been most well developed for linkage of environmental chemical exposures to cancer risk, but has also been applied to neurological and other disorders. In these settings, risk assessments might involve development of complex mathematical models of disease pathogenesis linked to human risk through detailed exposure analysis that might include pharmacokinetic models, with human epidemiological studies providing empirical validation of model predictions. Complete information on human exposure and outcomes is often unavailable, so risk assessments have sometimes extrapolated outcomes in animals to humans, and from high dose to low dose exposures. In such scenarios, risk assessment serves a more qualitative purpose of identifying data gaps and framing the range of possible risk, to aid with policy making and prioritization of research. Therefore structured risk assessments may be useful in determining the scope of a potential problem, under a range of plausible assumptions.

Risk assessment methods have been applied to evaluate the possible effects of thimerosal in vaccines [155,156],

as well as the risk of Bovine Spongiform Encephalopathy (BSE) from using bovine-derived products in vaccine manufacture [64]. The risk assessment of thimerosal was primarily qualitative and identified important gaps in knowledge. In contrast, the risk assessment of BSE from vaccines resulted in a quantitative estimate of the risk that was extremely low. In these examples, the risk assessments served an important role because of limited information and the need to make decisions under uncertainty. Risk assessment is likely to be used more often as mechanistic knowledge of adverse event pathophysiology improves and can be mathematically modeled, especially for rare exposures and outcomes that might be extremely difficult to study empirically, but for which quantitative estimates of risk are desired.

### C. Benefit–Risk Analysis

As discussed throughout this chapter, vaccine approval and usage recommendations rely on benefit–risk analysis, on both a societal and individual basis. Historically, the benefit–risk analysis has been informal, primarily relying on expert opinion to integrate data [22]. Formal methods of benefit–risk analysis [157], including cost–benefit calculations, have been developed and have begun to be incorporated into vaccine decision making. Cost–benefit analyses of several vaccines have been published and strongly support the benefit of routine childhood immunizations [158,159]. Adverse events have not been widely integrated into these analyses, both because limited information on the cost of adverse events has been available and the existing data have not suggested cost is high relative to other costs in vaccination programs [160]. This might suggest that safety concerns are overemphasized relative to vaccine benefit, or that there is a different threshold for what constitutes an acceptable benefit–risk ratio between public health experts and the general public [161–163]. Better understanding and quantification of how benefits and risks are perceived and valued will be important for making informed benefit–risk evaluations and communicating and managing vaccine safety concerns [164].

### D. Comprehensive Assessment in Practice: Institute of Medicine Safety Review Committee

Previously, we discussed the role of the IOM in reviewing vaccines safety concerns in response to the National Childhood Vaccine Injury Act of 1986. Recognizing the continued need for comprehensive analyses of vaccine safety, the CDC and NIH asked the IOM to establish an independent Immunization Safety Review Committee. The committee has been chartered to meet three times per year over the 3-year study period (2001–2003) to review immunization safety issues by examining the current biologic and epidemiologic evidence of causality, the biological mechanisms of adverse events, and the larger societal context. To date, the committee has evaluated and released reports on MMR and autism [165], thimerosal-containing vaccines and neurodevelopmental disorders [166], multiple immunizations and immune dysfunction [167], and hepatitis B vaccine and neurological

disorders [168]. In addition, a separate committee to evaluate the safety and efficacy of anthrax vaccine was convened at the request of the Department of Defense because of concerns from within and outside of the military [56]. With regard to MMR and autism, the IOM concluded that the evidence favors rejection of a causal relationship at the population level between MMR vaccine and autism spectrum disorders (ASD) [165]. The committee found inadequate evidence to accept or reject a causal relationship between thimerosal-containing vaccines and neurodevelopmental disorders [166]. The IOM committee evaluating anthrax vaccine concluded that the anthrax vaccine is an effective vaccine to protect humans against anthrax and that it was “reasonably safe” [56]. For each of the above immunization safety concerns, the IOM recommended additional research to clarify any possible connections and to improve the way the government communicates benefits and risks of vaccination to vaccine recipients.

### E. Risk Management and Communication

Risk management in the context of immunizations is the process of maximizing the benefits of vaccines while minimizing associated risks when considered in the context of the population as well as the individual [169]. Risk management occurs at all stages of product development and use, as has been outlined in this chapter. Participants in risk management decisions include scientists developing vaccines, manufacturers, regulatory agencies, immunization advisory bodies (e.g., the Advisory Committee on Immunization Practices and AAP’s Committee on Infectious Diseases), other government public health agencies (e.g., CDC, NIH, VICP), federal and state legislators, vaccine providers and patients. A vaccine is licensed when regulatory authorities judge that the benefits of using the vaccine outweigh the risks for the intended population and use. A major goal of the prelicensure studies and review is to ensure that accurate information about benefits and risks of vaccination is available to those participating in risk management decisions following licensure.

Once a vaccine is licensed, responsibility for risk management expands from regulatory authorities to include others making decisions on appropriate use of the product, including immunization advisory bodies, other government agencies monitoring and assessing vaccine safety, immunization providers, and individuals receiving vaccinations. However, the decision making capacity of individuals and healthcare providers regarding immunizations may be limited by school entry laws or by service in the military. In this context, delineating the benefits and risks is only the first step. Successful immunization strategies require an understanding of the ethical underpinnings of immunization policy [170], the role of risk perception in vaccination decisions [164], and optimal risk communication strategies [171,172]. At the heart of ethical immunization policies is the equitable allocation of benefits and risks between individuals and society. A systematic approach for developing immunization policy, integrating epidemiologic, economic and ethical concerns, may help focus risk management decisions and sustain societal consensus on immunizations [170].

Because science does not speak for itself, dissemination of accurate and meaningful information on the benefits and risks of immunization is essential to maintain public confidence in immunizations. Given the complexity of vaccine science and the many factors entering vaccine policy, there is concern that misinformation can adversely impact informed decision making, with consequences for the individual and the community [2,173–175]. The field of risk communication has developed from the need to find effective ways to communicate health risks. Researchers in this field have recognized the discrepancy between how scientists explained health risks and what the public believed [176], and have drawn upon scientific facts, ethical principles, cognitive and social psychology, and behavioral decision theory to improve approaches for conveying risk information [177,178]. In this context, communication begins by identifying the information of most relevance to individuals making immunization decisions, determining what these individuals know and filling in the gaps, recognizing that different populations are likely to have different information needs [171, 178–180].

Many factors influence the acceptability of risks to individuals; risks that are voluntary and controllable, considered natural (as opposed to man-made), and memorable are more likely to be accepted [181]. Risk communication research has demonstrated that individuals are unlikely to undertake a risk control measure, such as immunization, unless they perceive both a serious threat and some control over it [182], emphasizing the importance of involving individuals in immunization decisions.

In our contemporary society, individuals seek and receive immunization information from a variety of sources, complicating the task of public health officials and healthcare providers seeking to promote immunizations. The internet provides a wealth of relevant information but can serve as an unfiltered stream of anecdotes and allegations regarding adverse events following vaccination [183]. The media plays a critical role in shaping public perceptions on vaccine benefits and risks. The development and dissemination of accurate and balanced information at the time of vaccine licensure, and the prompt evaluation of new safety concerns arising postlicensure, may prevent an “early idealization–sudden condemnation” portrayal of a vaccine in the media that can affect public opinion and undermine immunization programs [184].

## V. INTEGRATING SAFETY CONSIDERATIONS INTO NEW VACCINE DEVELOPMENT

In the preceding sections of this chapter, we have presented an overview of vaccine safety with important lessons learned from historical examples and reviewed the methods currently employed for evaluating and communicating safety concerns. Several themes emerge that are important for new vaccine developers. First, vaccines have real risks that may include serious adverse effects. Second, despite the favorable benefit-to-risk ratio in favor of vaccination, public concern about vaccine safety is legitimate and is best dealt with through the application of sound scientific methods to

vaccine evaluation, with clear communication of findings to the public. Third, the perceived risk of a vaccine is as vital to its success or failure as the efficacy and safety profiles. Fourth, we can learn from history, because public concerns about vaccine safety have demonstrated recurring themes, such as the need for quality control of production, philosophical beliefs about individual choice, and changing benefit-to-risk ratios.

The best way to prepare for vaccine safety issues is to build them into the product development cycle by “reverse engineering” potential safety concerns. This can be carried out by focusing on the target population and the product. At the earliest phases of development, vaccine researchers should bear in mind the product’s ultimate indication and intended target population to be reflected in the product label, and apply this information in a development plan to acquire necessary data on safety and efficacy. Considering the “the label as the product” gives the vaccine developer the perspective needed to make judgments as to the type and quantity of safety data required to support licensure, including preclinical toxicity testing and sample size of clinical studies. For example, the required data might differ for a vaccine intended for universal use in children compared with one to be used in more niche populations such as adult travelers.

Depending on the product class, some potential safety concerns are known *a priori* or can be predicted from the historical experience of development of vaccines from the same class. Examples of particular concerns include the potential association of group A streptococcal vaccines with rheumatic heart disease due to cross reaction between the M proteins of vaccines with human tissues [185] inactivated RSV vaccines and enhanced RSV disease [17], and OPV and vaccine-associated paralytic polio. Even for product classes for which there is limited human experience, e.g., DNA vaccines, theoretical concerns or those generated from laboratory experience can guide the vaccine developer through the first steps of safety testing. Specific preclinical testing and clinical evaluations depend on the type of product under development, e.g., adventitious agent testing in vaccines produced in animal or human cell substrates, and monitoring for clinical symptoms and evaluating persistence of vaccine strains in studies of live attenuated vaccines.

Understanding the background incidence of illness occurring in the target population and anticipating risks that might be perceived as related to vaccination may be as important as understanding the product-related risks, because ultimately the intended population will need to be convinced that the vaccine is safe enough to use. The developer can begin this process by identifying the diseases in the target population that might be suspected to be related to the vaccine because onset or diagnosis may coincide with the timing of immunizations. History is a good guide in this arena. Neurological, rheumatological, and other immune-mediated disorders have been attributed to vaccines when other etiologies could not be established. In addition, disorders that are not well understood but have occurred with some temporal relation to immunization, such as Sudden Infant Death Syndrome or Gulf War syndrome, have also been linked with immunization in the minds of the public.

To deal with such concerns, researchers should decide whether it is necessary, based on benefit–risk considerations and incidence in the target population, to develop evidence that the vaccine does not cause a particular condition. Considerations should take into account risk perception in addition to actual risk, and whether such perceptions may affect public acceptance of the vaccine. For example, vaccine developers may choose to evaluate a possible association between a new rotavirus vaccine and intussusception. For concerns that warrant further evaluation, the next step is to decide where in the development cycle it can and should it be evaluated, e.g., preclinical testing, licensure clinical trials, or Phase IV studies. Ultimately, the aim of safety assessments should be to provide adequate data to support licensure and recommendations for use as well as communicating the benefits and risks of the vaccines to health care providers and the public.

## VI. CONCLUSION

The current system of vaccine development and monitoring has resulted in vaccines with very low risk of serious adverse effects. However, continued vigilance regarding immunization safety is necessary based on lessons from the past, as well as the need to ensure the safety of new vaccines and new immunization technologies. Perceptions of vaccine risks can affect public acceptance of immunizations and the success of immunization strategies. Immunization safety requires careful application of preclinical evaluation and quality control testing, well-designed clinical studies, and postlicensure assessments including surveillance for adverse events. The challenge remains to apply the best scientific methods to the task, and effectively communicate that science to the public.

## Polio Eradication: Capturing the Full Potential of a Vaccine

R. Bruce Aylward, Rudolph Tangermann, and Roland Sutter

*World Health Organization, Geneva, Switzerland*

Stephen L. Cochi

*Centers for Disease Control and Prevention, Atlanta, Georgia, U.S.A.*

### I. INTRODUCTION

In 1980, certification of the eradication of smallpox finally confirmed that certain diseases could not only be successfully controlled at very low incidence, but actually eradicated such that the control measures could be stopped, potentially for all time [1]. That a vaccine was the tool behind this first successful eradication initiative reaffirmed the promise and the potential of immunization in achieving this “ultimate goal of public health” [2]. The eradication of smallpox is frequently cited as the most important international public health achievement in the 20th century, and for many years has stood as a unique testament to humankind’s capacity to completely eliminate a significant cause of morbidity and mortality [3].

It is now increasingly certain, however, that the early years of the 21st century will see the successful eradication of another important pathogen, in this case poliomyelitis, and again with immunization as the core strategy [4]. Despite having been launched in an environment that was rather hostile to targeted programs in the years following smallpox eradication [5], the global polio eradication initiative has grown to become the largest international health initiative ever, with the capacity to not only eliminate one of the leading causes of permanent disability, but to substantially enhance the capacity to control other important diseases, particularly those that are vaccine-preventable [6,7].

This chapter outlines the rationale for launching an eradication initiative against polio in 1988, the progress that has been made as of end-2001, and the challenges that remain to certify the world as polio-free, to achieve containment of wild poliovirus stocks, and to develop international consensus on postcertification polio immunization policy.

### II. RATIONALE FOR POLIO ERADICATION

Building on the lessons of nearly 100 years of disease eradication, two international conferences in the late 1990s proposed three major criteria that should be met prior to undertaking the eradication of a specific disease [8,9]. These criteria provide a useful framework for explaining the rationale for launching the global polio eradication initiative: (1) biological and technical feasibility, (2) a positive benefit:cost ratio, and (3) sufficient societal and political support (Table 1).

#### A. Technical Feasibility

The issues that are central to evaluating the biological and technical feasibility of eradicating a disease [10] can be summarized as follows:

- An effective intervention and delivery strategy that can interrupt transmission
- Practical diagnostic tools with sufficient sensitivity and specificity
- Absence of a nonhuman reservoir.

There must also be “proof of concept,” with the application of these interventions, strategies, and tools having been proven to interrupt the transmission of the target organism in a large geographical area [9]. By 1988, these issues had been largely resolved for polio through a combination of the available scientific background information and the progress toward regional eradication in the western hemisphere (WHO Region of the Americas) [11,12].

In terms of an effective intervention and delivery strategy, health authorities in Cuba had demonstrated as early as 1962 that the intermittent pulsing of the child population with oral poliovirus vaccine (OPV) in mass campaigns could

**Table 1** Poliomyelitis and the 1997 Dahlem Eradication Criteria

Criteria for targeting a disease for eradication	Poliomyelitis
Biological and technical feasibility	
Etiologic agent	Virus
Nonhuman reservoir	No
Effective intervention tool	OPV
Effective delivery strategy	NIDs
Simple/practical diagnostic	Stool culture
Sensitive surveillance	Facility-based active surveillance
Field-proven strategies	Western hemisphere
Costs and benefits	
Cases averted per year	> 350 000
Coincident benefits	Improved immunization and surveillance capacity
Intangible benefits	Culture of prevention and social equity
Estimated annual direct global savings	US\$1.5 billion
Estimated total external financing	US\$2.75 billion
Societal and political considerations	
Political commitment (endemic/industrial countries)	Variable/variable
Societal support (endemic/industrial countries)	Strong/strong
Disease burden in politically unstable areas (% cases from war-torn countries)	10–20% (estimated)
Core partnerships and advocates	WHO, Rotary, CDC, UNICEF
Technical consensus	World Health Assembly
Donor base (number of donors of US\$1 million or more in 1998–1999)	26

WHO = World Health Organization; CDC = U.S. Centers for Disease Control and Prevention.

rapidly interrupt the transmission of wild poliovirus [13,14]. By the 1980s, this strategy was having a similar impact in Brazil [15], leading the Regional Director of the Pan American Health Organization (PAHO) to launch a regional elimination campaign in 1985 [16].

The eradication initiative relied on the use of OPV in countries where polio was endemic or had recently been endemic, because inactivated poliovirus vaccine (IPV) had only interrupted transmission in three industrialized countries, all in northern Europe and all with very high routine immunization coverage (Finland, the Netherlands, and Sweden). Not only had OPV been found capable of stopping transmission in tropical climates, it also induced

secretory intestinal immunity superior to that of IPV and protected some close contacts of vaccinees [17,18]. Furthermore, the low cost and oral administration route of OPV made it much more suited to the mass delivery strategy required for eradication. Although there has been substantial opposition to the use of this campaign strategy, routine immunization alone was proven to be insufficient to stop wild poliovirus transmission in most developing countries [19], even as coverage increased steadily after the establishment of the Expanded Program on Immunization (EPI) in 1974 [20].

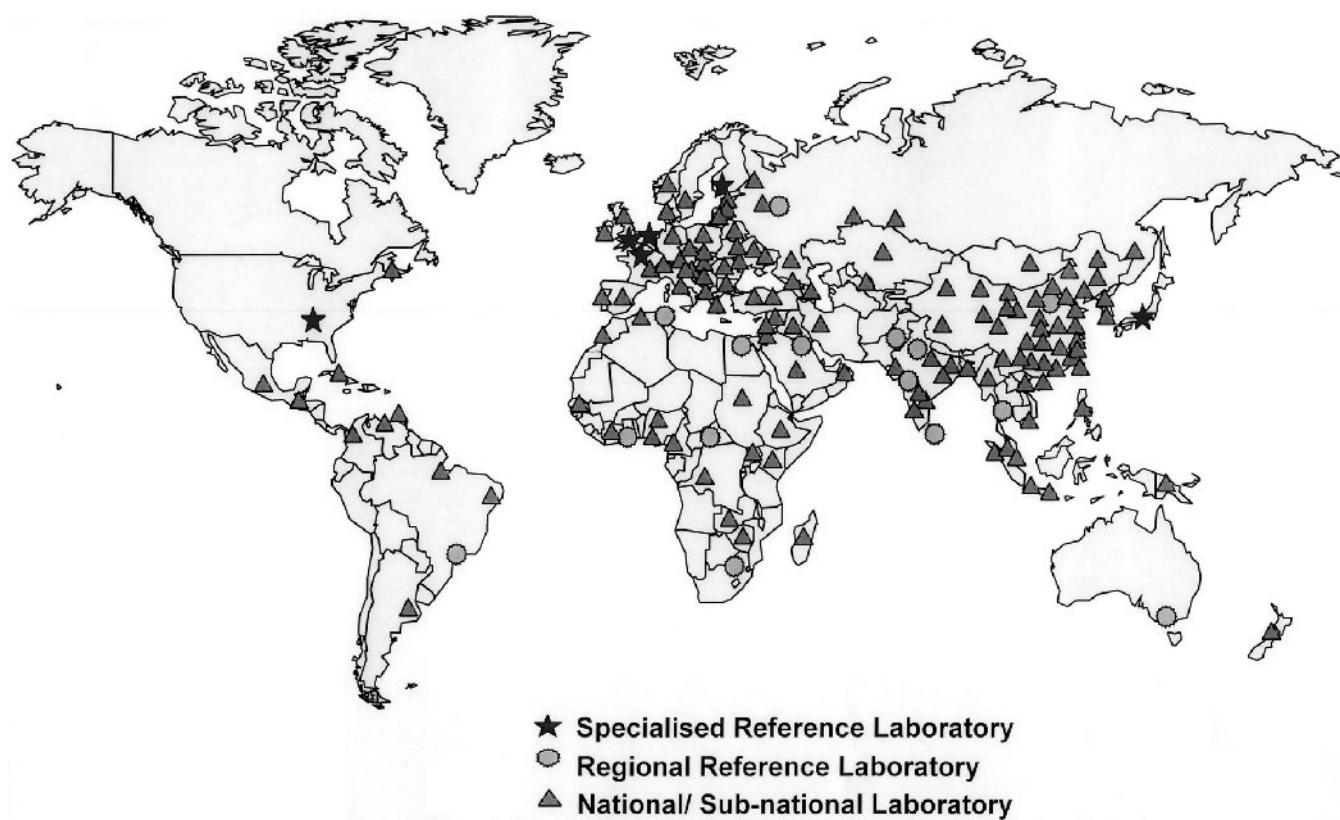

Establishing a sensitive and specific system for polio diagnosis was as demanding as the challenges of implementing mass OPV campaigns. Unlike the characteristic rash and consequent scarring caused by smallpox, the majority of wild poliovirus infections (> 99%) are subclinical [21] and cannot be definitively confirmed clinically, even when there is paralysis [22,23]. Serological testing was inadequate for polio diagnosis because it could not reliably distinguish antibodies due to wild polioviruses from those produced by the vaccine. Consequently, viral culture from stool specimens became the preferred method for diagnosing polio in the eradication initiative [24].

To practically apply this tool, PAHO developed a strategy of acute flaccid paralysis (AFP) surveillance, whereby all cases of AFP in persons aged less than 15 years were to be investigated, with the collection of two stool specimens within 14 days of paralysis onset [25]. Because AFP cases occur in the absence of polio, a standard of >1 case of non-polio AFP per 100,000 population aged less than 15 years was established as the principal indicator of surveillance sensitivity for eradication [26–28]. Combined with indicators for the completeness of specimen collection (target > 80%) and their processing in a World Health Organization (WHO)-accredited laboratory (target 100%), this allowed international comparisons of surveillance performance [29] and the demonstration that surveillance was sufficient for certification [30]. A global network of enterovirus laboratories, with a detailed accreditation system, was developed to ensure reliable isolation, identification, and genomic characterization of poliovirus from the stool specimens of AFP cases [31,32] (Fig. 1).

Finally, polio eradication is biologically feasible because humans are essential for the life cycle of the virus, which has no other reservoir and does not amplify in the environment. Although polio has been described among orangutans, chimpanzees, gorillas in captivity, and chimpanzees in the wild, these species appear to be incidental hosts with populations too small to sustain transmission [33]. Similarly, viable viruses cannot be found in sewage or surface water for more than several weeks after circulation ceases among humans [33].

## B. Benefit:Cost Ratio of Eradication

The direct humanitarian benefits of ensuring that polio will never again be experienced by any person in perpetuity are substantial. In the absence of vaccination, 0.5% of children (i.e., 650,000) in every annual birth cohort of ca. 130 million infants would become paralyzed as a result of poliovirus

**Figure 1** Network of enterovirus laboratories that comprise the Global Polio Laboratory Network as of June 2002.

infection [34]. As recently as 1988, the year the eradication goal was adopted, an estimated 350,000 cases of paralytic polio were still occurring [35]. Because the majority of victims survive the acute illness, the prevalence of paralytic cases may be as high as 20 million. Lame ness surveys in the 1970s revealed polio to be a leading cause of permanent disability in developing countries [36,37]. In the 1990s, surveys in Afghanistan and Cambodia demonstrated that polio continued to be a leading cause of permanent disability even in war-torn countries [38].

Economic analyses of disease eradication are problematic and somewhat controversial because of the lack of consensus on how to value benefits that accrue in perpetuity [39]. Despite these limitations, several attempts have been made to estimate the economic costs and benefits of polio-myelitis eradication [40–42]. The most comprehensive analysis estimated annual global savings of US\$1.5 billion per year once polio has been eradicated and all control measures have been stopped [40]. A more recent analysis suggests that even in a “worst case scenario” in which a universal IPV strategy was implemented following global certification, the cost per DALY saved would still be quite low at less than US\$50 [42].

Although these direct benefits of polio eradication are substantial, it was the indirect or consequent benefits that formed the basis for launching the initiative in the Americas [43] and were central to the World Health Assembly resolu-

tion that endorsed the global eradication target [44]. The “indirect benefits” included the potential for boosting immunization programs and for establishing sensitive surveillance systems, and were as important as the eradication of the disease itself [45].

### C. Societal and Political Support for Eradication

Perhaps the least understood determinant of the feasibility of eradicating an organism is the need for sufficient societal and political commitment to launch and to sustain such an initiative through the 15–20 years that will be required to implement the necessary strategies [46]. Although the successful conclusion of the smallpox eradication campaign in 1977 created some momentum for new eradication efforts, this enthusiasm was countered by concerns that pursuing targeted objectives could compromise efforts to develop strong primary health care systems [5]. Within the scientific community, substantial doubts as to the technical feasibility of polio eradication [47] were increasingly resolved with the progress in the Americas by the mid-1980s.

The event that is considered to have been pivotal in transforming the regional PAHO elimination goal into a global effort was a March 1988 meeting convened by the Task Force for Child Survival and Development [48]. During this meeting, the Director-General of WHO was convinced of the merit of a global eradication effort and, only 2

months later, put the matter to a vote at the World Health Assembly. In May 1988, the World Health Assembly, consisting of the Ministers of Health of all member states, unanimously endorsed the polio eradication resolution [44]. The eradication goal was subsequently reviewed and endorsed by the World Summit for Children in 1990, the largest ever gathering of Heads of State [49]. Health and political leaders from low-income, middle-income, and high-income countries have continued to reconfirm their commitment through resolutions adopted in forums such as the Organization of African Unity (OAU), the South Asian Association for Regional Cooperation (SAARC), and the 2002 G8 summit [50,51]. These leaders have repeatedly reinforced and publicly demonstrated their leadership role by participating in highly visible events such as the launching of National Immunization Days (NIDs).

### **III. PROGRESS TOWARD GLOBAL POLIO ERADICATION**

#### **A. Implementation of the Eradication Strategies**

The principal strategies employed by the global polio eradication initiative were developed in the WHO Region of the Americas during the 1980s [43] and consist of: (1) achieving and maintaining high coverage with at least three doses of oral polio vaccine (OPV3); (2) providing supplementary doses of OPV to all children aged < 5 years during NIDs; (3) surveillance for all cases of AFP in children aged under 15 years of age, with the virological examination of stool specimens from each case; and (4) house-to-house OPV “mop-up” campaigns, targeting areas with persisting wild poliovirus transmission.

Reaching and maintaining high OPV3 coverage is the foundation of polio eradication. In a number of temperate, industrialized countries, high OPV3 alone has been sufficient to interrupt the transmission of wild poliovirus [52]. In developing countries, however, polio transmission usually persists, even with good OPV3 coverage, due to suboptimal sanitation, high population density, and lower levels of seroconversion compared with temperate climates [53]. Furthermore, global OPV3 coverage was only 67% in 1988, the year the global initiative began, and never reached more than 80% in the subsequent years [54], with substantial differences between WHO regions. As recently as 1999, the African Region had coverage of less than 50%.

The use of supplementary OPV campaigns for polio eradication is based on the work of Sabin et al. [55] and Grachev [56], who first used mass immunization to control polio epidemics in Hungary [57] and the Soviet Union. The PAHO refined the strategy prior to recommending NIDs for all endemic countries in the Americas in 1985. The effectiveness and global applicability of the NID strategy were further established in China and other countries of the Western Pacific Region [58,59] in the mid-1990s. National Immunization Days are conducted during the low season of poliovirus transmission in two rounds, 4–6 weeks apart [60]. During each round, OPV is administered to all children < 5 years of age, regardless of previous immunization status. By

rapidly increasing the systemic and intestinal immunity in this group, NIDs raise the overall level of immunity of the population, decreasing further spread of the virus [61]. As of 1999, NIDs had been introduced in all countries endemic for wild poliovirus, with subnational rounds added where appropriate.

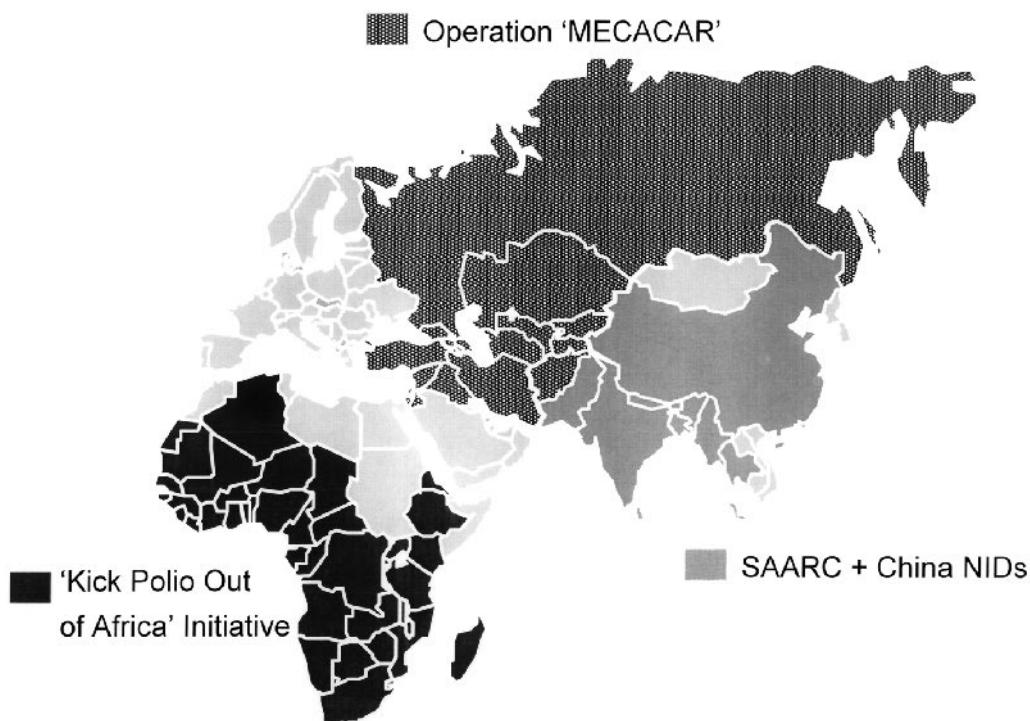

Even with high-quality NIDs in individual countries, however, people crossing borders could transmit polio in the interval between the NIDs in one country and its neighbor, thus reestablishing virus circulation and reducing impact. Recognizing this, many countries decided to synchronize their NIDs (Fig. 2). In “Operation MECACAR,” for example, 18 countries of the Mediterranean, Caucasus, Central Asian Republics, and Russia immunized 56 million children in each of two rounds in April and May 1995 [62]. Similar activities followed in South Asia and West Africa [63,64]. In July 2001, the conflict-affected countries of the Democratic Republic of the Congo, Angola, Congo, and Gabon began three rounds of synchronized NIDs, reaching 15 million children [4,64]. In most countries, NIDs were the largest public health activities ever conducted. China repeatedly immunized > 80 million children during NIDs, whereas up to 150 million children continue to be targeted during NID rounds in India [63,65]. In 2001 alone, NIDs or sub-NIDs reached over 575 million children in 94 countries [4].

Although process indicators and coverage estimates help evaluate the quality of NIDs, surveillance outcomes have been the real measure of their effectiveness [66]. By 2001, all WHO regions were approaching “certification quality” AFP surveillance, as measured by the three key AFP performance indicators (Table 2) [4]. Through a massive investment in human resources, equipment, and training, certification standard AFP reporting had been achieved or was imminent in countries as challenging as Afghanistan, Angola, the Democratic Republic of the Congo, Somalia, and southern Sudan. In the year 2001, every one of the 63,392 diagnostic specimens from 31,429 AFP cases in the world were processed in 1 of 145 WHO-accredited “polio” laboratories worldwide, with results for 91% of cases reported within 28 days after receiving the specimens [32].

Once surveillance has identified a final reservoir of wild poliovirus, mop-up campaigns are conducted on a house-to-house basis to ensure that every child in the area is found and immunized [12,17,43]. Massive mop-up campaigns were first used to interrupt the last foci of transmission in the Americas in Colombia in 1991 (850,000 children) and in Peru in 1992 (1.9 million children) [43]. During 1995–1997, mop-up campaigns targeting 3 million children eliminated the last polio reservoir of the WHO Western Pacific Region in the Mekong River delta area [67]. A two-region, four-country mop-up operation across Turkey, Syria, Iran, and Iraq interrupted the last chains of transmission in the WHO Region of Europe [68].

#### **B. The Polio Eradication Infrastructure**

Although polio eradication activities have been led, coordinated, and implemented by the governments of the polio-infected countries themselves, the support of an extraordinary partnership has been essential. This public-

**Figure 2** Selected examples of coordinated NIDs for the purpose of polio eradication (see text).

private partnership, spearheaded by the WHO, Rotary International, the U.S. Centers for Disease Control and Prevention (CDC), and the United Nations Children's Fund (UNICEF) has facilitated the inputs of donor governments (e.g., bilateral development agencies), other international organizations (e.g., UN funds, agencies, and programs), foundations, corporations, nongovernmental organizations (NGOs), and humanitarian organizations. The most remarkable of these partners is Rotary International, the private sector service organization which, through its Polio-Plus Program and 1.2 million members worldwide, will have contributed nearly US\$600 million by end-2005 (Fig. 3).

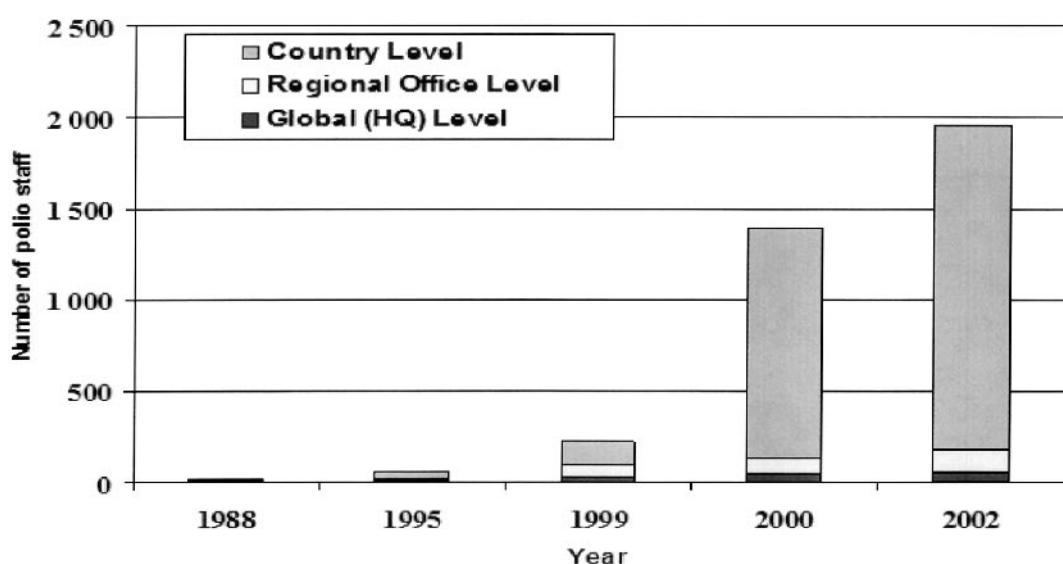

Nongovernmental and humanitarian organizations such as the International Red Cross and Red Crescent Movement, Médecins Sans Frontières (MSF), Save the

Children Fund, World Vision, and CARE have collaborated, particularly in conflict-affected areas. United Nations agencies have facilitated activities through the provision of transport, human resources, security, and communications. The WHO alone has deployed 2000 national and international staff to assist the implementation of eradication activities worldwide (Fig. 4).

A variety of mechanisms were established at the global, regional, and country levels to coordinate this partnership. Strategical planning, policy development, and priority setting are discussed and agreed through technical oversight bodies convened by WHO every 6–12 months at the global and regional levels. Resource mobilization and financing is managed through Interagency Coordinating Committee (ICC) meetings, at the regional and country levels. Similar mechanisms have been established to manage the core partnership and the global laboratory network.

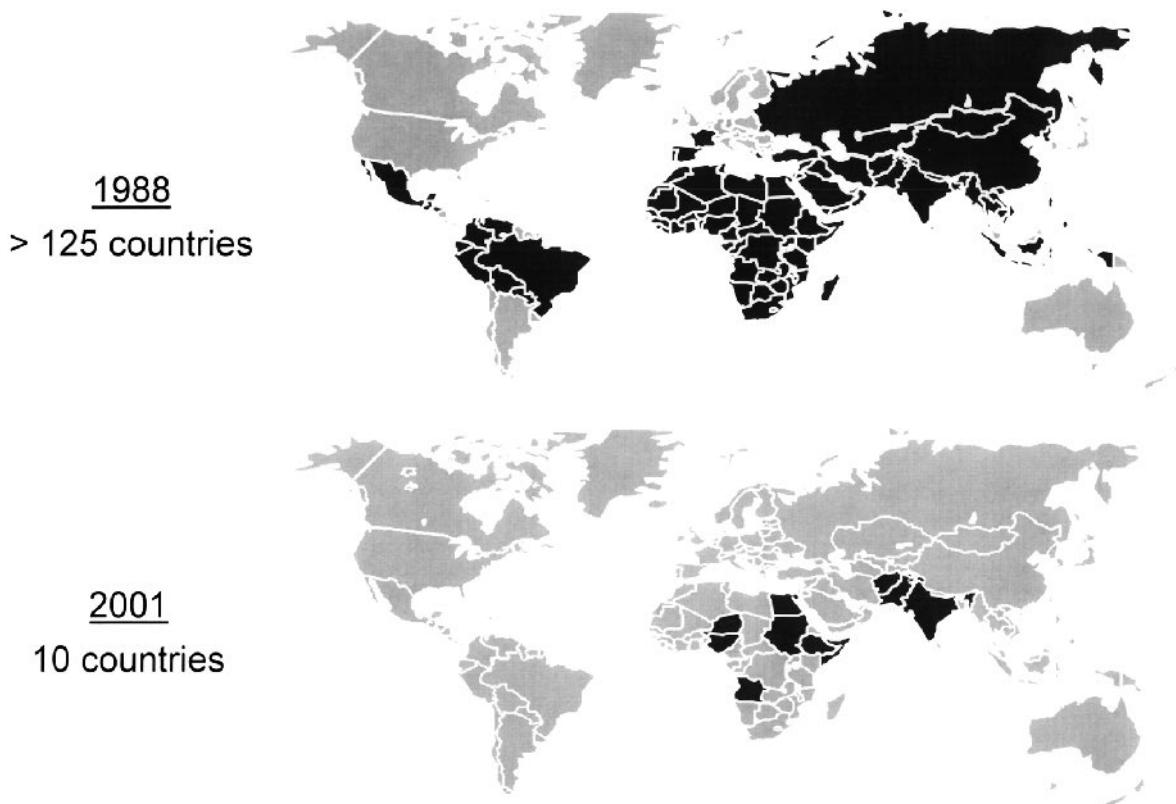

### C. Impact on Polio Transmission

When the global polio eradication initiative was launched in 1988, over 125 countries on five continents were known or suspected to have had indigenous transmission of wild poliovirus (Fig. 5). Wild poliovirus transmission was confirmed in all six of the WHO geopolitical regional groupings. Although only 35,031 cases were reported worldwide in 1988 [69], it is estimated that over 350,000 children were actually paralyzed in that year, with over 90% having gone unreported [3,35]. Fully half of these cases occurred on the Asian subcontinent, with the majority in India. Outside of the Americas, which had launched its regional eradication initiative in 1985, only a handful of areas, mainly industrialized countries and small island nations, were free of polio at that time.

\*Long term polio staff including secondments, but excluding contracts of less than six months and drivers. (year 2002 total including drivers = 2 515).

**Figure 4** Growth of WHO national and international staff deployed through the polio eradication initiative, as of June 2002.

**Figure 5** Known and suspected distribution of indigenous wild poliovirus in 1988, the year the global polio eradication initiative was launched, and at end-2001.

Following the WHA resolution to eradicate polio, progress was most rapid in the Americas, with the last case occurring in Peru in August 1991 [43]. In fact, it was only in the early to mid-1990s that strategy implementation began in earnest in other areas, most notably the Western Pacific, Eastern Mediterranean, and European Regions of WHO. Of the 28 countries of the Western Pacific, only six were still endemic by 1993: China, Cambodia, the Lao People's Democratic Republic (Lao PDR), the Philippines, and Vietnam [67]. As NIDs and mop-up campaigns were introduced by the mid-1990s, transmission was rapidly interrupted, with the last case occurring in Cambodia in March 1997 [67]. In the European Region, progress accelerated when NIDs were synchronized with the Eastern Mediterranean in Operation MECACAR, beginning in March–April 1995 [62]. Although repeated importations continued to plague the European Region, by 1998, the only focus of indigenous transmission was in southeast Turkey, where the last case occurred in November of that year [68].

In the Southeast Asian Region of WHO, one of the most important milestones was the launching of NIDs in India in 1995 [51]. By 2001, transmission had stopped in 9 of 10 countries in this most densely populated of WHO regions [4]. The exception was India, where indigenous polio was restricted to only 2 of 30 states by late 2000. The cessation of transmission in Indonesia (last case in 1995) and Bangladesh

(last case in 2000) reinforced the effectiveness of the eradication strategies in even the most highly populated areas [4]. Many of the 23 countries of the Eastern Mediterranean Region introduced the strategies in the early 1990s and stopped transmission soon thereafter, particularly in north Africa, the countries of the Levant, and the Arab Gulf States [70]. By end-2001, intense transmission was limited to Pakistan, with less than 10 virus-confirmed cases from each of Afghanistan, Somalia, the Sudan, and Egypt in that year [4]. In the WHO Region of Africa, which comprises 46 countries mostly in sub-Saharan Africa, eradication really began with the 1996 “Polio-free Africa” declaration at the OAU, championed by Mr. Nelson Mandela [50]. Within 2 years, transmission had been interrupted in all countries of southern and eastern Africa, with the exception of Angola [71]. By end-2001, the intensity and quality of NIDs had increased in the region such that indigenous polio was restricted to Nigeria, Niger, and Angola [4]. Even the Democratic Republic of the Congo appeared to be polio-free by the end of that year.

By end-2001, polio was on the brink of eradication, with only 10 countries still endemic for the wild virus (Fig. 5) and just 480 virologically confirmed cases worldwide in that year [4]. The 10 remaining endemic countries constituted three “high-transmission” zones (north India, Pakistan/Afghanistan, and Nigeria/Niger) and three “low-transmission”

zones (Horn of Africa—consisting of Ethiopia, Sudan, Somalia; Angola; and Egypt). India was of particular concern, with 56% of all cases worldwide, even though there had been a 50% reduction in the number of infected districts and a two-thirds decline in the number of lineages of circulating type 1 wild poliovirus compared with 2000. Of particular note, type 2 wild poliovirus has not been isolated anywhere in the world since October 1999 [72].

During 2001, the rapid containment of wild poliovirus importations into four previously polio-free areas reaffirmed the robustness of the progress that has been made. In Bulgaria, Georgia, Algeria, and Zambia, virus importations from other countries were successfully eliminated with large-scale surveillance and immunization response activities.

#### D. Impact on Other Health Services

Although there is widespread consensus that progress has been made in eradicating polioviruses [4], there is substantial controversy as to whether this has strengthened the delivery of other health services [6,73]. Some observers have felt that polio eradication has been detrimental to a sound, integrated approach to health systems development, whereas others have argued that any untoward effects of the initiative have been relatively minor and have been outweighed by the benefits [74–76]. A number of studies have attempted to reconcile these positions through evaluations of the relationship between polio eradication and routine immunization service delivery, disease surveillance, the delivery of other preventive services, health systems development, broader social and societal benefits, or a combination of the above.

Irrefutable benefits in the delivery of other health services include a marked expansion of vitamin A supplementation, enhanced global disease surveillance capacity, improved cooperation among enterovirus laboratories worldwide, and stronger partner coordinating mechanisms [7,77]. Including vitamin A supplements in polio NIDs averted an estimated 400,000 childhood deaths in 1998–1999 alone, and strengthened the links between EPI contacts and micronutrient supplementation [78,79]. The surveillance capacity developed for polio has now been used to detect and respond to outbreaks of important diseases such as measles, meningitis, cholera, and yellow fever [80]. The international consensus on the value of this “indirect benefit” is reflected in widespread support for plans to expand and sustain this capacity to enhance the control of other important public health problems. In most WHO regions and in many countries, the mandate of the ICC that was established for the coordination of polio eradication partner inputs has now been expanded to facilitate the broader immunization goals of the Global Alliance on Vaccines and Immunization (GAVI) [81,82].

More controversial has been the impact of eradication on the delivery of routine immunizations [75,83,84]. That the polio initiative has made a huge investment in the physical and human resources for routine immunization is incontrovertible; the cold chain, communications, and transport capacity have been largely replaced or refurbished in many low-income countries, particularly in sub-Saharan Africa, and tens of thousands of vaccinators have been trained or

retrained worldwide. The question remains as to whether the disruptions caused by polio NIDs will have only short-term effects or long-term impacts on routine services [6].

Despite the many studies that have been undertaken to evaluate the broader impact of polio eradication on health systems, most were hampered by a lack of credible baseline data, the absence of “control groups,” and the concurrent implementation of major health system reforms, such as decentralization and sectorwide approaches [6,85]. Most commentators do agree that positive synergies exist between polio eradication and health systems development but that these opportunities must be better exploited [7,85,86].

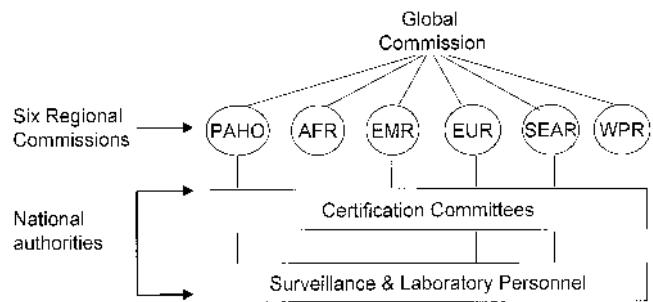

### IV. THE “POSTERADICATION” ERA

As was the case with smallpox, substantial work is required in the areas of certification, containment, and postcertification polio immunization policy to realize the full benefits of the polio eradication initiative.

#### A. Certification of Global Polio Eradication

In 1995, an independent 13-member Global Certification Commission (GCC) was established to develop the criteria for, and oversee the process of, certification of eradication of wild poliovirus transmission [87]. A formal process has now been developed, which focuses on epidemiological blocks of countries, the length of polio-free time, and the quality of surveillance (Fig. 6) [30]. The GCC has stated that the key criterion for global certification will be the absence of wild poliovirus transmission throughout the world for three consecutive years in the presence of excellent surveillance [87, 88]. Surveillance for cases of AFP will provide the most important information, with the quality demonstrated by the standard AFP indicators now in use by the eradication initiative [29,88]. Of particular importance will be the investigation of at least one case of nonpolio AFP per 100,000 children aged less than 15 years, with the collection of adequate stool specimens from at least 80% of cases. Such quality surveillance has now proven to be a key indicator of whether a surveillance system could detect polio if the virus was present.

The GCC also decided in 1995 that certification would be on a region-by-region basis, with commissions estab-

**Figure 6** Structure of the process for global certification of the interruption of wild poliovirus transmission.

lished for each of the six WHO regions [87,88]. No region could be certified until every country had achieved the abovementioned criteria, with the data submitted and verified by a National Certification Committee. In 1997, the GCC stated that global certification would also require laboratory containment of wild poliovirus stocks and potentially infectious materials [88] as detailed in the *WHO Global Action Plan for the Containment of Wild Polioviruses* [89]. When two polio outbreaks were caused by circulating vaccine-derived polioviruses (cVDPVs) in 2000–2001 (see below), the GCC reviewed the implications for certification, deciding that it would be premature to include the absence of such events as a precondition for global certification [90].

The experience in three WHO regions (the Americas, Western Pacific, and Europe certified in 1994, 2000, and 2002, respectively), which comprises a total of 115 countries and over 3 billion people, has now demonstrated that the process and the criteria for certifying eradication of indigenous wild poliovirus transmission are sound [91].

### B. Containment of Wild Polioviruses

That the last case of smallpox occurred as a result of a laboratory containment failure in Birmingham, England in 1978, 1 year after the global eradication of smallpox [92], serves as an important reminder of the need for effective containment of wild polioviruses. Consequently, the WHO began work on a global action plan for laboratory containment of wild polioviruses in 1997 to identify and to inventory laboratories worldwide that store wild poliovirus and potentially infectious materials, and to ensure that those materials are handled under appropriate biosafety conditions in the postcertification era. The goal of the containment plan is to reduce the risk of an accidental or intentional reintroduction of wild poliovirus into the community from a laboratory or vaccine production site.

The process of laboratory containment was developed through international consultation with a draft action plan widely distributed for comment in 1998, prior to publication of the WHO global action plan for laboratory containment of wild polioviruses in 1999 [89]. In mid-1999, the World Health Assembly unanimously passed resolution WHA52.22, urging all Member States “to begin the process leading to the laboratory containment of wild poliovirus” [93].

Implementation of the global action plan is a tremendous logistical challenge due to the large number of biomedical laboratories worldwide that need to be contacted. However, progress in the WHO European and Western Pacific Regions demonstrates that effective laboratory containment is feasible [94] (Table 3). As of mid-2002, 129 of 216 (60%) countries and territories had appointed a National Coordinator for containment and 122 (56%) had created a National Plan of Action. One hundred thirteen (52%) had begun listing biomedical laboratories, including several large industrialized countries such as Japan, Australia, Canada, and the United States [94,95]. Worldwide, over 80,000 laboratories had been identified for surveying. Over 50 countries (25%) had completed the precertification activities and had finalized an inventory of laboratories storing wild poliovirus materials. Finally, in collaboration with IPV manufacturers and regulatory authorities, WHO has also produced guidelines for the safe production and quality control of IPV manufactured from wild polioviruses [96].

### C. Postcertification Polio Immunization Policy

Although the goal of all eradication initiatives is the elimination of the target organism such that control measures may be stopped [2], the ongoing debate as to the future of polio immunization policy demonstrates the complexity of this goal [91,97,98]. Although the economic benefits of stopping all polio immunization are an estimated US\$1.5 billion per year, leading public health experts have expressed opposing views as to whether OPV cessation is feasible [97,98]. Consequently, the WHO has developed a framework to assess the risks of paralytic poliomyelitis in the postcertification era, and the potential options for managing those risks (Table 4). In summary, there are risks due to the continued use of the OPV and risks associated with the handling of wild polioviruses in IPV production sites and laboratories. In both categories, the risks are increasingly understood and quantifiable.

First and foremost is the well-defined risk of vaccine-associated paralytic poliomyelitis (VAPP). Vaccine-associated paralytic poliomyelitis will occur at a rate of approximately one case per million children receiving their first dose of OPV [99,100] in all areas where that vaccine continues to be used, with nearly the same number of cases associated with subsequent doses and among vaccinee contacts. Less well understood is the risk of polio outbreaks due to

**Table 3** Status of Laboratory Containment Activities, as Measured by Key Indicators, by WHO Region, June 2002

Region (number of countries)	Coordinator appointed	Plan of action drafted	Laboratory list compiled	Survey conducted	Inventory completed
AMRO (47)	19	10	10	9	0
EURO (51)	51	51	51	51	20
WPRO (36)	36	36	36	36	32
EMRO (24)	18	18	12	12	2
SEARO (10)	7	7	4	4	0
AFRO (48)	0	0	0	0	0
Global (216)	129 (60%)	122 (56%)	113 (52%)	111 (51%)	54 (25%)

**Table 4** Potential Risks of Paralytic Poliomyelitis in the Era After Global Certification of the Interruption of Wild Poliovirus Transmission (i.e., the “Postcertification” Era)

Risk factor	Potential risks
Continued use of OPV	(1) VAPP (2) cVDPV (3) Immunodeficiency syndrome with long-term excretion of a vaccine-derived poliovirus (iVDPV)
Continued handling of wild polioviruses	(1) Inadvertent release of a wild poliovirus from IPV production site (2) Inadvertent release of a wild poliovirus from a laboratory setting (3) Intentional release of a wild poliovirus

cVDPVs. Although the risk of such events had been postulated for some time [101], it was only in the year 2000 that the first cVDPV outbreak was identified when 22 children were paralyzed over a 12-month period on the Caribbean island of Hispaniola [102]. A second such outbreak occurred in the Philippines in 2001, paralyzing three children [103]. A third was under investigation in Madagascar as of mid-2002 [104]. Retrospective analyses of viruses from Egypt suggest that a VDPV also circulated in that country and paralyzed children between 1982 and 1993 [105]. Although cVDPVs appear to be much rarer than VAPP, their potential to reestablish widespread paralytic polio in the postcertification era is substantially greater.

The third risk of paralytic polio due to continued use of OPV is the potential for long-term carriers of VDPVs identified among immunodeficient persons to reseed the general population in a postimmunization era. Such carriers are extremely rare, however, with only 14 identified in the 40 years of widespread use of the vaccine. Of these, only two are known to be continuing to excrete a VDPV. An analysis of the risks posed by such persons suggests that it is minimal [91].

The risks of paralytic polio due to wild poliovirus handling in the postcertification era are three: (1) inadvertent release from an IPV production site; (2) inadvertent release from a laboratory; and (3) intentional release. The risks associated with the first two situations can be minimized through high-quality containment work to promote the safe handling and use of wild poliovirus stocks (described above). Experience with the containment guidelines in a number of large industrialized countries has now demonstrated that this is a manageable task [94,95]. Although the potential for intentional reintroduction of polio into the human community cannot be eliminated through containment efforts alone, it can be substantially reduced. Furthermore, standard assessments of potential biological agents suggest that poliovirus would not be a biowarfare candidate organism and would be an unlikely agent for bioterrorism [91,106].

The WHO’s technical oversight body for polio eradication has outlined the following potential options for discontinuing OPV in the postcertification era [107]: (1) discontinue OPV after a mass campaign with OPV, with the option to continue IPV; (2) switch to universal IPV immunization; and (3) develop new vaccines that would not cause VAPP or cVDPV. Coordinated discontinuation of OPV would have the major advantage of stopping OPV at a time when population immunity will be very high, thus minimizing the risk of cVDPV. Although all countries would have the option of continuing to vaccinate with IPV, the continued use of IPV in industrialized countries as some experts advocate would protect against virus escaping from IPV manufacturing sites, deter the use of poliovirus as a biological weapon in these countries, and further minimize the risk of spread of a cVDPV from a long-term VDPV carrier.

Universal IPV would ensure that populations have at least some level of protection against cVDPV and would decrease the consideration of polio as a bioterrorism agent. However, this strategy would incur substantial costs, for relatively low population immunity, given the low seroconversion rates for IPV (type 1, ~60%; type 2, ~60%; and type 3, ~90%) when given at the usual EPI contact ages in developing countries [108]. In addition, manufacturers would need to greatly increase production capacity. Although the development of new live vaccines has been promoted, this may not be feasible based on current scientific knowledge and regulatory concerns. Furthermore, the costs of developing, testing, and seeking regulatory approval for a new vaccine would be enormous. Thus, it is unlikely that a new vaccine could be available during the timeframe of the eradication initiative unless huge public sector investments were made [106].

Although the first option described above is the most attractive in terms of programmatic feasibility and costs, it would be premature to endorse any strategy until there is a better understanding of the risks of cVDPV and iVDPV, the costs and benefits of alternate strategies, and how the perception of some risks may affect long-term policy decisions (including the risk of intentional release of wild poliovirus) [109]. Recognizing the need to establish international consensus on the future use of OPV, the WHO is coordinating a program of scientific research and country consultation that such decisions might be taken as early as 2004–2005. Regardless of the strategy selected, it will be necessary to establish a global stockpile of, and a production capacity for, OPV in case wild polioviruses are detected in the postimmunization era [91,110,111].

## V. CONCLUSION

By end-2001, progress toward the interruption of wild poliovirus transmission worldwide had established the technical and operational feasibility of polio eradication. Ironically, with only 10 countries remaining endemic for the virus as of June 2002, a financing gap of US\$275 million for the period 2003–2005 is the single greatest risk to achieving this goal [110]. Consequently, the first priority of the polio eradication initiative is to secure sufficient resources and

commitment to achieve the quality of supplementary immunization needed to interrupt the final chains of transmission worldwide. During this period, increasing attention will also be given to the processes of certification, laboratory containment, and postcertification policy development so that the economic and humanitarian benefits of this initiative can be fully exploited. The final challenge facing this global initiative is to ensure that the legacy of polio eradication includes the adaptation of this infrastructure to successfully tackle other important public health problems.

## ACKNOWLEDGMENTS

The authors are extremely grateful to Ms. Joan Hawe of the WHO for her assistance with the references for this article, as well as to Mr. Chris Wolff for his input on specific sections of the manuscript.

## Recent Advances in Immunology that Impact Vaccine Development

**Marcelo B. Sztein**

*University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.*

### I. INTRODUCTION

The last decade witnessed an explosion in information concerning the mechanisms underlying the host's immune response to invading microorganisms, as well as during pathological conditions such as autoimmune diseases and cancer. This was largely a result of impressive technological advances, which include: (1) engineering of a multitude of single and multiple gene-knockout and transgenic animals (and more recently, "conditional knockout" and "knock-in" mutants); (2) the ability to track specific T cells by using fluorochrome-labeled peptide-major histocompatibility complex (MHC) tetramers; (3) sophisticated multicolor and flow cytometric sorting techniques that allow the identification and functional characterization of cell subpopulations based on the concomitant expression of multiple surface and intracellular molecules; (4) the availability of many cytokines, chemokines, and other immunoregulatory molecules produced by recombinant techniques; (5) gene expression profiling using DNA microarrays that allows one to simultaneously determine the expression of thousands of individual genes in response to infection; and (6) the advent of proteomics (i.e., the large-scale analysis of proteins and their interactions). Moreover, the disclosure of the DNA sequence of entire genomes, not only of humans, but also from an ever-increasing number of other eukaryotic (e.g., yeasts, worm, and fly) and prokaryotic (currently over 20) organisms, is allowing the identification of large numbers of potential novel target antigens (Ag) for vaccine development.

In spite of the knowledge gained in recent years, there is no existing consensus on a general set of critical immunologic principles that should guide the development of new vaccines. Based on the information available to date, it is likely that the desired immunological response that must be elicited by effective vaccines will have to be tailored to each individual pathogen. This is due, in no short measure, to the complexity of the immune response, the diversity of patho-

genic microorganisms, the various routes of entry into the host, and the ability of some invading pathogens to subvert the generation of protective immune responses. Consequently, it is difficult to select "a priori" among the many factors that influence the development of a successful vaccine, such as the choice of the appropriate "protective" Ag, route of administration, dose, schedule of immunization, adjuvants, and/or carriers used in the formulation. It is also difficult to accurately predict how the immunological status of the recipient will affect responses to the vaccine.

This review is intended to highlight, rather than to discuss in depth, recent advances in understanding the mechanisms underlying the generation of immune responses and immunological memory. Emphasis will be placed on those mechanisms that have directly advanced (or can potentially advance) the development of new vaccines or can improve existing vaccines. This chapter will succinctly review novel concepts on the integrated nature of innate and adaptive immunity and focus on recent findings in the areas of Ag processing and presentation, including costimulatory molecules, the role of cytokines and chemokines in linking adaptive and innate immunity, the molecular determinants underlying lymphoid cell trafficking, and the generation of memory lymphocytes. Because of space limitations, the reader will be referred, throughout this chapter, to excellent recent reviews for additional information.

### II. AN INTEGRATED VIEW OF THE IMMUNE RESPONSE

The host's immune defense mechanisms against infectious agents can be divided into two main components: innate (i.e., native immunity) and adaptive (i.e., acquired immunity). Both of these complementary and highly interrelated components of the immune system are essential to protect the host from disease-causing viruses, bacteria, fungi, and parasites.

## A. Innate Immunity

This component of the immune response plays a critical role immediately after a pathogen enters the host, providing a first line of defense against invading microorganisms. Innate immunity is primarily responsible for the elimination, or at least the control, of the invading microbe during the 4–7 days required for the establishment of an early adaptive immune response [1,2]. Moreover, it is now widely recognized that innate immunity and the resulting inflammatory process play a key role in initiating the adaptive immune response and determining its nature. A distinctive feature of innate immunity is that the response does not increase with successive exposures to the microbes.

Many cells are involved in innate immunity, including phagocytes (e.g., neutrophils, macrophages), dendritic cells (DC), natural killer (NK) cells, and eosinophils. A key characteristic of the cells that form part of the innate immune system is their ability to recognize a wide range of microorganisms through surface receptors [pattern recognition receptors (PRRs)] that recognize invariant molecules present in a wide range of microbes [pathogen-associated molecular patterns (PAMPs)], but not in the host [1]. This important area of research has received a remarkable degree of attention over the past few years [2–4]. Examples of PAMPs, which are present in both pathogenic and nonpathogenic microorganisms, include bacterial cell wall peptidoglycans of Gram-positive bacteria and lipopolysaccharide (LPS) of Gram-negative bacteria.

Pattern recognition receptors can be expressed on the cell membrane, in intracellular compartments or secreted [2]. Examples of PRRs expressed on the cell surface include the macrophage scavenger receptor (MSR), which recognizes polyanionic ligands [e.g., double-stranded RNA (dsRNA), LPS], lectin-like binding receptors on NK cells, and macrophage mannose receptors (MMR), which recognize carbohydrate structures present in bacteria and fungal pathogens. Intracellular PRRs include the protein kinase PKR and the 2'-5'-oligoadenylate synthase which binds dsRNA (present in viruses), as well as the nucleotide-binding oligomerization domain (NOD) family of proteins, which appears to respond to LPS. Secreted PRRs (e.g., C-reactive protein, mannan-binding lectin, etc.) function by binding to microbes, leading to their elimination by complement-mediated mechanisms or phagocytosis. Toll-like receptors (TLRs) are an important family of PRRs that play a pivotal role in innate immune recognition. TLRs are characterized by extracellular domains that contain leucine-rich repeats and cytoplasmic portions, responsible for intracellular signaling, similar to the intracellular domain of the type-1 IL-1 receptor. Ten TLRs which recognize a variety of different PAMPs have been described to date in mice and humans (Table 1). Of note, TLRs sometimes require other molecules to participate in the recognition of PAMPs. For example, TLR4 has to be coordinately associated with MD-2 and CD14, as well as CD11b/CD18 heterodimers, to enable optimal LPS-signaling leading to nuclear translocation of nuclear factor  $\kappa$ B (NF- $\kappa$ B), and TLR2 has to dimerize with other TLRs, such as TLR1 or TLR6, to detect ligands and induce signaling [3–8]. To add to the complexity

of PAMP recognition, a CD14-independent LPS receptor cluster on the cell surface, composed of several proteins (i.e., hsp70, hsp90, CXCR4, and growth differentiation factor 5 [GDF5]), as well as the possible existence of intracellular receptors for LPS and invasive bacteria have recently been reported [3].

Recognition of “microbial nonself” through PRR recognition of PAMPs triggers signaling pathways that result in activated phagocytes, which are better equipped to engulf and destroy the offending pathogen, as well as to secrete many molecules responsible for the initiation of an inflammatory process. Molecules secreted following TLR-PAMP interactions include inflammatory cytokines (e.g., interferon (IFN)- $\alpha$ , IFN- $\beta$ , interleukin-1 $\alpha$  (IL-1 $\alpha$ ), IL-1 $\beta$ , IL-6, IL-12, and tumor necrosis factor (TNF)- $\alpha$ ), chemokines (e.g., CXCL8 [IL-8], CCL20 [MIP-3 $\alpha$ ], CXCL10 [IP-10] and CCL2 [MCP-1]), and other moieties that directly or indirectly participate in the destruction of the microbe. As discussed in more detail below, these molecules profoundly affect the behavior of many cell types, modulate the type of adaptive immune response induced, and recruit macrophages, neutrophils, DC, lymphocytes and other cells to the inflammatory site. Of note, TLR-PAMP interactions on the surface of DC, a key Ag-presenting cell (APC), play a critical role in the induction of adaptive immunity by upregulating the expression of costimulatory molecules required for the activation of naive T cells specific for antigenic peptides expressed on the same DC in conjunction with MHC molecules [1]. It is also important to emphasize that cytokines and other molecules secreted by cells of the adaptive immune system (e.g., IFN- $\gamma$  secreted by activated T lymphocytes), in turn, have marked effects on the innate immune response through activation of macrophages and other cells that ultimately participate directly in the destruction of the microbe.

## B. Adaptive Immunity

In contrast to innate immunity, the effector mechanisms of adaptive immunity that include, among others, antibodies (Ab) and cell-mediated immune responses (CMI) [e.g., cytotoxic T lymphocytes (CTL) and cytokines such as interferon- $\gamma$  (IFN- $\gamma$ ) and interleukin-4 (IL-4)] are induced following exposure to antigens (Ag) or infections agents and increase in magnitude with successive exposures to the specific Ag. This ability to “recall” previous exposures to Ag and respond rapidly with immunological effector responses of increased magnitude (immunologic memory) constitutes the foundation for immunoprophylactic vaccination against infectious agents. Therefore this chapter will focus on some of the most significant recent advances in understanding the mechanisms which underlie the development of adaptive immune responses and immunologic memory. The main cell types involved in adaptive immune responses, responsible for the recognition of specific Ag, are T and B lymphocytes. However, it is very important to emphasize that an adaptive immune response can only be initiated after cells typically considered part of the innate immune response (e.g., DC and other APC) uptake, process, and present Ag to naive recir-

**Table 1** Toll-Like Receptors

TLR	Cell location	Major ligands/agonists	Microbes	References
TLR1 [+ TLR2]	Surface	Phenol-soluble modulin ( <i>S. epidermidis</i> )	Gram(+) bacteria	[121]

culating lymphocytes in secondary lymphoid tissues [e.g., regional lymph nodes (LN)].

### 1. Immune Responses Mediated by B Lymphocytes

B cells, derived from the bone marrow, are the precursors of Ab secreting cells [plasma cells (PC)]. B cells recognize Ag (proteins, carbohydrates, or simple chemical groups) through immunoglobulin (Ig) receptors on the cell membrane [9–11]. Following Ag recognition, they clonally expand and switch their expression of Ab isotype (e.g., IgM to IgG, IgE, or IgA) under the influence of cytokines derived from T cells, macrophages, and other cell types. Somatically mutated, high-affinity B cells are generated and selected by Ag in and around the germinal centers that are formed in LN, spleen, Payers' patches (PP), and more disorganized lymphatic aggregates of the peripheral lymphoid system [9–12]. This process gives rise to two types of B cells: nonsecreting, long-lived memory B cells and Ab-secreting plasmablasts. Terminally differentiated, end-stage PC then migrate to other locations, such as bone marrow, through the differential expression of chemokine receptors (e.g., CXCR4), where they continue to secrete high-affinity Ab for many months [9]. Memory B cells also leave the germinal centers, homing to draining areas of LN and spleen, as well as extra lymphoid tissues such as the intestinal lamina propria. Following secondary exposure to Ag, a rapid and massive clonal expansion of memory B cell occurs, generating several-fold more PC than the level following the primary stimulation [9–12].

Antibodies are particularly effective against extracellular microbes and in neutralizing microbial toxins through several mechanisms, which differ depending on the particular Ig isotype. For example, IgG binding to specific antigenic determinants (epitopes) present in the infectious organisms leads to opsonization and increased phagocytosis by macrophages and neutrophils, which, in turn, leads to intracellular killing of the microbes. Furthermore, Ab binding to microbes might also result in bacterial cell lysis through a mechanism known as Ab-dependent cell-mediated cytotoxicity (ADCC). In ADCC, recognition of pathogens coated with IgG or IgA via Fc receptors present on the effector cells (e.g., neutrophils, macrophages, and particularly NK cells; eosinophils in the case of IgE) results in destruction of the microbes by several mechanisms, such as the release of lytic proteins stored in the granules of the effector cells. Binding of human IgG1, IgG3, and IgM to microbes also activates the complement pathway, which leads to lysis of the pathogenic organisms and promotes opsonization and enhanced phagocytosis. Another critical role of Ab is to neutralize potentially lethal Ag (e.g., bacterial toxins), through the formation of Ag–Ab complexes. In contrast to the epitopes being recognized by T cells (which are composed of aminoacid (aa) sequences that are continuous in the primary protein structure), B cells and Ab bind to epitopes that consist of aa that are either continuous or discontinuous (usually associated with lipids or carbohydrates) in the primary protein structure, but that are brought together during protein folding. Epitopes composed of continuous and discontinu-

ous aa sequences are referred to as linear and conformational epitopes, respectively. Most Ab recognize conformational epitopes in native proteins. Production of Ab to most nonprotein Ag, such as glycolipids, nucleic acids, and polymeric polysaccharides, does not require help by cognate T cells and are, therefore, referred to as thymus-independent (TI) Ag [13–16]. In contrast to T-dependent Ag, TI Ag induce mostly IgM Ab of low affinity and, in the majority of cases, do not show significant heavy chain class switching, affinity maturation, or memory [13,15]. Thymus-independent Ag have been further subdivided into types 1 and 2, depending on whether they are able (type 1) or unable (type 2) to induce immune responses in neonates [15]. Examples of TI-1 Ag include LPS and *N. meningitidis* outer membrane protein, while most bacterial capsular polysaccharides and carbohydrates are TI-2 Ag. The fact that Ab responses to TI-2 Ag develop later in life is demonstrated by the limited responses observed in small infants immunized with, for example, polysaccharide vaccines. In contrast, it is now well established that immunization with conjugate vaccines composed of polysaccharides from, for example, *Haemophilus influenzae* type b or *Salmonella enterica* serovar Typhi coupled to T cell-dependent protein Ag elicit strong antipolysaccharide Ab responses, which can be increased with repeated immunization and which are very effective in protecting small infants from invasive *H. influenzae* type b or preschool children from *Salmonella enterica* serovar Typhi infection [14,17,18]. It is unclear what mechanisms underlie these responses and to what extent cytokines derived from APC or small numbers of nonspecific T cells are required to provide a second signal for B cell triggering after exposure to TI-2 Ag. Because of its importance in vaccine development, this remains an area of intense investigation.

## 2. Immune Responses Mediated by T Lymphocytes

T lymphocytes, in contrast to B cells, recognize peptides (short continuous aa sequences) derived from protein Ag that are presented on the surface of APC in conjunction with class I or class II MHC molecules (pMHC) in the presence of costimulatory molecules [19–21]. These Ag may originate from bacteria, viruses, or parasites that have infected host cells and reside intracellularly, or from the extracellular environment following internalization by endocytosis. Spectacular advances in the ability to track *in vivo* T cells of known specificity have led to the widely accepted view that naive T cells expressing TCR of appropriate specificity are activated, almost exclusively, by pMHC complexes presented by DC that have acquired the Ag at the site it entered the host and that, in the presence of the appropriate inflammatory stimuli, migrated to the T cell areas of secondary lymphoid tissues (e.g., LN, spleen, and PP). Following Ag presentation and activation in the presence of inflammatory stimuli (e.g., IL-1), T cells undergo an explosive clonal expansion (later to be followed by a contraction phase), mature into effector cells, and migrate to effector sites [22,23]. Some Ag-specific T cell clones remain for long periods of time as memory T cells ( $T_m$ ) that, upon subsequent exposures to Ag, provide a stronger, rapid, and sometimes qualitatively different specific immune response. Induction of effective  $T_m$

cells is critical for successful vaccination. Recent evidence from several laboratories indicates that there are at least two pools of  $T_m$  cells: (1) central memory T cells ( $T_{cm}$ ), which recirculate through LN and quickly acquire the capacity to produce effector cytokines upon Ag stimulation, and (2) effector memory T cells ( $T_{em}$ ), which recirculate through nonlymphoid tissues and are capable of immediate effector function (see Section 8) [23–25].

There are two main populations of T cells, those expressing CD4 molecules and those expressing CD8 molecules. CD4 and CD8 molecules are T-cell surface glycoproteins that serve as important accessory molecules (coreceptors) during Ag presentation by binding to class II and class I MHC molecules, respectively [19,21]. Consequently, CD4 and CD8 molecules, whose original use was primarily as markers to identify T-cell populations with different functional characteristics, play a major role in class II and I MHC-restricted T-cell activation.  $CD4^+$  cells [T helper (Th)] are mainly involved in inflammatory responses and in providing help for Ab production by B cells, while  $CD8^+$  cells, in addition to secreting cytokines, compose the majority of cytotoxic T lymphocytes (CTL) primarily involved in class I MHC-restricted killing of target cells infected by pathogenic organisms, including bacteria, viruses, and parasites [26–28].

T-cell activation triggered by cross-linking of TCR by pMHC complexes, aided by costimulatory molecules, results in the production of a multitude of molecules with strong immunoregulatory properties collectively known as cytokines and chemokines. Acting in concert, cytokines not only modulate the growth, maturation, and differentiation of all cells involved in the generation of adaptive immunity [19], but also strongly regulate innate immunity. An important finding in understanding the mechanisms of protection against infectious diseases was the realization, first reported by Mossman et al. in 1986 [29], of the existence of distinct Th cell populations that exhibit polarized patterns of cytokine production. These cell subsets, designated type 1 (Th1) and type 2 (Th2)  $CD4^+$  T cells, are characterized by the production of IFN- $\gamma$  and TNF- $\beta$ , or IL-4, IL-5, IL-9, IL-10, and IL-13, respectively [26,27,29,30]. As discussed in more detail below, the predominance of these polarized patterns of cytokine production plays a pivotal role in determining the type and characteristics of the effector immune responses generated upon antigenic stimulation, e.g., whether the predominant responses will be Ab production (and of which isotypes), enhanced intracellular killing by macrophages, generation of effector CTL, etc. [26,27,29–32].

## III. ANTIGEN PROCESSING AND PRESENTATION BY ANTIGEN PRESENTING CELLS

The presentation of Ag to T cells involves a series of intracellular events within the APC, including the generation of antigenic peptide fragments, binding of these peptides to MHC molecules to form stable peptide–MHC complexes, and transport of these complexes to the cell surface where they can be recognized by T-cell receptors (TCR) in the surface of T cells. Two main pathways of Ag processing and

presentation (“classical pathways”), i.e., cytosolic and endosomal, have been described. The “cytosolic pathway” is predominantly used for presentation of peptides produced endogenously in the APC, such as viral proteins, tumor Ag, and self-peptides, associated with class I MHC molecules [33]. The presentation of large numbers of self-peptides complexed to class I MHC molecules results from the inability of APC to differentiate between self and nonself. Under normal conditions, most T cells selected to recognize self-peptides were eliminated during T-cell differentiation, or are actively downregulated, and consequently cannot be activated by self-peptide-class I MHC complexes. The second “classical pathway” of Ag processing and presentation, “endosomal pathway,” which is predominantly used for presentation of soluble exogenous Ag bound to class II MHC molecules, involves the capture of Ag by APC, either by binding to a specific receptor or by uptake in the fluid phase by macropinocytosis [34–37]. Triggering of T cells through the TCR has been shown with as few as 200–600 pMHC complexes in the case of influenza nucleoproteins [38]. In most immune responses, antigenic fragments (epitopes) associated with class I MHC molecules trigger the activation of CD8<sup>+</sup> CTL responses, while epitopes derived from soluble proteins complexed to class II MHC molecules are recognized by CD4<sup>+</sup> Th cells. The existence of “alternative pathways” have also been recently described. The in-depth understanding of the mechanisms involved in these early stages of immune activation is critical for the development of successful vaccines.

### A. Antigen Processing and Presentation by Class I MHC Molecules

This is the most commonly used pathway for processing of cellular proteins present in most, if not all, cellular compartments, including the cytosol, nucleus, and mitochondria, that, in association with class I MHC molecules, are available for recognition by CD8<sup>+</sup> T cells [33,38,39]. Class I molecules, whose expression is regulated by cytokines (e.g., IFN- $\gamma$ ), are expressed at high levels in T cells and APC (e.g., B cells, DC, and macrophages), and at moderate levels in most nucleated cells (e.g., neutrophils, hepatocytes).

#### 1. Binding of Peptides to Class I MHC Molecules

Class I MHC molecules are composed of two separate, noncovalently linked polypeptide chains. The heavy chain ( $\alpha$  chain) is an MHC-encoded, transmembrane polypeptide of 44 kDa (325 aa), and  $\beta 2$ -microglobulin is a non-MHC encoded polypeptide of 12 kDa (100 aa), which is not attached to the cell, but that binds noncovalently to the extracellular portion of the  $\alpha$  chain [39]. Class I MHC molecules bind peptides within a defined region, one per MHC molecule, called the “cleft,” formed by aa of the  $\alpha 1$  and  $\alpha 2$  segments of the  $\alpha$  chain, and is located on the surface of the MHC molecule. These epitope-binding clefts, which contain a high concentration of polymorphic aa, consist of a  $\beta$ -pleated sheet floor and  $\alpha$ -helical sides. Peptides that are able to successfully trigger T-cell activation should not only contain aa that bind class I molecules by forming noncovalent bonds with both

the  $\beta$ -pleated sheet floor and  $\alpha$ -helical sides of the cleft, but also contain some aa whose side chains point away from the cleft and are therefore available for recognition by T cells.

Epitope binding clefts of class I molecules have “closed” ends and one or more pockets in the  $\beta$ -pleated sheet floor to fit side chains of certain aa. Thus only peptides of the appropriate length that can fit inside the groove (typically 8–10 aa, although in some cases they can be up to 11 aa in length), and that usually contain 2 aa whose side chains bind noncovalently to the pockets, can bind class I MHC molecules with high affinity. One of these two rather invariant aa for a defined allele, called “anchor residues,” is usually located in the carboxyl terminal position of the 9 aa sequence of the epitope. In most cases, it consists of a hydrophobic aa and binds to the F pocket of the MHC peptide-binding site. The second anchor residue is usually located in position 2 from the N-terminus of the peptide and binds to the B pocket of the MHC peptide-binding site. The remaining aa of the antigenic peptides do not bind or bind to a lower extent to the cleft, and their side chains are therefore available for recognition by T cells. In addition to recognition of MHC-bound peptides, the direct interaction of polymorphic aa of MHC molecules with TCR also contributes to T-cell activation [39,40].

Although MHC molecules bind peptides somewhat promiscuously, it is clear that defined peptide binding motifs bind defined MHC alleles. The existence of specific anchor residues in the majority of octa- or nonameric epitopes that bind to specific class I alleles led to the identification of “allele-specific consensus-motifs.” Moreover, aa located near the “anchor residues,” inside and outside the epitope, have also been shown to influence, either positively or negatively, the formation of stable MHC-peptide complexes [39,40]. The existence of “allele-specific consensus-motifs” has provided researchers with a powerful tool to assist them in the identification of potentially immunogenic (although not necessarily “protective”) epitopes based on the primary aa sequence of the protein being targeted as a potential Ag to form part of subunit candidate vaccines [41,42].

Over the past few years, the number of consensus-motifs has increased, and continues to expand dramatically. However, the existing tools fall short in accurately predicting immunogenic epitopes because of several factors, including (1) differences in the precursor protein expression, (2) stability and rate of peptide transport into the ER, and (3) post-translational modifications present in a sizable proportion of naturally occurring epitopes [33]. Several MHC ligand databases that list some of the known human leukocyte antigen (HLA)-binding motifs and predictive algorithms are available over the Internet (e.g., [http://bimas.dcrt.nih.gov/molbio/hla\\_bind/](http://bimas.dcrt.nih.gov/molbio/hla_bind/); <http://hlaligand.ouhsc.edu/>; etc.). Following the recommendations of a panel of experts recently convened by the National Institutes of Health (June 5, 2001), a comprehensive, unified, publicly accessible, searchable, centralized database of all known MHC-binding motifs and analysis/prediction tools, as well as standards to determine peptide binding affinity, is being established. The widespread availability of such information and computational tools will, without a doubt, greatly accelerate the pace of discovery of epitopes that can be of importance in the development of

novel and more effective vaccines. A detailed description of the most current methods available for the prediction of immunogenic epitopes and the use of bioinformatics to process the vast amounts of information generated by these techniques is presented elsewhere in this book.

Based on their broad peptide-binding specificities, many HLA-A and -B alleles in humans can be grouped into major supertypes that bind defined class I HLA molecules. Among them are the HLA-A2 supertype, which includes A\*0201–0207, A\*6802, and A\*6901 HLA molecules; the HLA-A3 supertype, which includes A\*03, A\*11, A\*3101, A\*3301, and A\*6801 HLA molecules; and the HLA-B7 supertype, which includes B\*0702, B\*3501–03, B\*51, B\*5301, and B\*5401 HLA molecules [43]. If confirmed, these observations can be of extraordinary importance for vaccine development, because the use of vaccines including a “cocktail” of only a few epitopes containing those supermotifs, in theory, could successfully trigger protective immune responses in the vast majority of individuals, regardless of the ethnicity of origin [43].

The use of defined epitopes is an attractive vaccine strategy, offering the following advantages: (1) the selection of epitopes from conserved regions of various proteins from the microorganism, i.e., avoiding variable antigenic epitopes which can lead to immune evasion; (b) increased safety; (c) the ability to select only those epitopes which are likely to play key roles in host-defense, or that tilt the immune response toward desired effector mechanism(s); and (4) the fact that multiple epitopes can be incorporated in a single vaccine. However, it is unlikely that a vaccine solely consisting of CTL epitopes will be successful. Accumulating evidence indicates that successful subunit peptide vaccines might require the use of the appropriate CTL epitopes in combination with “universal T helper epitopes” (i.e., able to bind to a large number of MHC class II molecules) and powerful adjuvants [44]. Moreover, significant efforts are being directed toward enhancing the immunogenicity of subunit vaccines by rationally modifying antigenic determinants (i.e., creating “agonistic peptides”) to enhance the host’s immune response through upregulation of Ag recognition [45].

## 2. Cytosolic Pathway for Antigen Processing and Presentation by Class I MHC Molecules

It is generally accepted that class I MHC-associated peptides represent samples of the whole cellular protein content [33,38,46]. In general, the more abundant the protein of origin, the higher the frequency of MHC-peptide complexes, although some proteins present in low amounts have also been found to represent a significant percentage of MHC-peptide complexes [33,38,46]. Chief among the factors influencing the frequency of the MHC-peptide complexes is the stability of the class I-MHC complexes, which depends, to a large extent, on the aa sequence of the ligand (presence of appropriate anchor residues, etc.) and that can last from a few hours to several days or, in some cases, weeks.

Proteins synthesized intracellularly are degraded to peptide fragments of 8–11 aa in length by proteasomes, which consist of large (650 kDa), multicatalytic proteases

of 16–24 protein subunits that form a cylindrical organelle present in the cytoplasm of APC. Proteins probably have to be covalently linked to ubiquitin before they can be targeted for proteolytic degradation by proteasomes. Peptide fragments originating in this way can either be of the correct size or can be extended in their amino-termini [46]. In the latter case, they are subsequently trimmed by aminopeptidases into peptides of the correct length. Small peptide fragments are then transferred across the membrane of the endoplasmic reticulum (ER) by an adenosine-5-triphosphate (ATP)-dependent heterodimeric complex of two proteins encoded by the “transporter in Ag processing” (TAP) 1 and TAP 2 genes. Within the lumen of the ER, antigenic fragments bind to newly synthesized class I MHC  $\alpha$  chains (bound to tapasin and calreticulin), stabilizing the association of  $\alpha$  chains with newly synthesized  $\beta 2$ -microglobulin chains to form stable trimeric complexes and preventing continued association with both tapasin and calreticulin. These class I MHC-peptide trimeric complexes are then transported to the Golgi apparatus. From there, class I MHC-Ag complexes reach the cell surface and become available for recognition by TCR.

Peptides that can optimally stabilize the trimer constitute the majority of the overall class I expression. Those peptides that can only weakly stabilize the trimer will be less represented because they may fail to reach the cell surface or, if they do, they will be prone to peptide dissociation, giving rise to most of the free class I-binding sites that allow exogenous peptide to sensitize target cells [33].

## 3. Cross-Presentation and Alternative Pathways for Antigen Processing and Presentation by Class I MHC Molecules

Cross-presentation was originally described as a process by which Ag was capable of being transferred from cells expressing the Ag to host APC [47–49]. Historically, this term has been associated with class I-restricted Ag, although cross-presentation can involve class I- or class II-restricted Ag [49]. T-cell activation resulting from cross-presentation can lead to T-cell priming (cross-priming) or T-cell tolerance (cross-tolerance) [49]. Cross-priming of naive T cells, largely a function of DC rather than macrophages, has been described for many Ag, including minor histocompatibility Ag, graft tissue Ag, self Ag, tumor Ag, viral proteins (e.g., Epstein–Barr virus, poliovirus, cytomegalovirus, influenza), ovoalbumin, etc. Although the Ag has no obvious mechanism for accessing the cytoplasmic processing and transport machinery of the APC, depending on the individual system, cross-priming has been shown to be dependent, or not, on proteasome- and TAP processing.

Several alternative routes have been proposed to explain this “exogenous pathway” in cross-presentation: (1) an endosome-only route in which Ag is loaded into class I molecules in the endosomes by using previously occupied (by peptide exchange) or unoccupied class I MHC molecules, or on the cell surface following the “regurgitation” of peptides processed in vacuolar phagocytic compartments to the cell membrane where they bind surface class I MHC molecules, and (2) a cytosolic route in which Ag are trans-

ported from the endosome to the cytosol, allowing them to follow the “classical” pathway. The latter mechanism might also be involved in allowing the escape into the cytosol of proteins synthesized by bacteria or protozoa (e.g., *Salmonella enterica* serovar Typhimurium, *Salmonella enterica* serovar Typhi, *Mycobacterium tuberculosis*) confined to the phagolysosomal compartment, which can then become available for processing through the cytosolic pathway [50–53]. Several hypotheses have been proposed to explain why cross-priming is a function of DC and not of macrophages, including (1) the fact that the uptake of apoptotic cells is mediated by different receptors in DC and macrophages, (2) the existence of an endosome-to-cytosol transport mechanism present in DC but not in macrophages, and (3) DC are much more efficient in stimulating primary CD8<sup>+</sup> CTL responses than macrophages. Whatever the mechanisms involved, an active cross-priming pathway in which DC can process Ag from apoptotic and/or necrotic cells is critical, in that it endows these potent APC with the capacity to capture and present Ag from (1) virus-infected, malignant, and transplanted cells that typically lack the accessory functions to be efficient APC and (2) from pathogens that either do not directly infect APC, or that suppress their Ag processing and presentation ability following infection.

## B. Antigen Processing and Presentation by Class II MHC Molecules

The “endosomal or endocytic pathway” is predominantly used for the processing and presentation of exogenous Ag, such as proteins produced by extracellular bacteria and other infectious microorganisms that, in association with class II MHC molecules, can be presented to CD4<sup>+</sup> T cells. Class II molecules, whose expression is also regulated by cytokines (e.g., IFN-γ), are expressed at high levels on APC (e.g., B cells, DC, and macrophages) and thymic epithelial cells, and at moderate levels on T cells, but are absent from most other nucleated cells.

### 1. Binding of Peptides to Class II MHC Molecules

Class II MHC molecules consist of noncovalently associated α/β heterodimers. Both α chains (33 kDa) and β chains (29 kDa) are polymorphic, transmembrane polypeptide chains that are encoded by two separate MHC genes. Similar to class I, class II MHC molecules bind peptides within a defined peptide-binding region, one per MHC molecule and consisting of a β-stranded sheet floor and α-helical sides, formed by aa of the α1 and β1 segments of the α and β chains, respectively [37]. However, in contrast to class I MHC molecules, the binding cleft of class II molecules is open at both ends, allowing bound peptides to extend beyond the cleft. This characteristic results in the lack among class II-associated peptides of the strict aa length restriction and the presence of certain aa at either end observed for peptides associated with class I. In fact, although peptides isolated from class II molecules are typically 12–24 aa in length, peptides of more than 30 aa have also been recovered [37,54]. These characteristics have delayed the identification of a large number of peptide binding motifs for class II MHC

alleles. However, it has been possible to identify some binding motifs that involve two or three anchor positions from among a core region of 7–9 aa, which are presumed to occupy polymorphic pockets similar to those described for class I molecules [39,55]. However, these “anchor-like” positions are not as stringent in occupancy requirements as with class I motifs.

### 2. Endosomal Pathway for Antigen Processing and Presentation by Class II MHC Molecules

The first step in the “endocytic” Ag processing and presentation pathway involves the capture and uptake of native Ag by APC. The main mechanisms involved in the internalization of exogenous Ag include binding to nonspecific (e.g., mannose receptors) or specific (e.g., specific membrane Ig on B cells and receptors for the Fc portion of Ig and complement in macrophages and DC) receptors, or uptake from the fluid phase by macropinocytosis [34]. Ag bound to membrane receptors usually enter the cells by receptor-mediated endocytosis in clathrin-coated vesicles, while other soluble Ag in fluid phase are taken up by pinocytosis. These internalized Ag become localized in membrane-bound vesicles involved in intracellular transport and degradation of Ag called endosomes. It is unclear how the endosomal compartment associates with the lysosomal compartment, which contains a large number of proteolytic and other catalytic enzymes. However, it is well established that Ag processing occurs in both the endosomal and lysosomal compartments. Cleavage of native proteins into peptide fragments of 12–24 aa in length that can then bind to the peptide-binding region of class II MHC molecules, is mostly performed by cellular proteases that function optimally in the acidic environment of the endosomal and lysosomal compartments [37,56].

Class II α and β chains synthesized in the ER bind noncovalently with the non-polymorphic invariant chain (Ii)-associated peptide (CLIP) to form a stable trimeric complex, which promotes the proper folding of class II molecules, precludes the binding of antigenic fragments to the peptide-binding groove within the ER, and targets the movement of nonameric complexes, composed of three α chains, three β chains, and three Ii chains through the Golgi apparatus, to the trans-Golgi network and into the endosomal pathway. It is widely believed that, while some trimers might lose the Ii and bind peptide in the early endosomes, most of the degradation of Ii chains takes place in the more acidic and proteolytically active late endosomal/prelysosomal compartments. CLIP remains associated to the class II binding site throughout the proteolytic process involved in Ii degradation (which includes cathepsins S and L) until it is exchanged for other ligands, a process facilitated, in humans, by HLA-DM and HLA-DO molecules [54,56]. These ligands appear to be primarily unfolded, partially degraded proteins, rather than short peptides [37]. This binding preference explains the need for the ends of the class II binding site to be open to ensure continued degradation by exoproteases, leading to the eventual formation of bound peptides with differing N and C termini.

It is believed that loading of processed Ag to newly synthesized or recycled class II MHC molecules transpires in

two compartments. The major compartment (called MIIC) contains newly synthesized class II molecules that are targeted by the Ii [54,56]. The second compartment consists of early endosomes containing mature class II MHC molecules that are internalized from the cell surface and recycled back [36,54,56]. The existence of these two compartments suggests that internalized Ag are processed all along the endocytic pathway and generate different epitopes, while encountering increasingly denaturing and proteolytic conditions [37,56]. Peptides generated at an early stage may bind recycling class II MHC molecules, whereas peptides generated later might be loaded into newly synthesized class II MHC molecules. Class II-peptide complexes within the endosomes are then transported to the cell surface and become available for recognition by TCR [37,39].

### 3. Alternative Pathways for Antigen Processing and Presentation to Class II MHC Molecules

In addition to exogenous Ag, peptides derived from endogenously synthesized proteins have also been shown to be processed through the endosomal pathway, bind to class II MHC molecules and those complexes expressed on the cell membrane. Autologous proteins can gain access to the endosomal pathway through “alternative” pathways, including: (1) the entrapment of cytosolic proteins in autophagosomes, which then fuse with vesicles of the lysosomal and endosomal compartments; (2) endogenous proteins expressed on the cell membrane that gain access to the cytoplasm employing the same pathway used by exogenous proteins; (3) the transport of cytosolic proteins into the endocytic compartment by molecules such as Hsc70; and/or (4) endogenously synthesized peptides present in the ER and Golgi compartments that bind through still unknown mechanisms to class II molecules in those compartments [39]. As discussed above with regard to the alternative pathways of Ag processing and presentation by class I molecules, the significance and processes involved in endogenous Ag presentation by class II in the presentation of self Ag and in immunity to pathogenic organisms have not been fully elucidated [39]. Understanding the mechanisms of these alternative pathways of Ag presentation might prove to be of great importance in the design of novel vaccine strategies.

## C. Nonclassical MHC Class I and Other Molecules Involved in Antigen Presentation

In addition to class I and II MHC molecules, a number of other molecules, characterized by their limited polymorphism and lower surface expression, have also been shown to participate in Ag presentation. These include nonclassical MHC class Ib molecules, as well as non-MHC-encoded proteins, such as CD1 and the neonatal Fc receptor (FcRn) [57].

### 1. Class Ib Molecules

Class Ib molecules are nonclassical, nonpolymorphic MHC-like molecules that include, in humans, HLA-E, -F, -G, and -H (also known as HFE), and MIC (MHC class I chain related) A and MICB [57]. Probably the best characterized of

these molecules is HLA-E, which plays an important role in NK function. The HLA-E molecules bind nonamers derived from the leader sequences of most classical class I molecules, as well as HLA-G, in a TAP-dependent process. HLA-E binds the inhibitory and activating forms of the CD94/NKG2 receptor (CD94/NKG2A and CD94/NKG2C, respectively) present in NK and some T cells. Binding of HLA-E to NK expressing CD94/NKG2A inhibits NK activity, while binding to NK expressing CD94/NKG2C, enhances NK killing of target cells. This system provides NK with a mechanism to monitor the expression of class I molecules in host cells by using a single receptor. In this way, cells that have downregulated class I molecules, as is frequently the case in tumor cells or virus-infected cells, will become susceptible to killing by NK [57]. Similar mechanisms might be operative in a subset of T cells. HLA-G expression at the maternal/fetal interface has rendered this molecule the subject of considerable attention. Although its function remains controversial, investigators have proposed that HLA-G might be responsible for the inhibition of maternal NK that may otherwise attack the trophoblast. Both MICA and MICB have been predominantly found in epithelial cells of the gastrointestinal tract and thymus, suggesting that they may play a role in Ag presentation to  $\gamma\delta$ T cells, as well as in the selection of the T cell repertoire. In contrast to other nonclassical MHC molecules, HFE plays a role in iron metabolism. No information is available on the role of HLA-F.

### 2. CD1 Molecules

CD1 comprises a family of nonclassical, nonpolymorphic MHC molecules, preferentially expressed by DC and other APC that, based on sequence similarities, have been subdivided into two groups, i.e., group 1 (CD1a, CD1b, and CD1c) and group 2 (CD1d) [58–60]. Although these molecules are remarkably conserved in mammalian species, group 1 CD1 molecules are not present in rodents. A large body of evidence indicates that CD1-restricted T cells play an important role in protection from microbial infection by responding rapidly following recognition of defined microbial Ag. Ag presented by CD1 molecules include microbial lipid, glycolipid, and other nonprotein Ag, such as those present in *M. tuberculosis* and *M. leprae*. Both CD4<sup>+</sup> and CD8<sup>+</sup> T cells have been shown to recognize Ag restricted by group 1 CD1 molecules, suggesting that they may comprise a sizable proportion of T cells. A particular lymphocyte subset, NKT cells, has been shown to be CD1d-restricted. The canonically rearranged TCR $\alpha$  in these cells creates a semi-invariant TCR that may represent a novel “adaptive” PRR, which recognizes common glycolipid structural motifs [58]. CD1-mediated Ag processing and presentation takes place via the endosomal processing pathway and does not depend on products encoded by either TAP genes or the Ii for intracellular Ag transport [58–60].

## D. Antigen Presenting Cells

The ability of cells to function as effective APC depends on their ability to process Ag for class I MHC-restricted CTL responses and/or class II MHC-restricted Th responses. As

most of the cells of the body express class I MHC molecules and have the ability to express on the cell surface endogenously produced peptide complexes to class I MHC molecules, they have the potential to function as APC for CD8<sup>+</sup> CTL. In fact, cells which are endogenously producing viral, parasitic, or bacterial proteins or tumor Ag that gain access to the cytosol can be recognized and destroyed in a class I MHC-restricted fashion by specific CTL. In contrast, the main characteristics of APC required for presentation to Th cells in a class II-restricted fashion are the ability to take up soluble Ag from the extracellular compartment and process them to produce appropriate peptides that will then be complexed to class II MHC molecules and expressed on the cell membrane for recognition by Th cells. The cells that most efficiently present Ag to Th lymphocytes, the so-called “professional APC,” include DC, macrophages, and B lymphocytes. Most professional APC express moderate to high levels of class II MHC molecules constitutively, and their expression can be upregulated upon activation by cytokines such as IFN- $\gamma$ . Moreover, professional APC express many costimulatory and adhesion molecules, which are very important during the early stages of T-cell activation. In contrast, “nonprofessional APC,” such as endothelial, epithelial, and mesenchymal cells, typically do not express class II MHC molecules constitutively, but can be induced to express them following exposure to T cell-derived cytokines, such as IFN- $\gamma$ . Their role as APC in vivo is still unclear.

### 1. Dendritic Cells

A large body of evidence accumulated over the past few years clearly demonstrates that DC are the most effective APC involved in the activation of naive T cells [61–63]. Because of their key role in the induction of immunity, a thorough understanding of DC biology is of paramount importance in vaccine development. Dendritic cells comprise a heterogeneous cell population that originates in the bone marrow from hematopoietic stem cells and that reside, as immature DC, largely in peripheral tissues exposed to the environment, i.e., the sites of Ag entry. In the absence of ongoing inflammation and immune responses, DC's main function is to be vigilant for invading microbes in both lymphoid and non-lymphoid tissues (e.g., secondary lymphoid tissues, skin, blood, lymph, and mucosal surfaces). Immature DC express receptors for inflammatory chemokines that direct their migration to sites of inflammation. Upon recognition of microorganisms expressing PAMPs through PRRs, receptors for the Fc portion of Ig and other receptors (see Section II.A), exposure to cytokines, chemokines, and other inflammatory stimuli, and, under certain circumstances, self-Ag, DC quickly mature into efficient APC and migrate into draining LN where they initiate primary T cell responses. The maturation process involves the upregulation of MHC molecules, as well as costimulatory molecules (e.g., CD40, CD54, CD58, CD80, CC86), chemokine receptors (e.g., CCR7), and adhesion molecules which drive their migration into the lymphatic vessels and the T cell areas of the draining LN. To reiterate, in addition to presenting Ag, based on the type of cytokines they release and their expression of distinct

adhesion/costimulatory molecules, DC play a key role in determining the type of adaptive immunity elicited (e.g., polarized Th1 vs. Th2 responses).

Two main subsets of functionally distinct DC have been described in human peripheral blood, i.e., myeloid DC (mDC), also called “DC1,” and lymphoid or plasmacytoid DC (pDC), also called “DC2,” which can be differentiated based on the surface expression of molecules which determine their function [61,64–66]. Both populations of immature DC isolated from human peripheral blood lack lineage differentiation markers, including CD14, CD16, CD19, CD3, and CD56. mDC are lineage-negative, CD11c<sup>+</sup>, CD123<sup>-/low</sup>, CD4<sup>+</sup>, CD80<sup>hi</sup>, CD86<sup>+</sup>, CD45RO<sup>+</sup>, CD45RA<sup>low</sup>, CD33<sup>+</sup>, CD13<sup>+</sup>, CD54<sup>+</sup>, CD58<sup>+</sup>, CD62L<sup>-/low</sup>, CD36<sup>low</sup>, CD83<sup>+</sup> (small subset, most negative), HLA-DR<sup>hi</sup>, CD206 [mannose receptor]<sup>+</sup>, CCR7<sup>-</sup>, TLR2<sup>+</sup>, TLR4<sup>+</sup>, TLR7<sup>-</sup>, TLR9<sup>-</sup>, CD1a<sup>+</sup>, CD1b<sup>+</sup>, CD1c<sup>+</sup>, and CD1d<sup>+</sup> cells. Functionally, they exhibit high phagocytic potential and are likely to be rapidly recruited to the site of Ag entry (e.g., mucosal surfaces, skin). They are specialized to be the first to respond to microbial invasion via body surfaces. mDC produce large amounts of IL-12, IL-6, and TNF- $\alpha$  in response to TLR2 and TLR4 ligands, favoring the induction of Th1 responses [26,62]. However, the presence of other immunoregulatory molecules, such as prostaglandin E<sub>2</sub>, may favor mDC priming of Th2 cells.

On the other hand, pDC are lineage-negative, CD11c<sup>-</sup>, CD123<sup>hi</sup>, CD4<sup>+</sup>, CD80<sup>+</sup>, CD86<sup>+</sup>, CD45RO<sup>-</sup>, CD45RA<sup>hi</sup>, CD13<sup>-</sup>, CD62L<sup>hi</sup>, CD33<sup>-</sup>, CD83<sup>-</sup>, HLA-DR<sup>hi</sup>, CD206<sup>-</sup>, CCR7<sup>+</sup>, TLR2<sup>-</sup>, TLR4<sup>-</sup>, TLR7<sup>+</sup>, TLR9<sup>+</sup>, CD1a<sup>-</sup>, CD1b<sup>-</sup>, CD1c<sup>-</sup>, and CD1d<sup>-</sup> cells. These DC exhibit plasma cell-like morphology, and are functionally characterized by producing large amounts of IFN- $\alpha$  and IFN- $\beta$  in response to TLR9 ligation. These are poorly phagocytic, are located mainly in T cell areas of lymphoid tissues, and are likely to be specialized to recognize self-Ag or blood-borne pathogens. They also play an important role in antiviral innate immunity through production of IFN- $\alpha$  and IFN- $\beta$ . In general, pDC are believed to favor Th2 development, although this view has recently been challenged [26,62]. Because blood DCs do not migrate to inflammatory cytokines, they probably reach the LN by responding to SDF-1 (a chemokine expressed in LN) using CXCR4, and CD62L interaction with L-selectin ligands expressed in endothelial venules. This interaction may provide a maturational signal that couples CCR7 with migration, allowing the proper positioning of pDC in LN in response to secondary lymphoid tissue chemokines. To add to the complexity of the function of DC in Ag presentation, mDC and pDC regulate each other through the cytokines they release [61,62]. For example, IL-10 has been shown to induce apoptosis in developing DC, a process that can be overcome by the addition of tumor necrosis factor (TNF- $\alpha$ ) or CD40L. Moreover, DC exhibit immunoregulatory effects on B cell proliferation, differentiation, and isotype switching [67].

Based on the extraordinary capabilities of DC to prime the immune system, a number of clinical trials have recently explored the use of DC in immunotherapy for cancer based on the injection of Ag-pulsed DC [61]. These studies showed that this approach is safe and yielded promising preliminary

results, but definitive proof of efficacy is still pending. Further understanding of DC biology is undoubtedly one of the primary areas that, in the coming years, will provide critical information to advance novel vaccination strategies.

## 2. Other Antigen Presenting Cells

In contrast to DC, the main role of macrophages is to phagocytose, following recognition through PRRs and other receptors such as Ig Fc receptors, and destroy invading microbes. Ag peptides from the pathogens then become available for binding to MHC molecules for presentation to T cells. Once activated, they upregulate their expression of MHC and costimulatory molecules and can become rather effective APC. Nevertheless, macrophages are considerably less efficient than DC at activating naïve T cells. Macrophages are a major source of proinflammatory cytokines, including IL-1 $\alpha$ , IL-1 $\beta$ , IL-6, IL-8, IL-12, TNF- $\alpha$ , and TNF- $\beta$ , that exert potent immunoregulatory activities on T cell responses. B cells can also function as professional APCs by presenting to Th cells peptides derived from soluble Ag following internalization and processing of Ag bound to the B cell receptor complex, which consists of the specific membrane Ig and associated invariant Ig $\alpha$  (CD79 $\beta$ ) and Ig $\alpha$  (CD79 $\beta$ ) polypeptides [68].

## IV. APC-T CELL INTERACTIONS AND T-CELL ACTIVATION

### A. Antigen Recognition by $\alpha/\beta$ TCR-CD3 Complexes

The receptor on the surface of the majority of T cells which recognizes MHC-Ag complexes on the APC is a heterodimer composed of an  $\alpha$  ( $\sim$ 40–60 kDa) and a  $\beta$  chain ( $\sim$ 40–50 kDa) covalently linked by disulfide bonds [69]. Both  $\alpha$  and  $\beta$  chains are transmembrane glycoproteins, members of the Ig superfamily, that contain variable and constant regions. Amino acid residues in the hypervariable regions of both chains contribute to binding to the MHC molecules and the peptide fragment aa side chains extending out from the peptide-binding groove [69]. While the TCR  $\alpha/\beta$  heterodimer is responsible for recognition and binding to the MHC-peptide complexes, their ability to transduce signals inside the cells and trigger cell activation depends on several associated proteins, including the  $\gamma$ ,  $\delta$ ,  $\epsilon$ , and  $\zeta$  CD3 proteins, which associate noncovalently with the  $\alpha/\beta$  heterodimer to form the TCR-CD3 complex [70]. It appears that each TCR complex includes two TCR  $\alpha/\beta$  heterodimers per CD3 cluster [69]. All CD3 molecules contain, in their cytoplasmic tails, tyrosine phosphorylation motifs, named immunoreceptor tyrosine-based activation motifs (ITAMs), which are critical for TCR-mediated T-cell activation. However, it should be emphasized that the signals generated by the TCR-CD3 complex are not sufficient to trigger T-cell activation. As will be discussed later in more detail, the presence of costimulatory signals is critical for successful T-cell activation. It should also be noted that TCR molecules and all CD3-associated proteins are the same in CD4 $^+$  Th and CD8 $^+$  CTL. In addition to signal transduction, CD3

proteins also play a vital role in the assembly and transport of  $\alpha/\beta$  heterodimers to the cell surface [69].

### B. Antigen Recognition by $\gamma/\delta$ TCR-CD3 Complexes

In addition to  $\alpha/\beta$  heterodimers, a second type of TCR, consisting of evolutionarily conserved  $\gamma/\delta$  heterodimers, is expressed in a small proportion of peripheral blood T lymphocytes (1–5%) and in more substantial numbers in regional sites, such as in mucosal surfaces of the gastrointestinal tract (10% in humans and up to 50% of intraepithelial lymphocytes in mice) [71,72]. These  $\gamma/\delta$  TCR T cells seem to originate from a different lineage than T cells expressing  $\alpha/\beta$  TCR and the majority of them are double negative for CD4 and CD8 molecules, although minor subpopulations of  $\gamma/\delta$  TCR T cells have been shown to express CD8 consisting of  $\alpha/\alpha$  homodimers or the CD4 $^+$  CD8 $^+$  phenotype [71,72]. The biochemical structure of TCR  $\gamma$  and  $\delta$  transmembrane glycoproteins, containing variable and constant regions, resembles that of TCR  $\alpha$  and  $\beta$  chains [69]. These  $\gamma/\delta$  TCR are also expressed in association with CD3 proteins and depend upon them for expression on the cell surface and signal transduction inside the cells. It is not entirely known at present how and which Ag are recognized by  $\gamma/\delta$  TCR T cells, but it appears that these cells are activated by superantigens or Ag associated with nonpolymorphic MHC-like molecules (e.g., those encoded by the HLA-E, -F, and -G regions) or by CD1; only a small minority recognizes peptides presented in the context of classical class I and II MHC molecules [69,71,72]. Recognition by  $\gamma/\delta$  TCR T cells of proteins and small phosphoantigens (phosphate-containing nonpeptide Ag) isolated from mycobacterial extracts does not require Ag processing, i.e., Ag are recognized directly [71,72]. These differences between the way in which  $\gamma/\delta$  and  $\alpha/\beta$  T cells recognize Ag suggest that specialized APC might not be required for the activation of  $\gamma/\delta$  T cells, providing additional flexibility for the generation of effector CMI against infectious agents. T cells expressing the  $\gamma/\delta$  TCR-CD3 complex have been shown to play a significant role in protection against infectious organisms (e.g., *Leishmania*, *Mycobacteria*, *Plasmodium*, *Salmonella*), particularly in the gastrointestinal tract and other mucosal surfaces, by mediating a number of effector immune responses, including cytokine production and CTL activity [71,72].

### C. The Immunological Synapse

Studies conducted in the last decade have established that T-cell activation is a complex process that requires at least two signals, one provided by the interaction of the TCR complex ( $\alpha/\beta$  TCR and associated CD3 molecules) with pMHC on APC and a second, complementary signal provided by binding of CD28 (a costimulatory molecule on T cells) to members of the B7 family (e.g., CD80 [B7-1]) on APC [19,20]. Many additional molecules have also been shown to play important roles in T-cell activation. The term “immunological synapse” (IS) was recently coined to describe the organized molecular complex that is assembled at the interface between the T cell and the APC where the interac-

tion between the TCR complex and pMHC molecules takes place [19–21,73,74]. Formation of IS has been described not only for CD4<sup>+</sup> and CD8<sup>+</sup> T cells, but also for NK cells, suggesting that they may be a common feature of lymphocyte activation. The IS has been found to have a remarkable level of organization, characterized by a “bull’s eye” arrangement of supramolecular activation clusters (SMAC), which form within 30–60 min of T cell–APC contact [20]. The central portion of the IS (cSMAC) is enriched for TCR and pMHC complexes, as well as coreceptors CD4 or CD8 and CD28 and its ligand, CD80. The ring around the core (pSMAC) includes other costimulatory molecules [e.g., CD11a/CD18 (LFA-1) and its ligand, CD54 (ICAM-1), and CD2 and its ligands CD48 and CD58 (ICAM-3)], as well as signaling molecules in the cytoplasmic side of the T cell (e.g., protein kinase C θ and the src family kinase lck [19,20]). Interactions among adhesion molecules in the pSMAC, including LFA-1, CD54, CD2, CD48, and CD58, play key roles in maintaining small distances (~15 nm) between apposing T cell and APC membranes and in providing additional signaling [19,73,75].

Important findings derived from the study of the IS include the observations that an intact cytoskeleton is an absolute requirement for the T cell but not for the APC, and that the formation of a stable IS for at least 1 hr is required for full T-cell activation. Several temporal stages have been described in T-cell activation, including T-cell polarization, initial adhesion, IS formation (initial signaling), and IS maturation (sustained signaling) [20]. Exposure of naive recirculating T cells to chemokines/cytokines (e.g., signaling from the innate system) and the resulting T-cell polarization, which includes cytoskeletal rearrangements, are the required steps preceding the initial APC–T cell interaction and the subsequent IS formation. The precise functions of the mature IS remain controversial. For example, recent evidence showing that the very early events of TCR signaling occur before the formation of the mature IS suggest that this phenomenon is not a requirement for TCR triggering [76]. However, IS appears to play important roles in amplifying weak TCR signaling through concomitant CD28 engagement in the cSMAC and in allowing polarized secretion by T cells [73]. Functional synapses (characterized by the induction of calcium signaling, movement of surface molecules, etc.) between the majority of T cells and DC are formed in the absence of specific Ag, highlighting the uniqueness of T cell–DC interactions [77]. Novel findings in the burgeoning field of IS formation in T-cell activation and signaling will undoubtedly lead to new approaches to enhance and/or modulate the type of immune responses induced by vaccination.

#### D. Brief Summary of Signal Transduction Events Following Activation Through the TCR–CD3 Complex

Intense research efforts over the past decade have greatly advanced our understanding of the complex biochemical events triggered by the TCR complexes following Ag recognition that ultimately result in the activation of genes in the nucleus leading to the production of cytokines and other important molecules involved in effector CMI responses.

However, a detailed description of these events is beyond the scope of this review. Instead, we will provide a brief summary of these phenomena and refer the reader to numerous excellent reviews that summarize in great detail current understanding of these phenomena [20,78–81].

The first event detected following TCR–CD3 ligation is the lck-mediated phosphorylation of tyrosine residues within the ITAMs of the invariant CD3 and TCR  $\zeta$ -chain dimers, and the recruitment and activation of ZAP-70. In turn, ZAP-70 phosphorylates a number of adapter proteins, i.e., proteins lacking enzymatic activities, but that, upon activation, change their conformation allowing other enzymes or adapters to bind resulting in the formation of multiprotein complexes. Phosphorylation of these adapter proteins, including LAT (linker for activation of T cells) and SLP-76, leads to the recruitment and activation of phospholipase C $\gamma$ 1 [PLC- $\gamma$ 1], PI-3K, Itk, and GEFs to the activated TCR complex. Activation of these molecules initiates important signaling pathways. For example, PLC- $\gamma$ 1 cleaves phosphatidylinositol biphosphate (PIP<sub>2</sub>) to yield diacylglycerol (DAG) and inositol triphosphate (IP<sub>3</sub>). DAG, together with increased Ca<sup>2+</sup>, activates protein kinase C, which, in turn, activates the transcription factor NF $\kappa$ B. On the other hand, IP<sub>3</sub> increases intracellular Ca<sup>2+</sup>, leading to activation of calcineurin, which, in turn, activates the transcription factor NFAT. Other key molecules, guanine-nucleotide exchange factors (GEFs), activate Ras which, in turn, activates a mitogen-activated protein (MAP) kinase cascade, leading to the activation of Fos (a component of the AP-1 transcription factor). Together, NF $\kappa$ B, nuclear factor of activated T-cells (NFAT), and AP-1 induce specific gene transcription by binding to regulatory sites in the DNA (including the IL-2, IL-2R $\alpha$ , and IFN- $\gamma$  genes) [20,78–81]. The coordinated expression of genes which encode cytokines and other molecules, such as cyclins, ultimately results in T-cell proliferation and differentiation. Activation of these “early genes,” is also followed by the appearance of a number of cell surface molecules that play critical roles in T-cell activation, differentiation, and proliferation, including CD69, CD25 (IL-2R $\alpha$ ), class II MHC molecules, etc. Notably, tyrosine phosphorylation, calcium flux, and the generation of inositol phospholipids reach maximum levels within 30 sec to 5 min following activation, coinciding with the early stages of IS formation [81]. However, elevation of intracellular Ca<sup>2+</sup> ion levels, PI turnover, and transcription factors (e.g., NFAT) in the nucleus should be sustained for 60–120 min for effective signal transduction leading to cell proliferation, which coincides with the “commitment period” during the initial stages of T-cell activation and formation of the mature IS [74]. Naive T cells need 20 hr or longer of sustained stimulation to increase their size and become committed to proliferation [74].

#### E. Activation of T Cells by Superantigens

Superantigens consist of certain bacterial and viral proteins that, without processing, trigger activation of up to 20% of T cells, including CD4<sup>+</sup> and CD8<sup>+</sup> cells. This activation is triggered by high-affinity binding of these superantigens to the lateral sides of class II MHC molecules on APC and to

the  $\beta$  chain ( $V_\beta$ ) of  $\alpha/\beta$  TCR T cells [69,82,83]. The recognition between T cells and superantigens is specific and clonally variable, because superantigens activate T cells bearing particular  $V_\beta$  regions. Triggering of T cells by superantigens requires the complete TCR–CD3 complex and accessory molecules, including CD4, CD8, CD2, and LFA-1 ( $\alpha_L\beta_2$  integrin) [69,82,83]. Instead of priming an adaptive immune response to the pathogen, T-cell activation by superantigens causes a massive cytokine production, mainly by  $CD4^+$  T cells. The cytokine response not only causes systemic toxicity, but also downregulates the host's adaptive immunity and might be involved in the triggering of autoimmune diseases. In addition, superantigens induce the activation of APC, leading to the production of proinflammatory cytokines, such as IL-1 $\beta$  and TNF- $\alpha$ . The high levels of APC and T-cell activation, and the ensuing release of cytokines triggered by superantigens, play a significant role in the generation of toxic shock syndrome and food poisoning associated with some bacterial infections. Superantigens include products of bacterial and viral origin. Bacterial superantigens include staphylococcal enterotoxins (SE)-A, SE-B, SE-C, SE-D, SE-E, the toxic shock syndrome toxin-1 (TSST-1), and those produced by streptococci, *Yersinia*, and *Mycoplasma arthritidis*. Viral superantigens include retroviral glycoproteins, such as the minor lymphocyte stimulating Ag (MIs) produced by the mouse mammary tumor viruses, and products of rabies and moloney leukemia viruses [69, 82,83].

## **V. ROLE OF CD28, CD40, 4-1BB, AND OTHER COSTIMULATORY MOLECULES IN LYMPHOCYTE ACTIVATION**

From the discussion of the formation of the “immunological synapse,” it is apparent that many molecules, in addition to the TCR/CD3 complex interacting with pMHC, are involved in the induction of lymphocyte activation. Chief among them are coreceptors CD4 or CD8 and costimulatory molecules CD28 and its B7 family ligands, CD80 and CD86, CD40 and its ligand, CD154 [CD40L] and 4-1BB and its ligand, 4-1BBL [84–87]. Interactions among these molecules are complex. Some of them, such as coreceptors CD4 and CD8, have a dual role by contributing to T cell–APC cell-cell adhesion and by actively participating in the signal transduction processes triggered following TCR–CD3 complex–pMHC interactions. Moreover, recent data indicate that  $CD4^+$  and  $CD8^+$  T cells exhibit different requirements for optimal stimulation [88]. For example,  $CD4^+$  T-cell activation depends on CD154 (expressed predominantly in activated  $CD4^+$  T cells) interacting with CD40 (expressed in B cells, DC, and macrophages) and on CD28 (in  $CD4^+$  T cells) interacting with CD80 and CD86 in APC. Regarding  $CD8^+$  T cell responses, two types have been described, i.e., those that are relatively independent (e.g., Sendai virus, influenza virus) or those that are relatively dependent (e.g., adenovirus, herpes simplex virus, tumor Ag) on Th cells. Th-independent  $CD8^+$  T cell responses are less dependent on CD40/CD154 interactions than Th-dependent responses. In contrast, both types of  $CD8^+$  T cell responses are dependent, to a considerable extent, on CD28/CD80–CD86 and 4-1BB (in  $CD8^+$  T cells)/4-1BBL (in APC) interactions [88]. In addi-

tion to  $CD8^+$  T cells, 4-1BB is expressed in many other cells, including  $CD4^+$  T cells, NK, and APC, and 4-1BBL is expressed in APC and other cells. These observations suggest that these costimulatory molecules could also be involved in linking innate and adaptive immunity [84].

Some costimulatory molecules, such as CD28, are constitutively expressed in naive cells and their expression increases following activation, while others (such as CD152 [CTLA-4]) are only expressed after activation. CD152, despite binding the same receptors as CD28 (i.e., CD80 and CD86), is expressed later after activation and is involved in downregulating, rather than favoring, lymphocyte stimulation [85–87]. Furthermore, CD28 appears to play a key role in regulating the differentiation of Th1 and Th2 T cell subsets, favoring polarization toward Th2 responses [26]. The number of costimulatory molecules shown to be involved in lymphocyte activation is dramatically increasing, as is the complexity of their interactions. For example, new members of the B7 family were recently described [86]. These include ICOS, a receptor homologous to CD28 and CD152 (in activated T cells) that interacts with the ICOS-L (constitutively expressed in APC) providing positive costimulatory signals, and PD-1 (in activated T cells, B cells, and macrophages) interacting with PD-L1 and PD-L2 receptors (in activated DC, B cells, and macrophages) that downregulates lymphocyte activation [86]. A thorough understanding of the complex interactions among costimulatory molecules, which result in either enhancement or suppression of T-cell activation, will remain an important area of investigation in the coming years.

## **VI. CYTOKINES AND CHEMOKINES: LINKING ADAPTIVE AND INNATE IMMUNITY**

As discussed above, it has become apparent that particular patterns of cytokines and chemokines secreted following pathogen invasion, as well as the temporal sequence of their production, play a dominant role in determining the outcome of the host's immune response and its ability to control infection. Because of space limitations, it is not possible to describe the many roles and interactions among cytokines and chemokines and their receptors. Thus for detailed descriptions of individual cytokines and chemokines, the reader is referred to a number of excellent books and reviews that have been recently published [89–98]. Instead, we will concentrate in briefly describing our current understanding on how the coordinated induction of chemokines and polarized cytokine patterns play a role in resistance to disease by invading pathogens, as well as their role in downregulating immune responses, and provide some examples on the intricate interactions among these potent mediators in cross-regulating innate and adaptive immunity.

### **A. Cytokines**

These immunoregulatory molecules, secreted by immune, as well as other cells, play key roles in the clonal expansion of lymphocytes, in mediating the action of effector cells, and in regulating innate immunity. In spite of their diversity, most cytokines share the following characteristics: (1) they are

produced by more than one cell type and act on many different cells (pleiotropism), sometimes exerting more than one effect on a single target cell; (2) their production follows cell activation, requires de novo RNA and protein synthesis, and is transient; (3) similar activities are typically performed by more than one cytokine (redundancy); (4) production of individual cytokines follows the release of other cytokines producing a “cascading effect”; (5) they regulate each other, either positively or negatively, sometimes synergizing or exhibiting additive effects; (6) they exert their functions by interacting with high-affinity specific receptors on the target cells ( $10^{-9}$  to  $10^{-12} K_d$ ) that they help regulate; (7) they can exert their activities locally, systemically, or both by acting in an autocrine (i.e., on the cells that produce them), paracrine (i.e., on adjacent cells), or endocrine (i.e., on distant cells) fashion; and, (8) their actions on the target cells usually involve regulation of proliferation and state of differentiation [89,90,93–98].

The diversity of cell sources and targets, overlapping biological functions, and disparate biochemical structures have rendered cytokines difficult to classify into defined categories. Nevertheless, based on their dominant biological activities, cytokines can be divided into three main classes: (1) those involved primarily in regulation of hematopoiesis [e.g., granulocyte-macrophage colony stimulating factor (GM-CSF), monocyte-macrophage-CSF (M-CSF), granulocyte-CSF (G-CSF), IL-3 (or multi-CSF), IL-7, IL-9, IL-11]; (2) those involved in proinflammatory activities typically associated with innate immunity (e.g., IL-1 $\alpha$ , IL-1 $\beta$ , IL-6, IFN- $\alpha$ , IFN- $\beta$ , TNF- $\alpha$ , chemokines); and (3) those predominantly involved in regulating activation, differentiation, and function of lymphocytes and other cells during inflammatory responses associated with adaptive immunity [e.g., IL-2, IL-4, IL-5, IL-10, IL-12, IFN- $\gamma$ , TNF- $\beta$  (lymphotoxin), transforming growth factor- $\beta$  (TGF- $\beta$ )].

## B. The Th1/Th2 Paradigm

Distinct Th cell populations exhibit discrete or overlapping patterns of cytokine production that designate Th1 and Th2 CD4 $^+$  T cells [26,27,29–32,99,100]. Th1 cells are characterized by the production of IFN- $\gamma$  and TNF- $\beta$ , while Th2 cells are characterized by the production of IL-4, IL-5, IL-9, IL-10, and IL-13. Cells producing a combination of these cytokines were named Th0. CD8 $^+$  cells also exhibit type 1 (Tc1) and type 2 (Tc2) cytokine profiles [31,99]. The existence of CD4 $^+$  T populations with strong downregulatory activity, characterized by the secretion of defined cytokine patterns (e.g., TGF- $\beta$ ), was reported recently [30]. Many Th cells exhibit “mixed” cytokine production (e.g., IL-2, IL-4, IL-5, and IFN- $\gamma$ ), which does not allow them to be classified into Th1 or Th2 cells, even within populations that are polarized toward Th1 or Th2 patterns [100]. Moreover, there is a certain plasticity by which Th1 cells can revert to a Th2 phenotype, although reversion in the opposite direction is more difficult [100].

Typically, Th1 responses promote CMI, such as CTL activity, delayed-type hypersensitivity (DTH), ADCC, macrophage activation, and provide help for the production of certain Ig isotypes (IgG2a in mice, probably IgG2 in humans). Consequently, Th1 responses have been associated

with beneficial responses (or found to predominate) in infections caused by protozoa (e.g., *Leishmania major*, *Trypanosoma cruzi*), viruses (e.g., influenza), bacteria (e.g., *M. tuberculosis*, *M. leprae*, *S. enterica* serovar Typhi, *Bordetella pertussis*, *Chlamydia*, *Listeria monocytogenes*), and fungi (e.g., *Candida*) [31,101,102]. In contrast, Th1 responses have been associated with detrimental responses in helminthic infections and in pathological conditions, such as autoimmune disorders (e.g., experimental autoimmune encephalomyelitis, multiple sclerosis, and rheumatoid arthritis), chronic inflammation, transplant rejection, and pregnancy [31,32,101]. On the other hand, Th2 responses provide help for Ig production by B-cells, including IgE, IgG (IgG1 in mice, IgG4 in humans), and IgA, and promote mast cell and eosinophil growth and differentiation. Accordingly, Th2 responses were found to be associated with beneficial responses in infections caused by helminths (e.g., *Trichuris muris*, *Nippostrongylus brasiliensis*, *Brugia malayi*) and some bacteria (e.g., *Borrelia burgdorferi*), and with detrimental responses in infections caused by protozoans (e.g., *L. major*) and viruses (e.g., vaccinia, herpes simplex virus), and in pathological conditions such as allergy and atopic asthma [31,32,100,101].

To a considerable extent, Th1 and Th2 responses are mutually inhibitory phenotypes, leading to the predominance of either Th1 or Th2 responses. As soon as a T cell response progresses along a Th1 or Th2 pathway, it tends to become polarized in that particular direction [100], largely because of the inhibitory effects of Th1 cytokines on Th2 responses and vice versa. For example, IL-10 inhibits cytokine synthesis by Th1 cells and downregulates macrophage activation, while IFN- $\gamma$  inhibits Th2 cell proliferation. In many experimental systems in animals, the resistance or susceptibility to infection *in vivo* can be altered by modulating the type of cytokine patterns by injection of exogenous cytokines (e.g., IFN- $\gamma$ , TGF- $\beta$ , IL-12, IL-4) and/or neutralizing monoclonal Ab to cytokines (e.g., anti-IFN- $\gamma$ , anti-IL-4), during the early phases of the immune response. Many factors, including the nature and dose of Ag, the route of entry, the nature and maturation stages of the participating DC, the host's genetic make-up, and the cytokines and chemokines present in the microenvironment during the early stages of lymphocyte activation, are believed to play key roles in determining the predominant polarized cytokine patterns elicited by the invading pathogen [26,27,29–32,99,100]. For example, it has been suggested that the Th1-promoting capabilities of DC correlate with their ability to produce certain cytokines and chemokines, particularly IL-12, while the absence of these mediators might favor the generation of predominantly Th2 responses [26]. An in-depth understanding of the mechanisms involved in the generation of polarized Th1/Th2 responses has the potential, like few other areas in immunology, to dramatically impact vaccine development.

## C. Regulatory T Cells and Cytokines Involved in the Downregulation of Immune Responses

In recent years, the existence of several subsets of regulatory T cells (Tr, formerly known as “suppressor” T cells) exhibiting defined phenotypes and patterns of cytokine production,

distinct from Th1 and Th2 cells, has been firmly established [30]. Tr cells are believed not only to play a key role in maintaining self-tolerance by downregulating immunity to self Ag, but also to be intimately involved in the regulation of immunity to pathogens by suppressing pathogen-induced immunopathology or prolonging the persistence of microorganisms by downregulating protective Th1 immunity [30]. At least four distinct populations of Tr cells have been described to date: (1) Tr1 cells, which secrete high amounts of IL-10 and moderate levels of TGF- $\beta$ , but not IL-2, IL-4, or IFN- $\gamma$ ; (2) Th3 cells, which secrete high levels of TGF- $\beta$ ; (3) CD4 $^{+}$ CD25 $^{+}$  cells, shown to inhibit immunity through undefined mechanisms requiring cell-cell contact; and (4) CD8 $^{+}$  Tr cells, which can secrete either IL-10 or TGF- $\beta$ . Recent evidence showing that Tr1 cells suppress protective Th1 responses against *B. pertussis*, and the immunoregulatory properties of CD4 $^{+}$ CD25 $^{+}$  cells in a model of *P. carini* infection, highlights the importance of Tr cells in the host's immune response to microorganisms [30]. IL-10-secreting DC ("DCr") apparently direct naive T cells toward a Tr1 subtype. Because of their predominantly downregulatory properties, production of IL-10 and/or TGF- $\beta$  are the likely mediators of Tr activity. IL-10 suppresses adaptive immune responses and inflammation, while promoting the survival and differentiation of B cells [103]. Similarly, TGF- $\beta$  inhibits the differentiation of both CD4 $^{+}$  and CD8 $^{+}$  naive T cells into effectors, blocks Th1 and Th2 development by inhibiting transcriptional activators, and downregulates macrophage activation, class II MHC expression, cytokine synthesis, NK cytolytic activities, and activation of neutrophils and endothelial cells by proinflammatory cytokines, while promoting IgA production [89,104]. Because of these powerful biological activities, IL-10 and TGF- $\beta$  are likely to play a dominant role in preventing inappropriate responses to certain self- or environmental Ag.

Other cytokines have also been shown to play a role in downregulating immunity and inflammation. For example, the IL-1R antagonist (IL-1RA), mainly produced by macrophages, neutrophils, keratinocytes, and epithelial cells, acts as a competitive inhibitor of IL-1 by binding to the same receptors as IL-1 without triggering biological function [89]. In this way, IL-1RA acts as an antiinflammatory molecule by blocking IL-1-mediated proinflammatory activities. Soluble cytokine receptors for IL-1, IL-2, and many other cytokines have also been described and they are postulated to act as antiinflammatory mediators by binding to the corresponding cytokine in the microenvironment, thereby precluding them from binding to the corresponding cytokine receptor on the surface of the target cells. The understanding of the mechanisms underlying the induction and maintenance of Tr cells, as well as the release of other antiinflammatory cytokines, might lead to the development of novel vaccines against autoimmune diseases, as well as therapies to control graft rejection, inflammation, and allergy.

#### D. Chemokines

Chemokines are a distinct class of cytokines that exhibit chemoattractant properties, i.e., they cause cells with the appropriate receptors to migrate toward the chemokine source [91,92,105–107]. Moreover, recent data indicates that

chemokines might also regulate the polarity and magnitude of T-cell cytokine responses [92]. More than 50 chemokines have been identified to date. Most chemokines fall into two main families, cys-X-cys (also called C-X-C;  $\alpha$ -chemokines or inflammatory chemokines) and cys-cys (also called C-C or  $\beta$ -chemokines), depending on whether the two N-terminal cystein residues are adjacent or have an additional aa between them. The nomenclature of the ever growing number of chemokines and their receptors has been revised recently [108]. C-X-C chemokines (e.g., CXCL1–CXCL14) are mainly produced by macrophages, neutrophils, fibroblasts, endothelial cells, etc. and attract neutrophils predominantly. In contrast, C-C chemokines (e.g., CCL1-5, CCL7, CCL8, CCL11, and CCL13-27) are mostly produced by activated lymphocytes and attract monocytes, basophils, eosinophils, and lymphocytes [108]. Chemokine receptors have also been renamed, based on the chemokine subclass specificity of the receptor (e.g., CXCR1-5, CCR1-11) [108]. Chemokines and their receptors are now considered to be the most important regulators of leukocyte trafficking. They have been shown to play key roles in many fundamental immunological processes, including, among others: (1) leukocyte binding to endothelium leading to extravasation (together with selectins and other adhesion molecules); (2) control the traffic of developing B and T cells (through expression of defined sets of chemokine receptors at various maturational stages, e.g., naive T-cell activation, effector T cell differentiation and memory cell development; see below); (3) migration of DC to tissues and from tissues to LN (critical for immune surveillance, priming, and tolerance); (4) migration of monocytes to tissues in response to inflammatory stimuli; (5) interactions between naive T cells and DC and between T and B cells in secondary lymphoid organs; (6) Th2 attraction of eosinophils (through production of CCL11 [eotaxin-1], CCL24, CCL26, and others that bind CCR3 in eosinophils); (7) recruitment of Th1 cells to sites of inflammation (through CCR5 and CXCR3 expression); (8) migration of memory and effector CD4 $^{+}$  and CD8 $^{+}$  T cells to effector sites, such as the gut mucosa (through CCR9) or the skin (through CCR4 and CCR10) in conjunction with other adhesion molecules (e.g., integrin  $\alpha_4\beta_7$  for gut homing and CLA for skin homing; see Section VII.C); and (9) PMN migration and degranulation [through CXCR1 and CXCR2 binding CXCL8 (IL-8)] [91,92,105–107].

Many chemokines are spontaneously produced at specific sites. For example, CCL21 (SLC) and CCL19 (MIP-3 $\beta$ , ELC) produced in the T cell area of LN, attract DC, T cells, and other leukocytes expressing their ligand, CCR7. However, these chemokines are also released by other cells, such as DC, to attract naive T cells. Because of the key role of chemokines in inflammation, several therapeutic modalities directed to control their activity in diseases associated with tissue destruction resulting from inflammatory responses (e.g., allergies, asthma, rheumatoid arthritis, pneumonia) are being vigorously explored.

#### E. Cytokines and Chemokines Linking Innate and Adaptive Immunity

Cytokines and chemokines are the major mediators between APC, lymphocytes, and other cells, and are central to the

innate immune system's capacity to dramatically influence the type and magnitude of adaptive immunity and in the ability of the adaptive immune response to markedly affect inflammatory responses [109,110]. For example, cells of the innate immune system (e.g., macrophages, DC) secrete type I interferons (IFN- $\alpha$ , IFN- $\beta$ ), GM-CSF, IL-1, and TNF- $\alpha$ , which promote the activation and differentiation of DC (a major cell type linking innate and adaptive immunity), as well as IL-12, IL-15, and IL-18, which dramatically affect the adaptive immunity induced. Of note, IL-12 has been recently shown to induce DC and macrophages to secrete IFN- $\gamma$ , a cytokine traditionally considered to be produced by cells of the adaptive immune response [94]. In turn, IFN- $\gamma$  markedly affects the activation of cells of innate immunity, for example, by (1) stimulating the cytolytic activity of NK cells, (2) increasing the expression of class I and II MHC molecules and the production of an array of proinflammatory mediators including IL-1 $\alpha$ , IL-1 $\beta$ , TNF- $\alpha$ , IL-6, and IL-8 by APC, and (3) directly promoting nonspecific killing of bacterial organisms by enhancing the microbicidal activity of macrophages through induction of nitric oxide synthase and protease activity [109,110]. Because of the central role that cytokines, chemokines, and their receptors play at virtually all levels during the generation of immune responses and as major players in linking innate and adaptive immunity, continued studies on their functions and complex interactions will provide invaluable information to help in the development of novel vaccine strategies.

## VII. INTEGRINS, SELECTINS, AND CHEMOKINES IN CELL-CELL INTERACTIONS AND LYMPHOCYTE TRAFFICKING

A highly interrelated network of molecules and their receptors belonging to three separate families has been shown to play a leading role in directing the trafficking of immune cells to sites of inflammation and secondary lymphoid tissues. These include chemokines (see Section VI.D), integrins, and selectins.

### A. Integrins

Integrins are a superfamily of heterodimers consisting of noncovalently associated  $\alpha$  and  $\beta$  subunits that, by mediating cell-cell (e.g., endothelial cells) and cell-matrix (e.g., collagen, fibronectin) adhesion, play a major role in T-cell activation and homing to secondary immunological organs and sites of inflammation [111–113]. The fact that most members of the integrin family involve a common  $\beta$  subunit associating with specific  $\alpha$  subunits lead to the original classification of integrins into the so-called  $\beta$ -integrin families. A total of 8  $\beta$  subunits and 21  $\alpha$  subunits have been identified to date [111]. In some cases, a particular  $\alpha$  chain subunit can bind to more than one  $\beta$  chain. Among the key integrin families involved in lymphocyte homing are members of the  $\beta_1$  (CD29) family, which consists of at least nine members (heterodimers composed of  $\beta_1$  and  $\alpha_1$ – $\alpha_8$  or  $\alpha_v$ ), the  $\beta_2$  (CD18) family (heterodimers composed of  $\beta_2$  and  $\alpha_L$ ,  $\alpha_M$ , or  $\alpha_x$ ) and the  $\beta_7$  family (heterodimers composed of  $\beta_7$  and  $\alpha_4$  or  $\alpha_{HML}$ ).

The family of  $\beta_2$  integrins, which is expressed on all leukocytes and has been shown to mediate transmembrane signal transduction, includes three homologous heterodimers composed of a common  $\beta_2$  chain (CD18): complement receptor 3 (CR3, CD11b/CD18, found predominantly in monocytes, NK, and neutrophils, as well as in some lymphocytes), CR4 (CD11c/CD18, found in macrophages, granulocytes, and some T cells) and the  $\alpha_L\beta_2$  integrin (LFA-1, CD11a/CD18) that is expressed in lymphocytes, monocytes, NK, and other leukocytes) [114]. For example, CR3 recognizes the iC3b complement component, the intercellular adhesion molecule-1 (ICAM-1), fibrinogen, and other ligands and relays this “proinflammatory information” to the cytoplasm via exodomain interactions [114].

### B. Selectins

Selectins comprise a family of three carbohydrate-binding molecules involved in leukocyte–endothelial cell adhesion: L-selectin (CD62L; present in T and B lymphocytes, monocytes, NK, neutrophils, and other cells), E-selectin (CD62-E, ELAM-1; present in endothelial cells), and P-selectin (CD62-P; present in platelets, activated endothelial cells, and megakaryocytes). CD62L (peripheral lymph node homing receptor) is expressed at high levels in most naive CD45RA<sup>hi</sup>CD45RO<sup>lo</sup> T cells, and its expression declines after activation. Thus CD62L is expressed at low levels in most T<sub>m</sub> cells. CD62L plays a key role in the interaction of lymphocytes with high endothelial venules (HEV) by recognizing carbohydrate moieties in the surface glycoproteins of endothelial cells, including the glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1), CD34, and the peripheral-node addressin (PNAd) in LN [112,115].

### C. Role of Integrins, Selectins, and Chemokines: An Integrated View of Lymphocyte Tracking

Because the first step in lymphocyte migration to peripheral tissues involves leukocyte adhesion to the vascular endothelium, the capacity of integrins to bind to vascular addressins plays a critical role in lymphocyte homing. For example, integrins belonging to the  $\beta_7$  integrin family, such as  $\alpha_4/\beta_7$  (LPAM-1, lymphocyte Peyer's patch adhesion molecule 1) and  $\alpha_E/\beta_7$  (HML-1), appear to be critical for lymphocyte homing to mucosal tissues [107,115–117]. The  $\alpha_4/\beta_7$  integrin binds to the mucosal addressin cell adhesion molecule-1 (MadCAM-1) present in endothelial cells of HEV [107, 117]. HEV, present in LN, PP in the intestine, tonsils, adenoids, appendix, and aggregates of lymphoid tissues in the gut mucosa, as well as in chronically inflamed nonlymphoid tissues but not in spleen, are critical target sites for lymphocyte recirculation [115]. The  $\alpha_E/\beta_7$  (HML-1) integrin, which binds to the E-cadherin chain expressed by mucosal epithelial cells, appears to be important in lymphocyte homing to the gut epithelium [107,117].

Another integrin,  $\alpha_4/\beta_1$  (CD49d/CD29, very late antigen-4 [VLA-4], LPAM-2), which binds to the vascular ligand vascular cell adhesion molecule-1 (VCAM-1) that is primarily expressed on the endothelium of nonmucosal sites of inflammation, appears to play a key role in homing of activated T cells to nonmucosal sites [117]. Similarly, LFA-

$\alpha_L\beta_2$  integrin) is also involved in homing of activated lymphocyte to peripheral tissues by binding to the intercellular cell adhesion molecule-1 (ICAM-1) and ICAM-2 present in HEV [115]. Differential expression of integrins (e.g.,  $\alpha_6\beta_1$  in Th1 cells) can also contribute to the distinct homing behavior of Th1 and Th2 cells [112].

Taken together, the information discussed above on the role of chemokines, integrins, and selectins in lymphocyte trafficking clearly demonstrates that the homing potential of immune cells depends on the coordinated production of multiple molecules and expression of the appropriate receptors. For example, the fact that CD62L expression declines markedly after lymphocyte activation, which occurs concomitantly with the increased expression and affinity of adhesion molecules such as  $\alpha_4/\beta_7$  integrin,  $\alpha_4/\beta_1$  integrin and LFA-1 ( $\alpha_L\beta_2$  integrin), promotes activated T cells to leave the LN and migrate to sites of inflammation in peripheral tissues, including the gut associated mucosa. In addition, concomitant expression of other receptors (e.g., CCR9 in  $\alpha_4\beta_7^{hi}$  cells), might help direct their homing to particular areas of the mucosa, e.g., the intestinal mucosa, which has been shown to produce TECK, a CCR9 ligand [107]. TECK is absent or weakly expressed in other segments of the gastrointestinal tract (e.g., stomach and colon) and only a portion of lymphocytes in the colon express CCR9. Another example of the complexity of the signals involved in lymphocyte homing is trafficking to the skin. Lymphocytes with skin homing potential express the cutaneous lymphoma Ag (CLA) but do not express integrin  $\alpha_4\beta_7$ . These lymphocytes concomitantly express CCR4 (the ligand for CCL17, produced by cutaneous endothelium) and/or CCR10 (the ligand for CCL27, produced by keratinocytes) [107].

Elucidation of the molecular basis of lymphocyte homing will undoubtedly have an enormous impact on the vaccine development field in years to come. This knowledge will help determine the most appropriate routes of immunization or means to target Ag to the correct site for optimal presentation depending on the desired effector immune response. It will also help predict the most likely site and type of effector immunity elicited by immunization.

## VIII. GENERATION OF MEMORY T AND B LYMPHOCYTES

Because the ultimate goal of vaccination is to elicit long-term immune protection, a thorough understanding of the mechanisms involved in the generation and maintenance of long-lived memory T and B cells, as well as plasma cells, is of paramount importance. However, in spite of great progress over the past few years in understanding the mechanisms involved in the generation and maintenance of memory cells, significant gaps still remain. Many factors, such as site and length of Ag exposure, Ag concentration, cytokines, and other inflammatory stimuli present in the milieu, and duration of TCR stimulation, are now known to be important in the generation of effector and memory T cells.

Based on their expression of homing molecules CD62L and CCR7, recent evidence supports the existence of two

main populations of  $T_m$  cells: central memory T cells ( $T_{cm}$ ) and effector memory T cells ( $T_{em}$ ) [23–25,74].  $T_{cm}$  are CD62L<sup>hi</sup>CCR7<sup>+</sup>, while  $T_{em}$  are CD62L<sup>dim</sup>CCR7<sup>-</sup>. Several studies have shown that  $T_{cm}$  migrate to peripheral LN, while  $T_{em}$  recirculate through nonlymphoid tissues, such as liver and lungs. This is likely due to the fact that CD62L interacts with PNAd in HEV of LN, and that CCR7 binds to chemokines CCL19 and CCL21 present in the luminal surface of endothelial cells in LN. Evidence indicates that T cells that downregulate CCR7 and CD62L expression concomitantly upregulate the expression of CCR2 and CCR5, which favors migration to inflamed tissues.  $T_{cm}$  and  $T_{em}$  populations have been reported to be functionally distinct. Following Ag stimulation,  $CD4^+$   $T_{cm}$  rapidly secrete mainly IL-2 and little IL-4, IL-5, or IFN- $\gamma$ , while the reverse was observed to be true for  $T_{em}$  cells. Similarly, only the  $CD8^+$   $T_{em}$  population reportedly contains intracellular perforin, an important CTL effector molecule. Thus, because of their homing potential to peripheral sites and cytokine-secretion readiness, only the  $T_{em}$  populations appear to be ready for immediate effector action. On the other hand,  $T_{cm}$  cells would be available in secondary lymphoid tissues to stimulate DC, provide B cell help, and participate in the generation of a new wave of effector T cells. If confirmed, this model can be of great importance in guiding vaccine development.

Two key issues that remain largely unresolved focus on how memory T cells are generated and whether their long-term survival depends on continued Ag stimulation. The two leading theories to explain how memory cells are generated include: (1)  $T_m$  and effector cells are generated along separate pathways (as B memory cells do), e.g., depending on the cytokines and other stimuli present in the milieu, some cells become effector and some memory (divergent pathway), and (2) upon stimulation, T cells become effectors and following the active phase of the immune response, some develop into  $T_m$  cells (linear differentiation pathway), e.g., memory cells are directly derived from effector cells. A third model is a variation of the linear differentiation pathway in which the length of Ag stimulation determines whether  $T_{cm}$  (short stimulation) or  $T_{em}$  (long stimulation) populations are elicited. A fourth model, known as the “decreasing potential hypothesis,” suggests that the duration and level of Ag to which naive T cells are exposed determines whether effector T cells die (e.g., this mechanism may dominate during chronic infections) or differentiate into  $T_m$  cells [24].

Equally controversial is the issue of whether Ag is required to maintain  $T_m$  cells. Most recent evidence indicates that both  $CD4^+$  and  $CD8^+$   $T_m$  cells can persist in the absence of Ag for months or even years [25]. However, it is unclear whether, to persist for such long periods of time, these  $T_m$  cells must be periodically “restimulated” by non-specific mechanisms. Such mechanisms include responding to cytokines (e.g., IL-15), activation by cross-reactive Ag, or as bystanders in unrelated immune responses because of their “increased readiness state” resulting from the increased expression of adhesion/accessory molecules and/or cytokine receptors [25]. Reports that Ag can remain in follicular dendritic cells (FDC) for long periods of time has led some investigators to propose that APC can pick up these Ag for presentation to  $T_m$  cells in a predominantly MHC class II-

restricted fashion, suggesting that small amounts of Ag might be involved, at least to some extent, in maintaining CD4<sup>+</sup> T<sub>m</sub> cells and B memory cells [118,119].

More information is known on the generation of B memory cells. To some extent, this is attributed to the fact that secondary and subsequent Ig responses can be easily differentiated from primary responses based on a more rapid response (because of increased numbers of Ag-specific cells), the predominance of IgG, IgA and/or IgE isotypes over IgM and the increased affinity of the Ig produced. It is generally accepted that the generation of memory B cells takes place in germinal centers, where clonal expansion, somatic hypermutation of Ig V regions, affinity selection, and class switching also take place [9–12,120]. Consensus has emerged that memory B cells differentiate along a separate pathway than plasma cells. In fact, some of the signals driving these different pathways are already known. For example, signaling through CD40 appears to be crucial for differentiation into B memory cells, while the presence of IL-2 and IL-10 in the absence of CD40L favors the generation of plasma cells [9–12,120]. It is also known that memory B cells leave the germinal center, and via the circulation, become localized in the draining areas of LN, or in the marginal zone of the spleen, or recirculate among the secondary lymphoid tissues. Clearly, further studies are needed before information on the critical events leading to the generation of T and B cell memory can be rationally applied to the development of vaccines.

## IX. FUTURE DIRECTIONS

Throughout this chapter, owing largely to space constraints, I focused only on a handful of key areas during the generation of effector and memory cells that hold great potential to advance the development of safe, effective vaccines. These topics are, by no means, exclusive of many others (e.g., Ag-Ab interactions, B- and T-cell development and differentiation, Ig class switching, organizational structure of lymphoid organs and tissues, immunological tolerance, immunosenescence, etc.) that are undoubtedly of great importance in vaccine development.

In the coming years, the continued use of the novel technologies described above (e.g., genomics, proteomics) should bring spectacular advances in our understanding of the mechanisms underlying the induction, effector, and memory phases of the immune response. This information will continue to dramatically change our thinking of the strategies and molecular processes utilized by the immune system to protect the host against infectious microorganisms. The areas most likely to continue to be pivotal in further advancing the development of vaccines include: (1) the in-depth understanding of the pathways and antigenic epitopes involved in class I and class II MHC-restricted immune responses; (2) the further delineation of the function of DC cell subsets in linking the innate and immune system; (3) the precise role of costimulatory and adhesion molecules in Ag presentation and homing of effector and memory lymphocytes; (4) a better understanding of the rules governing the generation of cells secreting polarized cytokine

profiles; (5) novel cytokine- and chemokine-mediated immunoregulatory mechanisms; and (6) the generation and maintenance of large pools of memory lymphocytes. These advances should create new opportunities to modify antigen structure, vaccine formulations, and targeting, leading to more efficient immune induction, more persistent immune responses and enhanced memory. For example, high hopes are held for targeting Ag to APC in conjunction with immunoregulatory cytokines and on the effective use of adjuvants. This information might also play a key role in advancing the development of attenuated live vector vaccines directly expressing foreign antigens or carrying DNA vaccine plasmids encoding foreign Ag. It is conceivable that eventually we will be able to develop vaccines that are “better than nature” in the sense that they may induce immune responses that are superior to natural infections in generating protective immunity. Finally, the information to be gained from sequencing the entire genomes of additional microorganisms holds great promise for the identification of large numbers of novel Ag that could be exploited as potential targets for vaccine development.

### I. INTRODUCTION

Induction of epitope-specific T-cell responses may provide an effective means of protecting against diseases for which no conventional vaccines exist. Unlike B cells, which only recognize epitopes directly on the surface of free antigens, T lymphocytes recognize peptide fragments bound to class I or class II molecules encoded by the major histocompatibility

complex (MHC). A peptide that binds MHC and is recognized by the T-cell receptor (TCR) constitutes a T-cell epitope. In humans, MHC class I molecules include HLA-A, HLA-B, and HLA-C. The MHC class II molecules include HLA-DR, HLA-DP, and HLA-DQ.

In general, MHC class I molecules present peptides 8-10 amino acids in length and these MHC-peptide complexes are predominately recognized by CD8<sup>+</sup> cytotoxic T lymphocytes (CTLs). Class I peptides usually contain an MHC I allele-specific motif sequence of two main anchor residues, usually located at position 2 and at the carboxy-terminus of the peptide ligand [1,2]. The MHC class II molecules bind peptides of 11-25 amino acids and are predominantly recognized by CD4<sup>+</sup> T helper (Th) cells. Peptides presented by class II molecules are longer and more variable in size than those presented by class I molecules, and usually contain three main anchors located at relative positions 1, 6, and 9 [3-8].

T-cell epitopes are derived from foreign protein antigens via two different pathways of protein degradation. The MHC class I molecules present peptides obtained from proteolytic digestion of endogenously synthesized proteins. Host-derived or pathogen-derived intracellular proteins are cleaved by a complex of proteases in the proteasome [9-20].

Small peptide fragments are then transported by ATP-dependent transporters associated with antigen processing

<sup>\*</sup>Two of the contributing authors, William Martin and Anne S. De Groot, are senior officers and majority shareholders at EpiVax, a privately owned vaccine design company located in Providence, RI. These authors acknowledge that there is a potential conflict of interest related to their relationship with EpiVax and attest that the work contained in this research report is free of any bias that might be associated with the commercial goals of the company.

<sup>†</sup>Anne S. De Groot is also founder and scientific advisor to GAIA Vaccine Foundation, a not-for-profit organization that supports the development of a globally relevant, globally accessible AIDS vaccine. EpiVax and the TB/HIV Research Laboratory declared the "World Clade" vaccine project described in this manuscript to be a not-for-profit project in August 2000. The World Clade vaccine project is now directed by GAIA Vaccine Foundation.

<sup>‡</sup>Alessandro Sette is now with La Jolla Institute for Allergy and Immunology, San Diego, California, U.S.A. John Sidney is a shareholder of Epimmune.

(TAPs) into the endoplasmic reticulum (ER), where they form complexes with nascent MHC class I heavy chains and  $\beta_2$ -microglobulin [21–24]. The peptide-MHC class I complexes are transported to the cell surface for presentation to the receptors of CD8<sup>+</sup> T cells [25].

The MHC class II molecules generally bind peptides derived from the cell membrane or from extracellular proteins that have been internalized by antigen-presenting cells (APCs). The proteins are processed in an endosomal compartment called MHC class II compartment (MIIC), and the generated peptides are sorted by empty MHC class II molecules based on their affinity. The HLA-DM then catalyzes peptide exchange [26–31]. Class II molecules bound to peptide fragments are transported to the surface of APCs for presentation to CD4<sup>+</sup> helper T cells.

From these different antigen processing and presentation pathways, two different T-cell responses are generated: a CD4<sup>+</sup> Th immune response and a CD8<sup>+</sup> CTL immune response. These two types of responses are relevant for different mechanisms of immunity. Prophylactic and therapeutic intervention in different disease settings may require induction of CD4<sup>+</sup> response, CD8<sup>+</sup> response, or both. For this reason, strategies to elicit both types of responses are of interest.

In the past decade, several research groups have applied bioinformatics tools and biochemical assays, in conjunction with various types of T-cell assays, to identify T-cell epitopes from several pathogens. These strategies will accelerate the development of new-generation T-cell epitope-based vaccines against cancers, viral pathogens such as hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV, bacteria such as *Mycobacterium tuberculosis* (Mtb), and parasites such as *Plasmodium falciparum*.

## II. APPROACHES FOR IDENTIFYING T-CELL EPITOPEs FROM PROTEIN SEQUENCES

The first step in the development of an epitope-driven vaccine is the identification of allele-specific or promiscuous (presented by multiple HLA molecules) peptides that can be recognized by T cells in association with MHC class I or class II molecules. There are two different basic categories of approaches for identifying T-cell epitopes: the standard overlapping peptide approach and the bioinformatics approach.

The overlapping peptide approach identifies T-cell epitopes by constructing partially overlapping peptides covering the entire amino acid sequence of the protein of interest, and then by screening each of these peptides for their ability to bind HLA molecules or to induce a T-cell response. Although many T-cell epitopes have been identified using this method, the approach is laborious and expensive. Some investigators use 10- to 15-amino-acid-long peptides overlapping by five to eight amino acids, or variations on this theme. However, T-cell epitopes that fall in between the overlapping regions can be overlooked. This method also relies on peptide proteolysis, which may or may not occur *in vitro* when assays are being performed. For class I, the “exhaustive” overlapping approach involves making every possible overlapping peptide (often including 8-mer, 9-mer,

and 10-mer versions of the same potential epitope), covering the entire protein sequence. Although this approach is comprehensive, it is prohibitively expensive, labor-intensive for most laboratories, and unnecessary, given the precision of current epitope mapping tools.

With the rapid accumulation of accurate sequence information for a wide array of pathogens, the development of accurate informatics approaches to predicting antigenic sites from primary structure is particularly appealing. The decade spanning 1991–2001 saw the development of a large number of computer-driven algorithms that used the alphabetical representation of protein sequence information to search for T-cell epitopes.

DeLisi and Berzofsky [32] and Rothbard and Taylor [33] were the first research teams to suggest searching for a pattern of amino acids as a possible predictive tool for antigenicity, based on empirical observations of the periodicity of amino acid residues in T-cell epitopes. Predictions based on periodicity were a clear improvement over the overlapping method of epitope mapping, but they did not predict binding in an allele-specific manner. Consequently, the predictive value of these early algorithms was a limited improvement over previous methods [34], a mere first step. Allele specific motifs were first described in the late 1980s, as a result of the development of quantitative peptide-MHC binding assays [6,35–37].

Further development of improved computer-driven algorithms was made possible by three major technological advances: crystallographical studies of MHC molecules in complex with peptides, the sequencing of naturally occurring MHC-peptide ligands by Edman degradation, and the use of tandem mass spectrometry. The use of allele-specific “anchor-based” MHC binding motifs to prospectively identify T-cell epitopes [38] was described by Falk et al. [2] in 1991; Romero et al. [39] in 1991; Jarde茨ky [40] in 1991; Hunt et al. [8] in 1992; Leighton et al. [41], Geluk et al. [42], Wall et al. [43], Sidney et al. [44,47], Sette et al. [45], Ruppert et al. [46], O’Sullivan et al. [48], and Kondo et al. [49] beginning in the late 1980s; Chicz et al. [4] in 1993; Lipford et al. [50] in 1993; Parker et al. [51] in 1994; Hammer et al. [52] in 1994; and Meister et al. [34] in 1995.

Matrix-based approaches to mapping T-cell epitopes have also been developed by a number of different research teams. Matrix methods assign a positive or negative coefficient to each possible amino acid that could occupy each position in a peptide, based either on empirical data from many known epitopes binding that MHC molecule, or on computational estimates of the free energy of binding. The resulting 20×9 matrix of coefficients can be used to calculate a linear score for any given peptide sequence. Matrix-based algorithms were described by Sette et al. [53] in 1989 and have also been described by Parker et al. [54], Davenport et al. [55], Jesdale et al. [56], De Groot et al. [57], and Hammer et al. [52]. The crucial assumption that the matrix-based method relies on is that the contribution of each position along the peptide sequence is essentially independent of the other positions. This assumption appears to be quite accurate in most cases. There are, however, exceptions, which have shown the importance of pairwise interactions between neighboring residues in influencing peptide binding to MHC molecules,

exist [58]. The matrix method also allows the assessment of the contribution of secondary anchor residues, engaging secondary binding pockets of the MHC molecule as well as short-range secondary and conformational effects [46].

The issue of secondary anchors and secondary effects on MHC binding has been addressed by Ruppert et al. [46,59] who have demonstrated that predictions based on the main anchors alone were not very effective. These authors determined that the presence of the main anchor residues was necessary but not sufficient for binding to occur. Specifically, only about 20-30% of anchor motif containing peptides bound to MHC, whereas the predictive efficacy of a motif-based algorithm increased to 70-80% when the predictive effect of secondary anchors was considered.

In general, a matrix-based computer algorithm searches for putative T-cell epitopes by scanning the entire protein of interest in increments of 8-mers, 9-mers, 10-mers, or 11-mers. EpiMatrix is one of several such tools, which scores each 8-mer to 10-mer overlapping frame in a protein sequence based on the estimated probability of its binding (EBP) to a selected MHC molecule [60]. Studies have demonstrated that EpiMatrix, among other matrix-based programs, accurately predicts MHC ligands (in both retrospective and prospective studies).

A number of additional approaches to epitope mapping have been developed. These include predictive strategies based on neural nets, threading algorithms, and nonlinear functions [35,37,61-66]. In some cases, it has been reported that these more complex strategies might increase accuracy or effectiveness of prediction. In side-by-side comparisons, however, different methods have been found to be essentially equivalent [67], thus providing powerful support to the "independent side chain contribution hypothesis" on which the matrix methods are based. In the experience of the Epimmune and EpiVax groups, the most important determinant of the accuracy of the prediction is the actual quality and quantity of the binding data utilized to derive the predictive method. To predict the binding capacity of a 10-mer sequence, in which every position can be occupied by any one of 20 different amino acids, one needs to solve an equation with  $10 \times 20 = 200$  unknowns. It is intuitive that, if less than 200 data points are used, the results are probably questionable regardless of the method utilized. The more binding data points that are utilized to compose the matrix train, the neural network, or so on, the better. Epimmune's peptide database contains actual binding constants that have been measured for more than  $6 \times 10^4$  different peptide molecules. Researchers at the Kent Ridge Digital Laboratories (Vladimir Brusic) [68] who are engaged in the design of epitope mapping algorithms have also compiled databases of MHC binding peptides.

Most recently, the teams of Sturniolo et al. [69], Zhang et al. [70], and Sette and Sidney [71,72] have proposed that unknown motifs might be predicted by mixing and matching MHC binding pocket characteristics. In the hands of a number of epitope mapping researchers, this new means of developing epitope prediction tools is proving extremely useful.

Several independent studies have been performed to address the question of how effective MHC binding motifs

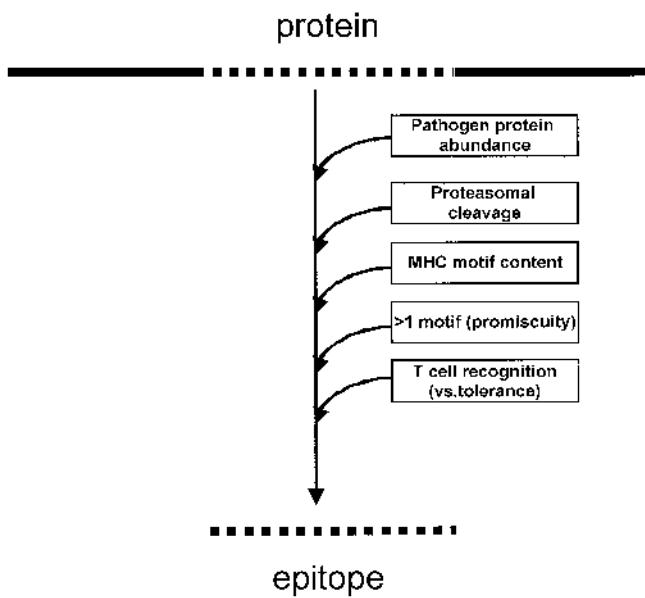

may be for the prediction of class I binding peptides. Specifically, in 1994 Kast et al. [73] synthesized all possible 9-mer peptides derived from the E6 and E7 proteins of Human Papilloma Virus (HPV)-18 and tested them for binding to HLA-A1, HLA-A2.1, HLA-A3, HLA-A11, and HLA-A24. They found that of 1200 peptide/HLA affinities measured, binding affinities of 500 nM or less were detected in only 22 cases (1.8%). In seven cases (0.6%), the affinity was high: 50 nM or less. Of the 22 peptides binding at the 500 nM level, 20 (91%) contained HLA-specific binding motifs. Most impressively, 7/7 (100%) of the peptides binding at the 50 nM level contained HLA-specific binding motifs. Thus, it was concluded that essentially all peptides binding to the HLA contained HLA-specific motifs. Although a total of 1200 HLA/peptide combinations were studied, the analysis of only 111 HLA/peptide combinations would have been required if the predictive power of HLA-specific motifs had been exploited. In other words, motif analysis could have reduced by more than 10-fold the number of peptides that needed to be considered for HLA binding analysis [73].

A number of different approaches have been used to demonstrate that class I MHC binding to HLA is predictive of a peptide's ability to induce CTL responses. First, in a series of studies by Van der Most et al. [74-76] and Vitiello et al. [77] where murine models of viral infection were used, all MHC binding peptides were tested for immunogenicity. Of 39 peptides that bound at the 500 nM level, 30 were tested for immunogenicity by direct peptide immunization, and at least 20 of them (67%) were immunogenic. It was also shown that at least 10/39 of the 500 nM binding peptides (26%) induced CTL capable of conferring protection from viral challenge, and/or recognized infected cells in vitro.

Second, the finding that HLA transgenic mice can mount an HLA-restricted T-cell response to approximately 85% of the peptide epitopes that are recognized by human T cells [78] provides strong support for the idea that the ability to bind to the HLA molecule plays the major role in determining peptide immunogenicity [79,80]. Similarly, it has been reported that HLA-A11 transgenic mice mounted responses to at least 75% and 54% of the peptides binding at the < 50 and 50-500 nM levels, respectively [81].

Binding affinity for HLA class I molecules and immunogenicity have been further characterized using HLA-A\*0201 transgenic mice [67] and T cells derived from hepatitis B-infected human patients. In both cases, an affinity threshold of approximately 500 nM (and preferably 50 nM or less) appeared to determine the capacity of a peptide epitope to elicit a CTL response. These data correlated well with additional class I binding affinity measurements made using either naturally processed peptides or previously described T-cell epitopes [82].

An independent series of studies by DiBrino et al. [83] have examined similar issues. These authors suggest that endogenous and antigenic peptides may be primarily selected (rather than using peptide processing) to form stable HLA-A2 complexes [54]. HLA-A1-, HLA-A3-, and HLA-B44-specific motifs were utilized to predict potential epitopes derived from various proteins of the influenza A virus and of 18 peptides synthesized, eight bound and six of them

**Figure 1** Aspects of antigen processing that determine whether an epitope is immunogenic in vitro and in vivo.

(75%) were recognized by CTL derived from individuals, presumably naturally exposed to infection with the influenza virus [83].

The affinity for the MHC molecule has the greatest impact on immunogenicity and immunodominance. Additionally, both the specificity of proteasomal cleavage, which is needed to create the appropriate peptide but could also destroy it [14,17,20,84,85], and the specificity of the TAP transporter, which selectively delivers peptides from the cytosol to the ER for loading onto class I MHC molecules [22,24,86–88], play critical roles in determining which epitopes are presented and which become immunodominant [89]. Indeed, the ability to induce an immune response can often be correlated to the relative amounts of peptide epitope that are processed and presented on the surface of the APC [90]. The abundance of a particular protein in intracellular compartments and the presence of proteolytic cleavage sites proximal and distal to the epitope are just two of many factors that determine whether an epitope is presented (Fig. 1) [12,91]. In this context, it is important to appreciate that generation of a given epitope as a result of antigen processing is not an all-or-none phenomenon. A number of studies have indeed shown that different epitopes are generated with different efficiencies [12,91], and efforts to estimate the efficiency of different steps involved in antigen processing have begun [16,92]. It appears that variation in epitope yield can modulate immunodominance and apparent immunogenicity [17,93]. It would also seem that the threshold number of peptide-MHC complexes necessary to stimulate a given T-cell is different between naïve and differentiated T cells. Accordingly, the thresholds necessary for induction of immune responses appear to be significantly higher than those necessary for triggering effec-

tor functions [94,95]. Thus, whether an epitope is scored as “being generated by antigen processing” or not is crucially dependent on the sensitivity of the assay method utilized. Indeed, it has been shown that vaccine optimization can increase the yield of a given epitope, and may allow elicitation of responses specific for such suboptimal “subdominant” epitopes [96].

However, the major determining factor for immunogenicity remains affinity for the MHC molecule. Thus, the ability to predict immunogenic peptides based on motif analysis and HLA binding measurements is quite high, in the range of 30–75%. Taken together, these data formally support the crucial role of determinant selection in the shaping of T-cell responses. Because high-affinity peptides seem to be immunogenic in most cases, these data further demonstrate that if holes exist in the functional T-cell repertoire, they remain relatively rare.

### III. IMMUNODOMINANT, CRYPTIC, AND SUBDOMINANT T-CELL EPITOPES

In general, natural immune responses (defined as the immune responses produced following infection or disease) do not exploit the full range of epitope possibilities, meaning that only a small fraction of all possible peptides derived from a given pathogen actually induces a T-cell response (Table 1). This phenomenon is known as immunodominance [97–99]. According to common definitions [75,77,100], a dominant epitope induces a response on immunization with whole native antigens. Such a response is cross-reactive in vitro with the peptide epitope. By contrast, in the case of cryptic epitopes, the response elicited by peptide immunization is not cross-reactive in vitro with intact native antigens. Finally, a subdominant epitope evokes little or no response on immunization with whole antigens, but the response obtained by peptide immunization is cross-reactive with whole antigen in vitro (unlike the case of cryptic epitopes).

The main cause of immunodominance is that only a small fraction of all possible peptides binds to a given MHC [98,101]. This phenomenon was called “determinant selection” and was predicted by Rosenthal [102] in the mid-1970s, before peptide–MHC interactions were actually demonstrated.

Induction of a cellular immune response requires that peptide binding to MHC molecules is of sufficient affinity to produce enough peptide-class I complexes to activate naïve CTL. The binding affinity of a particular peptide for a given HLA molecule is a chemical attribute, can be quantified, and

**Table 1** Variables Determining Immunodominance and Multispecificity in T-Cell Responses

Capacity to bind MHC (determinant selection)
T-cell responsiveness (holes in the repertoire)
Processing yield
Efficiency of transport
Clonal competition, antigen levels, duration of antigen exposure

is invariant in a given set of conditions. By contrast, the ability to detect T-cell activation is susceptible to many factors that can ultimately affect the apparent immunogenicity of an epitope. As a result, immunodominance and immunogenicity are not properties inherent to a peptide, they depend, rather, on a given immunological set of circumstances, i.e., a variety of factors, described in more detail below.

Not all epitopes that bind with good affinity to MHC are actually recognized during the “natural” course of immunity. In some cases, T-cell responses are not detected (“holes in the repertoire” [103]) because of immunoregulatory phenomena, thymic deletion, or peripheral tolerance. In other cases, the apparent lack of recognition occurs because during the natural processing of pathogen-derived proteins within host cells, the epitope is not efficiently generated [17] or properly transported into the ER [87]. Other factors related to antigen structure, route of administration, and differences of T-cell growth during immune activation can also influence immunodominance.

Whatever the reason for lack of prominent recognition of a given epitope in the course of natural infection, immunization with isolated or optimal epitopes can often induce a T-cell response that can actually recognize infected or cancerous cells. In these cases, the response is referred to as a subdominant response, and the epitope is correspondingly identified as a subdominant epitope [75,77]. These subdominant epitopes, along with the dominant epitopes, can play an important role in the development of effective epitope-based vaccines.

#### IV. HLA SUPERTYPE EPITOPES AND POPULATION COVERAGE

As mentioned above, T cells recognize a complex between a specific MHC type and a particular pathogen-derived epitope and, thus, a given epitope will elicit a response only in individuals that express an MHC molecule capable of binding that particular epitope. The MHC molecules are extremely polymorphic (several hundred different variants are known in humans). Therefore, selecting multiple peptides with different MHC binding specificities will afford increased coverage of the patient population targeted as vaccine recipients. The issue of population coverage in relation to MHC polymorphism is further complicated by the fact that different MHC types are expressed at dramatically different frequencies in different ethnicities. Thus, a failure to consider these matters may result in a vaccine with ethnically-biased population coverage. In any given population, however, it is possible to find five HLA class I molecules that are sufficient to cover at least 90% of the population [63].

One means of circumventing the problem of MHC restriction relies on the selection of epitopes restricted by MHC types that can be grouped in broad families or supertypes. These supertypes are characterized by largely overlapping peptide repertoires and are expressed at high frequencies in all major ethnicities [106–111] (see Refs. 71 and 72 and references therein for review). By targeting only three supertypes, population coverage in the 80-90% range can be achieved, regardless of the ethnicity of the target

population. Five supertypes allow coverage of virtually 100% of the population.

The HLA supertypes are not limited to human class I molecules. Recent studies have shown that nonhuman primates, such as chimpanzee [112,113], gorilla [114], and macaques [115–117], also express class I molecules that are functionally analogous to molecules of the human class I supertypes. These observations raise the possibility that the immunogenicity of epitope-based vaccines destined for human use might be tested in nonhuman primates. Furthermore, several studies have also demonstrated the existence of HLA-DR supertypes [118–120]. Two main DR supertypes seem to account for the vast majority of HLA-DR binding specificities.

A number of studies have shown that 85-100% of high-affinity binding peptides, which bind multiple HLA molecules, are recognized by recall responses detected in peripheral blood mononuclear cells (PBMCs) from immune or infected individuals [118,119,121–128]. Recognition by memory recall responses demonstrates that the epitope is not only generated *in vivo* in the course of natural infection, but also that a TCR repertoire, which is capable of recognizing that particular epitope, exists. Thus, CTL directed against that epitope should be expected to have potential clinical benefit.

Several reasons could contribute to the high frequency by which HLA supertype epitopes are antigenic. First, it has been shown that HLA supertype epitopes tend to bind with high affinity [106]. High-affinity epitopes could be intrinsically more immunogenic, and efficient capture of high-affinity epitopes by HLA molecules could also compensate for suboptimal epitope yield as a result of natural processing. It has also been suggested that components of the cell’s processing machinery have specificities that coordinate with HLA supertypes, thus giving an additional potential advantage to HLA supertype epitopes. In particular, coordinate specificities have been reported for human HLA supertypes and the human TAP complex [22].

Different approaches can be utilized to identify supertype epitopes. One approach is computational. For example, ClustiMer (EpiVax) is a computer algorithm that searches for clustered T-cell epitopes. It estimates the MHC binding potential of each 9-mer to 10-mer frame to a number of different HLA alleles, and thus identifies “clustered” or promiscuous epitopes. In work performed by the TB/HIV Research Laboratory in collaboration with EpiVax, it was confirmed that EpiMatrix and ClustiMer effectively predicted cross-MHC binding. As with any computer-driven epitope selection, the “clustered” and supertype predictions delivered by ClustiMer analysis have to be confirmed *in vitro*. Sette et al. [71] used a more direct approach, synthesizing and testing candidate supertype epitopes for their binding capacity to the most common members of a given supertype.

Additional tools developed by EpiVax and Epimmune permit the evaluation of HLA coverage. The tool developed by the Epimmune group is called Epicover. This program is based on actual frequencies of different HLA molecules and actual or calculated binding constants. It allows, for given a set of epitopes, to calculate the population coverage and the

number of epitopes recognized on average by a given population of vaccine recipients. It has been a useful tool to project population coverage in different ethnic groups, and to select sets of epitopes affording maximal, nonethnically-biased population coverage.

## V. PATHOGEN HETEROGENEITY IN VACCINE DEVELOPMENT

Although all pathogens are heterogeneous to a certain extent, in some cases, pathogen diversity can be extreme. Diversity within different Human Immunodeficiency Virus (HIV) isolates is described by grouping HIV isolates within more than eight separate clades, and a high degree of diversity exists even within a given clade. Similarly, several different genotypes of HCV exist. Just as with HIV, multiple variants of HCV are usually encountered even within the HCV viruses infecting a given individual. The extent of variation encountered has suggested the use of the term "quasi-species" to describe different primary viral isolates. Extensive variability has been documented in many important parasites (such as *P. falciparum*) responsible for malaria, and bacteria (such as *Pneumococcus*) responsible for infections in the young and the elderly.

Such a high level of variability poses an interesting challenge for vaccine development. One approach to address such variability relies on developing "customized" vaccines, directed against one particular pathogen strain or cancer isolate. Vaccines based on this approach are under investigation for HIV and several cancer types. However, it is obvious that such a vaccine concept poses formidable practical complications in terms of manufacturing, cost, and efficacy evaluations. Another approach is to combine antigens from all, or most, of the important strains of a pathogen. This approach has been pursued in the case of the multivalent polysaccharide vaccines currently in use for infant vaccination. A similar vaccine, based on 23 different polysaccharide antigens, is currently used for adults. This situation exemplifies how, even when a monospecific response may be adequate to prevent infection from a single strain, a multispecific response might be highly desirable to counteract pathogen variability existing at the population level (Table 2).

In an epitope-based vaccine setting, focusing on conserved epitopes allows for targeting responses around pathogen variability, whether it exists prior to infection, or develops in the natural course of disease. The use of conserved epitopes would be expected to focus the immune response on sequences crucial for retaining the biological function of the pathogen proteins, and thus with intrinsically lower variability, even under immune pressure. However, conservation is often not absolute; thus, epitopes that are totally invariant in 70-80% of different HCV or HIV strains are usually considered "conserved" epitopes. In these cases, the use of multiple epitopes will allow us to address pathogen variability more adequately.

For example, if epitope A is conserved in 70% of the pathogen strain and epitope B is also conserved in 70% of

**Table 2** Reasons for Higher Effectiveness of Multispecific Responses

Ethnically balanced coverage

the cases, provided that the epitope variants occur in different specific strains or isolates, the probability of finding a strain that is not addressed by either epitope would be  $[(1-0.7)(1-0.7)] = 0.09$ , corresponding to coverage of 91% of the strains. Addition of a third or fourth epitope also conserved in 70% of isolates would obtain 97% and 99% coverage of the different pathogen strains, respectively.

Various bioinformatic tools are available to address the issue of variability (or conservation) of epitopes, and to assist in the selection of epitopes with the desired pattern of conservation. One of the first programs to assess epitope conservancy quantitatively was developed by Chisari and Brown in 1994 and was utilized to identify conserved HBV-derived epitopes [121,129], and was also applied to identify HCV-derived *P. falciparum*-derived, and HIV-derived epitopes [118,119,122,123,125,127,130]. Conservatrix, developed at the TB/HIV Research Laboratory, is a computer algorithm that searches any large database of sequences, such as the Los Alamos National Library (LANL) database, for highly conserved regions across all the isolates of a given pathogen. The TB/HIV Research Laboratory has used Conservatrix to identify T-cell epitopes that are conserved across HIV isolates [131] and is currently applying this search engine to evaluating HCV and HPV. Conservatrix has also been used to evaluate the genomes of similar viruses such as HIV type 1 (HIV-1) and HIV type 2 (HIV-2) for cross-reactive epitopes (De Groot et al., submitted for publication) and to evaluate the potential efficacy of vaccines developed for one virus against a related virus (De Groot et al., submitted for publication).

## VI. EPITOPE IDENTIFICATION UTILIZING BIOINFORMATIC TOOLS

Since the description of MHC-specific motifs, hundreds of different studies have been performed, identifying epitopes from several different cancer, viral, bacterial, and parasitic targets. As of November 2001, a MEDLINE search using the key words [(MHC or HLA) AND motif\* AND epitope\*] yielded 575 hits. A few specific examples are described in more detail below. We wish to emphasize here that the list of

papers referenced in this chapter is not exhaustive, and we apologize in advance to the colleagues of many important contributions that may not be described or referenced herein.

### A. Identifying Hepatitis B Virus-Derived and Hepatitis C Virus-Derived T-Cell Epitopes

Chisari and Ferrari [132] were pioneers in the identification of HBV-derived epitopes. Some of their early studies have already been referred to above [67]; they have been seminal in establishing on a firm experimental basis the relationship between binding affinity and immunogenicity and antigenicity for T cells. Utilizing in vitro stimulation of PBMCs with HBV-derived synthetic peptides containing HLA-A2.1, HLA-A31, and HLA-Aw68 binding motifs, they originally described CTL responses to several epitopes within the HBV nucleocapsid and envelope antigens in patients with acute hepatitis [133]. In a subsequent study, six HLA-A2-restricted CTL epitopes located in the highly conserved reverse transcriptase and RNase H domains of the viral polymerase protein were also mapped. In that study, it was shown that the CTL response to polymerase is polyclonal, multispecific, and mediated by CD8<sup>+</sup> T cells in patients with acute viral hepatitis, but that it is not detectable in patients with chronic HBV infection or uninfected healthy blood donors. This study also demonstrated that these peptides represent naturally processed viral epitopes, and that nonresponsiveness at the CTL level was not due to infection by viral variants. Furthermore, CTL responses were detectable for more than a year after complete clinical recovery and seroconversion, reflecting either the persistence of trace amounts of virus or long-lived memory CTL in the absence of viral antigen [134].

A subsequent study was designed to identify highly conserved HBV-derived peptides that bind multiple HLA class I alleles with high affinity and are recognized as CTL epitopes in acutely infected patients [121]. The PBMCs from 67 patients with acute hepatitis B and 12 patients convalescent from acute hepatitis B were stimulated with panels of peptides, binding with high affinity to several class I alleles from the HLA-A2, HLA-A3, or HLA-B7 supertypes. Eight of the 19 peptides tested were recognized by two or more alleles in each supertype, and at the same time, sets of nested peptides were recognized in the context of alleles with unrelated peptide binding specificities. This was the first demonstration of the functional relevance of the supertype grouping of HLA class I molecules in a human viral disease setting. The data also represented a significant advance in the development of a totally synthetic vaccine to terminate chronic HBV infection. This study supported the notion that it was indeed feasible to use combined bioinformatic and biochemical methods, systematically, in the development of similar vaccines for the prevention and treatment of other chronic viral infections.

In the case of HCV, several laboratories have mapped epitopes presented by HLA-A2.1 molecules and capable of inducing CTL in patients and/or HLA-A2 transgenic mice [80,135–139]. Epimmune's group has focused on conserved

regions of the HCV genome to identify viral peptides that contain HLA class I binding motifs and bind with high affinity to the corresponding purified HLA molecules [130]. A total of 31 HLA-A1, HLA-A2.1, HLA-A3, HLA-A11, or HLA-A24 binding peptides were identified. Twelve conserved peptides that bind HLA-A2.1 with high or intermediate affinity were tested for immunogenicity in vitro in human primary CTL cultures and in vivo by direct immunization of HLA-A2.1/Kb transgenic mice. Six HLA-A2.1-restricted CTL epitopes were immunogenic in both systems. At least three of these peptide epitopes were endogenously processed and presented for CTL recognition. Using tetramers of HLA-A2.1 and an NS3 peptide of HCV, CTL frequencies in peripheral blood and liver could be quantitated, and shown to be at least 30-fold higher in liver than in peripheral blood [140].

A subsequent study was designed to identify CTL epitopes restricted by HLA types other than HLA-A2, to expand the epitope repertoire available for T cell-mediated therapeutic vaccine development [123]. Scanning of 14 different HCV genome sequences for the presence of conserved peptides containing the HLA-A3 and HLA-B7 motifs revealed 9-mer to 10-mer peptides. Peptides with good HLA binding affinities, which cross-reacted with at least three of five of the most common molecules of each supertype, were tested for the ability to stimulate a memory CTL response in the peripheral blood from selected HCV-infected patients and normal seronegative donors in vitro. Eight HLA-A3 supertype-restricted and one HLA-B7 supertype-restricted CTL epitopes, which were recognized by infected patients but not by healthy seronegative donors, were identified. In conclusion, these studies defined a set of CTL epitopes, which should enable the design of an ethnically unbiased therapeutic CTL vaccine for the treatment of patients with chronic HCV infection. The potential value of these epitopes was further underlined by a study that utilized the same set of supertype epitopes [124]. The CTL responses against multiple HCV epitopes were detected in 7 of 29 (24.1%) healthy family members (HFM) persistently exposed to chronically HCV-infected patients (HCV-HFM). The HCV-specific effector CD8<sup>+</sup> T cells were readily detected by ELIspot in freshly isolated PBMCs of HCV-HFM. Furthermore, combination of cell depletion ELIspot analyses showed that the effector cells were of the CD8<sup>+</sup> CD45RO<sup>+</sup> CD28<sup>-</sup> phenotype. The persistence of effector CD8<sup>+</sup> T cells specific for both these epitopes in uninfected HCV-HFM suggested that: (1) an immunological memory is associated with a subclinical infection without any evidence of hepatitis in a large cohort of HCV-exposed individuals; and (2) these cells should be capable of prompt HCV-specific effector function in vivo, possibly providing antiviral protection.

Finally, a series of studies also addressed the identification of HLA class II restricted epitopes because HLA class II-restricted T-cell response to HCV antigens is believed to influence the final outcome of hepatitis C. In a study by Lamonaca et al. [125], 22 subjects with acute HCV infection were studied and followed for an average time of 29 months. Several highly immunogenic T-cell epitopes were identified

within core, NS3, and NS4. All of the epitopes are immunodominant, highly conserved among the known HCV isolates, and promiscuous.

## B. Identification of T-Cell Epitopes in Human Immunodeficiency Virus

A number of research groups have applied the strategies and tools described above to the identification of HIV-derived epitopes [119,127,141–150]. A first study [126] tested the antigenicity and immunogenicity of peptides capable of binding to multiple HLA class I molecules of the A3-like supertype. Primary *in vitro* cultures of lymphocytes from healthy donors, as well as *in vitro* restimulation of lymphocytes from HIV-infected individuals, were utilized. Several of the peptides that were capable of binding more than one HLA-A3 supertype molecule were also found to be immunogenic in the context of this same group of HLA molecules (degenerate CTL recognition). Some of the CTL lines thus generated demonstrated even promiscuous recognition of the cognate epitope in the context of more than one A3 supertype molecule. Thus, similar peptide binding was demonstrated to be reflected in a remarkable similarity in the peptide-MHC complex structures engaged by the TCR and responsible for T-cell activation.

To gain additional insights into a potential correlation between recognition of supertype epitopes and clinical outcome, responses of long-term nonprogressors (LTNPs) [128] were analyzed. The LTNPs represent a minority of HIV-infected individuals characterized by stable or even increasing CD4<sup>+</sup> T-cell count and by stronger immune responses against HIV than progressors. A panel of A2 and A3 supertype epitopes was tested. ELIspot and specific major histocompatibility complex (MHC)-peptide tetramers detected HIV-specific effector and memory CD8<sup>+</sup> T cells. Both effector and memory resting cells were contained within a CD8<sup>+</sup> population with memory CD45RO<sup>+</sup> phenotype, with the former being CD28<sup>-</sup> and the latter CD28<sup>+</sup>. Remarkably, all A2 and A3 supertype peptides tested were recognized by the PBMCs of infected individuals.

An independent study [127] described the immunological characterization of a number of novel HIV-1-specific, HLA-A2-restricted CTL epitopes that share a high degree of conservation within HIV-1 and a strong binding to different alleles of the HLA-A2 superfamily. Among the novel epitopes identified by the approaches described above were the first reported CTL epitope in the Vpr protein and two epitopes immunodominant among the HLA-A2-restricted CTL responses of individuals with acute and chronic HIV-1 infection. These may be valuable for vaccine design and testing and for assessing the natural immune response to infection.

Finally, because HIV-specific helper T lymphocytes (HTLs) play a key role in the immune control of HIV-1 infection and, as such, are an important target of potential HIV-1 vaccines, Wilson et al. [119] also embarked in a systematic study to identify HIV-derived HTL epitopes. Accordingly, conserved HIV-1-derived peptides bearing an HLA-DR binding supermotif were tested for binding to a panel of the most representative HLA-DR molecules. Eleven

highly cross-reactive peptides were identified as binders, and all peptides elicited proliferative responses with PBMCs derived from multiple HIV-infected donors for each peptide. Several HIV-infected subjects recognized multiple peptides, and a strong association existed between the recognition of the parental recombinant HIV-1 protein and the corresponding HTL peptides, suggesting that these peptides represent epitopes that are processed and presented during the course of natural HIV-1 infection.

The aim of the HIV project in the TB/HIV Research Laboratory has been to use bioinformatics tools to design a “World Clade” HIV vaccine that will induce T-cell responses against the broadest possible range of HIV isolates. The HIV sequences database was downloaded from the LANL website (<http://www.lanl.gov>). Peptides were selected for their conservation across HIV-1 isolates using Conservatrix and screened for potential MHC class I binding using EpiMatrix. From the pool of peptides screened by EpiMatrix and Conservatrix, a total of 100 peptides were selected based on their restriction by the following MHC-I alleles: A2, A11, A3, and B7—25 peptides being restricted by each allele. Each set of 25 peptides contained one published positive control for the corresponding HLA allele. Assays using PBMCs from non-HIV-infected subjects were also performed. No responses to the selected HIV-1 peptides were observed in these negative control assays.

All the positive control peptides and 72% of the predicted peptides tested in the binding assays bound to the corresponding HLA allele. ELIspot results obtained from PBMCs derived from HIV-infected patients indicated that 44% of the B7 peptides, 40% of the A11 peptides, 24% of the A2 peptides, and 64% of the A3 peptides elicited IFN- $\gamma$  secretion. These novel T epitopes were conserved in as many as 1238 HIV-1 strains, including strains from Africa, Asia, and the Americas. These data showed that candidate T-cell epitopes predicted using the previously described bioinformatics tools were able to bind to the corresponding HLA molecules and were recognized by T cells from healthy HIV-infected patients. The novel epitopes identified here would therefore have to have been selected from naturally processed T-cell epitopes generated during HIV infection. Because these epitopes are highly conserved among HIV isolates, they can be presented by prevalent MHC class I alleles and can induce cross-clade T-cell activation.

In theory, inclusion of these epitopes in an HIV vaccine will induce a pool of anti-HIV T-cell memory clones able to recognize immunogenic and highly conserved HIV epitopes in the vaccine recipients. The recruitment of these memory T cells during the acute phase of infection would lead to a faster and more effective elimination of the infected cells, limiting the scope of the infection.

Transgenic mouse models are currently being utilized to test the ability of string-of-epitopes constructs such as these to generate an immune response against the corresponding epitopes. Another system that may prove useful in testing the efficacy of a multiepitope vaccine is the *in vitro* generation of de novo CTL responses using dendritic cells as APCs [151]. However, unlike *in vivo* systems, “*in vitro* immunization” may only approximate the strength and duration of the induced immune response.

### C. Identifying T-Cell Epitopes in the Tuberculosis Genome

Various models of Mtb infection have indicated a central role for MHC class I-restricted CD8<sup>+</sup> T cells in protective immunity. Accordingly, one study performed by Cho et al. [152] investigated which antigens and epitopes of Mtb proteins were presented by infected cells to CD8<sup>+</sup> T cells. In that study, 40 Mtb proteins were searched for HLA class I A\*0201 binding motifs. Predicted high-affinity binding peptides were assayed for recognition by CTL. Three epitopes, derived from three different antigens thymidylate synthase [ThyA(30-38)], RNA polymerase β-subunit [RpoB(127-135)], and a putative phosphate transport system permease protein A-1 [PstA1(75-83)], were identified when they were recognized by CD8<sup>+</sup> T cells of patients recovering from Mtb infection. Furthermore, CD8<sup>+</sup> T-cell lines specific for these antigens specifically recognized Mtb-infected macrophages, as demonstrated by production of IFN-γ or lysis of the infected target cells, and reduced the viability of the intracellular Mtb, providing evidence that CD8<sup>+</sup> T-cell recognition of MHC class I-restricted epitopes of these Mtb antigens might contribute to effective immunity.

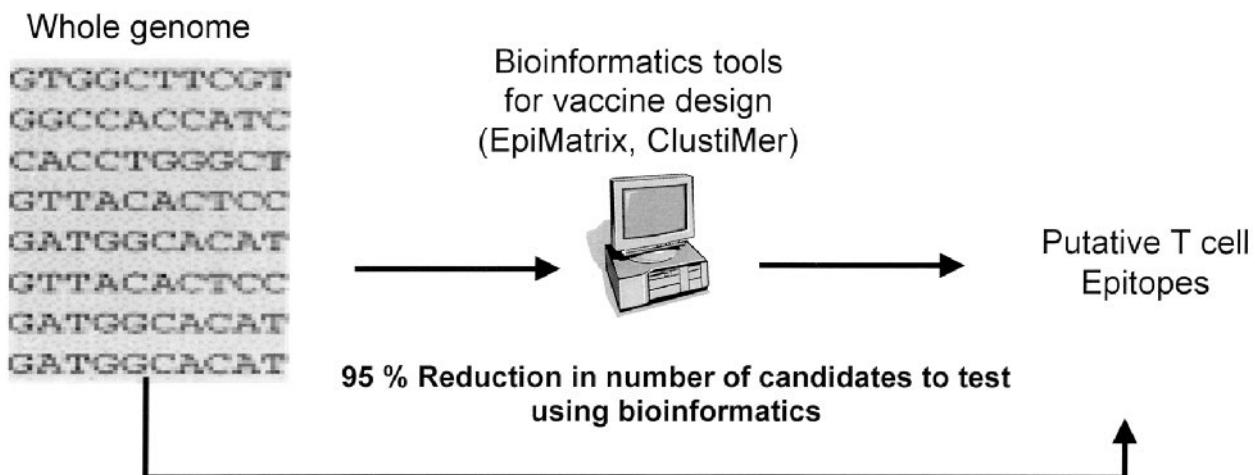

Several Mtb genomes have been sequenced and made available to researchers. Accordingly, the group at the TB/HIV Research Laboratory has analyzed the TIGR Mtb CDC-1551 genome, the H37Rv genome, and the available sequenced fragments (contigs) of the BCG genome for T-cell epitope content. In collaboration with EpiVax, the TB/HIV Research Laboratory has performed two genome scans. The initial focus of these scans has been on secreted antigens, because they have been shown to induce a strong TH1 immune response in the early phase of infection in patients [153,154], as well as upregulated proteins, because they are expressed during bacterial growth and may therefore play an important role in latent Mtb infection. Seventeen peptides were selected for synthesis from each genome scan based on the following criteria: a high EpiMatrix (EBP) score for MHC class II binding and potential MHC promiscuity. The

first-pass analysis resulted in a 95% reduction in the number of peptides to be tested (Fig. 2). These peptides were tested in thymidine incorporation T-cell proliferation assays and IFN-γ ELIspot assays. Immunogenic epitopes were assayed for recognition by T cells in healthy Mtb-infected individuals. In the genome scan for secreted antigens, 11 of 17 tested peptides were recognized in T-cell proliferation and ELIspot assays. From this set of 11 immunogenic peptides, one novel immunodominant T-cell epitope that induced IFN-γ secretion in 15 of 27 Mtb-infected patients was identified. In the genome scan for upregulated proteins, 13 of 17 peptides induced IFN-γ release. This pilot study represents the first step in a genome-derived TB vaccine project funded by the Sequella Global TB foundation.

### VII. THE ROLE OF BREADTH AND MULTISPECIFICITY IN SUCCESSFUL IMMUNE RESPONSES AND VACCINE DESIGN

T-cell responses against certain T-cell specificities may go undetected during the course of natural immunity because of the fact that the corresponding epitopes are poorly generated by natural processing—the breakdown of the pathogen-derived proteins within the cells of the host [16,76,84,92,155-163]. The issue of whether a given epitope is generated (or not) by natural antigen processing in sufficient amounts to allow for T-cell recognition is a crucial one. This is because the ultimate targets of T-cell responses are cells producing the naturally processed antigen, such as infected cells or cancer cells. Hence, a T-cell response that does not recognize the cancer cells or the infected cell would be useless ultimately in terms of prevention, control, or eradication of the disease.

However, the particular assay system utilized can influence whether a given peptide is scored as being generated by natural processing or not. For example, a given HCV-derived epitope elicited T cells that did not recognize natu-

**Figure 2** T-cell epitope mapping from the genome.

rally processed HCV antigens expressed by transfected cells, as determined by chromium release killing assays. However, the same CTL line was fully capable of recognizing the same transfected cells, if the production of IFN- $\gamma$  was utilized as a readout [164]. In a different study [165], it was similarly shown that HBV peptide-specific CTL lines apparently incapable of killing endogenous targets or even producing significant amounts of IFN- $\gamma$  in vitro were nonetheless capable of controlling viral replication in vivo in HBV transgenic mice.

Collectively, these examples illustrate that it is not safe to conclude that the failure to detect a response against a given epitope means that a particular epitope is nonimmunogenic or that it is not generated by natural processing. As long as the peptide binds to MHC molecules with the required affinity, failure to detect CTL response or recognition of naturally processed antigen under a given condition does not preclude the possibility of detecting immunogenicity under different conditions.

As noted above, in certain cases, the recognition of a particular epitope results in the suppression of other epitope-specific responses. This ability of an epitope to dominate a response is relative. The hierarchy of epitope recognition can be altered by the prior experience of the immune system as in memory T cells [166]. Likewise, the deletion of the immunodominant epitope from a protein antigen can also dramatically change the pattern of epitope recognition, resulting in the activation of T cells against previously subdominant peptides [74].

Finally, a complex interplay between T cells, APCs, and antigen production during natural infection also influences immunodominance. T cells specific for a given epitope might be present in higher numbers than those for other epitopes, or they may be stimulated earlier or more vigorously because their corresponding peptides are produced in greater abundance or bind with higher affinity to MHC. Their dominant expansion can limit the expansion of other T-cell specificities by competition for space or nutrients, competition for cell-cell interactions, and simply because a vigorous dominant response might rapidly eliminate or decrease the pathogen concentration before other specificities are effectively stimulated [167,168]. In these cases, immunization with epitope-based vaccines and immunogens offers an opportunity to alter immunodominance patterns and obtain responses directed against subdominant as well as dominant epitopes.

Immunodominance can be very profound, resulting in only one or few specificities dominating the response to a given pathogen and a large fraction of activated T cells specific for a single epitope/MHC combination. This rather absolute type of immunodominance is actually frequently observed in the mouse but more rarely in humans. Indeed, it has been shown in a number of different cases that human responses are often multispecific, directed against multiple proteins derived from a given pathogen, and broad, directed against multiple epitopes within a given protein [169,170]. For example, simple perusal of the Los Alamos HIV database ([hivweb.lanl.gov/immunology/index.html](http://hivweb.lanl.gov/immunology/index.html)) reveals that several hundred different HIV-derived T-cell epitopes have already been defined. These facts are hard to reconcile with certain dogmatic and simplistic views of immunodominance.

Indeed, it would appear that, depending on the particular type of situation and perhaps animal species considered, either a narrow response or broad multispecific response can be obtained.

The issues raised above have broad implications for the design and evaluation of vaccines directed against infectious diseases and cancer. According to one point of view, effective vaccines should focus on and optimize responses for one or a few immunodominant epitopes. The rationale for this argument is that this strategy would most closely mimic natural immune responses. However, in our view, the opposite is true, and vaccine constructs eliciting broad and multispecific immune responses offer several advantages, discussed in more detail in the present and following sections.

What are the characteristics of successful versus unsuccessful immune responses? In the case of HBV infection, individuals that recover from acute hepatitis and clear the virus are characterized as having a very broad and often multispecific T-cell response. In contrast, chronically infected individuals have weak and less diverse responses [132]. In chimpanzees experimentally infected with HCV, spontaneous clearance of the virus is accompanied by a vigorous and multispecific T-cell response, whereas chimpanzees with restricted responses remained chronically infected [171]. In the case of malaria, immunity from *P. falciparum* challenge is achieved by vaccination with parasites inactivated by irradiation. In the case of these individuals, recall memory responses directed against multiple epitopes, restricted by multiple HLA alleles and derived from each of four different antigens, were demonstrated [118,122].

In the case of chronic HIV infection, long-term non-progressors are characterized by the presence of low viral loads and potent, broadly reactive HIV-1-specific CTL responses [104,105,172–174]. Thus, the breadth of CTL responses appears to be critical to the control of the virus in these persons as responses focused on limited numbers of viral gene products are more often associated with viral persistence and more rapid disease progression [175,176].

The observations described above raise the question of why a multispecific response may be more effective. A number of different factors should be considered. First, a multispecific response might offer a key advantage in terms of accessing a higher number of precursors. The overall disease-relevant immune response is the total number of immune T cells, which is the sum of the T cells specific for each epitope. By accessing more epitopes, and therefore a higher number of precursors, a more vigorous response can be obtained. A higher number of precursors can also offer another distinct temporal advantage. Because following encounter with the pathogen-derived epitopes, T-cell precursors divide exponentially, accessing more precursors leads to achieving a set level of active T cells sooner. This temporal advantage can play a key role in allowing the immune system to outpace the pathogens, which also is dividing exponentially.

Second, another important advantage of multispecific and broad responses is that they counteract escape from immune surveillance resulting from pathogen's heterogeneity, either already existing at the time of infection, or

originating by mutation or loss of expression of the targeted antigen. It is well appreciated that mutation rates play a key role in the persistence of pathogens such as HIV, HCV, and *P. falciparum*. Any given sequence, placed under immune pressure, will have a certain mutation rate, which then defines the probability of selecting for a mutated pathogen, now potentially invisible to the T-cell response. However, if responses against two epitopes are present, the probability of a pathogen simultaneously mutating both epitopes is the product of the probabilities of each epitope mutating separately. It is a well-established paradigm that responses directed against multiple pathogen targets, such as T-cell epitopes, greatly decrease the probability of pathogen escape.

Likewise, monospecific responses could also select a tumor variant that had lost expression of the targeted antigen. However, it is logical to assume that targeting multiple tumor antigens would significantly decrease the probability of tumor escape because that would require loss of antigen expression to occur twice.

### VIII. OPTIMIZING EPITOPE-BASED VACCINES

Enhancing the immunogenicity of multiepitope vaccines has been approached in several ways. One approach has focused on how best to package multiple epitopes in a vaccine construct. One option is to present the epitopes as a “string of beads,” without any spacer sequences separating the individual epitopes. Indeed, some studies have indicated that flanking sequences have minimal effects on epitope presentation [177]. The actual role of flanking spacer sequences is currently under investigation, partly because our understanding of how multiepitope constructs are processed remains incomplete. In a “string of beads” construct, the individual epitopes are usually very closely apposed, without their natural flanking sequences; this has raised concern that their proteolytic processing may be compromised and that peptides other than the specific peptides of interest may be generated as a result of the processing [178,179]. There is some evidence that the introduction of spacer sequences to separate the individual epitopes may therefore help focus the immune response on the specific epitopes [180]. A study by Velders et al. [181] compared the immunogenicity of two similar HPV epitope string DNA constructs that differed only in the presence or absence of spacers between the epitopes, and found that the addition of AAY spacers between the epitopes was crucial for the epitope-induced tumor protection.

A recent study by Livingston et al. illustrated how a comprehensive strategy can be derived to optimize a multi-epitope vaccine construct. These authors derived empirical rules to maximize proteosomal cleavage and epitope immunogenicity. A bioinformatic tool (EpiSort) was next derived to generate optimal spacer sequences tailored to each epitope pair, simultaneously optimizing for proteosomal cleavage and minimizing the occurrence of undesired junctional epitopes. The effectiveness of this strategy has been verified in several different disease models, by the use of transfected target cells and HLA transgenic mice [96].

Costimulatory molecules play a central role in the initiation of T-cell immune responses [182]. CD28 and CTLA4 represent the costimulatory receptors on T cells, and B7 molecules represent their corresponding ligands on APCs. Several studies carried out in murine models suggest that the APC signal mediated via CD28 is required for TCR-mediated T-cell activation [183]. CTLA4, on the other hand, appears to play an antagonistic role in T-cell activation. Two members of the B7 family have been identified: B7-1 (CD80) and B7-2 (CD86). These two molecules show comparable affinity to CD28 molecules and may differentially activate Th1 or Th2 immune responses [182]. Lack of costimulation can lead to T-cell tolerance. Peptide epitopes presented by nonprofessional APCs may fail to activate T cells if signal 1 is delivered in the absence of signal 2, and instead may lead to T-cell anergy. Because of the role played by costimulatory molecules in the initiation of T-cell responses, they can be manipulated to either stimulate the immune system, to potentially prevent infection, or to inhibit the immune system, for immunotherapy against allergies and autoimmune diseases. The addition of costimulatory molecules or cytokines to vaccine constructs has been used successfully to amplify responses to vaccines [141,184–190].

One additional strategy to enhance CTL responses is to target the T-cell epitopes of interest to the proteasome of the host cell [191]. It is known that the ubiquitination of proteins acts as a tag to target proteins to the proteasome and to enhance the proteolytic degradation of the introduced epitopes within the cell. Similarly, targeting the epitopes for either secretion or cell membrane expression can enhance Th responses. Past studies have exploited lysosome-associated membrane proteins (LAMPs), which, when fused to foreign antigens, can target antigens for lysosomal entry and destruction and enhanced class II presentation [192].

Another major strategy that takes advantage of bioinformatics methods described here for predicting peptide binding to MHC molecules is epitope enhancement—the modification of the epitope sequence to enhance immunogenicity [79,141,189]. The sequence modifications may be designed to increase the affinity for the MHC molecule or to increase the affinity of the peptide-MHC complex for the TCR. In the former approach, one can modify anchor residues that are suboptimal or alter secondary anchors [46,193].

The matrix algorithms for predicting binding to MHC molecules lend themselves well to this approach, although empirical methods and screening of combinatorial libraries can also be used [194]. Epitope enhancement has been used successfully to improve CTL epitopes for HIV [195], a hepatitis C viral antigen [196], and melanoma tumor antigens [197–199], as well as an HIV helper T-cell epitope [200,201], to name a few examples.

In the latter case, it was found that the enhanced helper epitope, attached to an unmodified CTL epitope, not only induced more CTL and better protection against a viral challenge, but also qualitatively changed the helper response, skewing it toward Th1 phenotype. This was shown to be due to increased induction by the higher-affinity peptide of CD40L on the helper T-cell, which greatly increased IL-12 production by dendritic cells, making them

more polarizing and in turn skewing the Th cells toward Th1, as well as making the dendritic cells more effective at stimulating a CTL response [200]. The alternative approach, of increasing the affinity of the peptide-MHC complex for the TCR, has also been used successfully for improving the immunogenicity of tumor antigens [202–204].

Until recently, there was no simple way to predict alterations that would improve binding to the TCR, except in the rare cases when a crystal structure of the TCR-peptide-MHC complex was available. However, recently, Tangri et al. examined a large number of cases and found a pattern of conserved substitutions at positions 3, 5, and 7 in the CTL epitope sequence that were likely to result in increased affinity for the TCR. This discovery allows a more streamlined systematic approach to identifying good candidates for this type of epitope enhancement [205]. As the bioinformatics approaches to predicting epitopes improve further, these will likely be applicable to the prediction of sequence modifications for epitope enhancement as well. Such improved epitopes are likely to be critical in the cases of chronic viral infections, in which the natural response to the native pathogen is not sufficient to eradicate the infection.

Finally, it is widely appreciated that dose, schedule, and route of immunization can significantly influence the nature of the generated immune response. The role of vaccine dose and route of immunization varies with vaccine design (synthetic peptide, genetic recombinant vector, and so on). In general, low doses and slow release of antigen appear to facilitate optimal T-cell activation. In contrast, high doses of antigen are more prone to induce T-cell tolerance. A delicate balance exists between the induction and the anergization of protective T-cell responses. Therefore, an immunization program should be carefully designed to target the desired immune response—stimulation in the case of an infection, and tolerance in the case of allergies or autoimmune diseases.

## **IX. PRECLINICAL ASSESSMENT OF THE IMMUNOGENICITY OF EPITOPE-BASED VACCINES**

After using in vitro T-cell assays to select for naturally processed T-cell epitopes, it is important to evaluate the ability of vaccines derived from these epitopes to induce an immune response *in vivo*. Transgenic mice expressing human MHC class I or class II molecules represent a suitable preclinical model for this purpose. The advantage of using HLA transgenic animals is that they can develop physiologically relevant HLA-restricted T-cell responses. Transgenic mouse strains that express either the entire most common HLA-A, HLA-B, and HLA-DR molecules [78,81,206,207] have been developed. HLA-A2 transgenic mice have been used to assess the immunogenicity of peptides that bind to HLA-A2. An excellent correlation has been found between CTL responses in infected individuals and CTL responses induced in immunized HLA transgenic mice [78,80,208–213]. The use of HLA transgenic mice to assay and to optimize multiepitope-based vaccines has been described in detail by the studies described above. An alternative assay, which allows the direct evaluation of the amount of each

epitope generated by a given vaccine construct, has also been reported. This “antigenicity assay” takes advantage of human cells transfected with a given vaccine candidate, assayed in parallel to untransfected cells and a dose titration of synthetic epitope [96,214].

Induction of the desired immune response with defined T-cell epitopes facilitates the monitoring of the specificity of the immune response using new epitope-specific reagents such as MHC dimers and tetramers. The MHC tetramers were first developed just a few years ago by Altman and Saffrit [215] and Altman et al. [216], who have written several excellent reviews on the topic. These specialized constructs bear four MHC molecules complexed with  $\beta_2$  microglobulin and a specific pathogen-derived peptide ligand. Tetramers can bind directly to T cells that recognize the MHC-peptide complex. They can be used for direct ex vivo analysis of the frequency and phenotypes of epitope-specific T cells by flow cytometric technique. Tetramers permit the following types of experimental confirmations of epitope-specific T-cell responses *in vivo*: (1) direct quantitation of the number of epitope-specific T cells prior to and following vaccination; (2) phenotyping of responding T cells (examination for cell surface markers such as CD8, CD4, CD38, and additional activation markers); (3) monitoring of the immune response to specific epitopes following vaccination; and (4) direct evaluation of the effect of combinations of epitopes, epitope spacers or linkers, and signal sequences on T-cell responses. These reagents will prove to be useful as epitope-driven vaccines move into Phase I trials, as they provide a means of directly measuring and timing immune response to the vaccine. Likewise, intracellular cytokine staining flow cytometry assays and ELISPOT assays can be used to enumerate cells responding to a given antigen or epitope.

## **X. ADVANTAGES OF EPITOPE-BASED VACCINES AS COMPARED TO WHOLE PROTEIN VACCINES**

The use of whole protein as a vaccine allows not only the induction of cellular immune responses, but also the induction of humoral immune responses. However, immunization with whole organisms or proteins does not always induce the desired immune response. Immunization with the whole protein typically induces an immune response against the immunodominant epitopes, which may apply selective pressure on the pathogen to evolve to mutate its immunodominant epitopes [217–219]. Examples of such a selection pressure, characterized in several pathogens, including HCV [220], HIV [221], and *Plasmodium* [217,218], result in immune escape by the pathogens. Thus, the induction of immunity against epitopes that are subdominant, highly conserved, and critical to the life cycle of the pathogen may be useful for the design of therapeutic vaccines. A number of recent studies of vaccines against viral diseases have demonstrated that CTL responses to subdominant epitopes can compensate for the loss of a dominant epitope and can provide efficient protection [166,222]. Another potential disadvantage of using whole proteins as vaccines is that immunization with pathogenic functional antigens

can lead to toxicity and potential complications in the host [223]. These adverse effects can be minimized by using a T-cell epitope vaccine that contains immunogenic epitopes for the induction of protective immunity, and that excludes epitopes that can induce harmful immune responses.

Another disadvantage of whole protein-based vaccines in the setting of cancer therapeutics was addressed in a study by Disis et al. These investigators found that peptide-based, (but not whole protein), vaccines elicited immunity against an oncogenic self-protein [224]. It has been proposed that tolerance to self-proteins is directed only to dominant epitopes of proteins and not to subdominant epitopes [100,225]. Tolerance can therefore be circumvented by immunization with subdominant epitopes, not whole protein.

Perhaps the most important advantage of epitope-driven vaccines is their superior potency [214]. Because of the knowledge of the exact epitope recognized and targeted for immunization, each epitope can actually be optimized in terms of MHC binding, proteolytic processing, and TCR recognition, as detailed in the preceding paragraphs.

## XI. CONCLUSION

Bioinformatics and high-throughput MHC-peptide binding assays are ushering in a new era of vaccine design. The ability to induce an immune response to a broad repertoire of epitopes that are universally recognized across continents and across genetic backgrounds is considered to be a critical characteristic of an effective vaccine. Opportunities for epitope discovery are expanding as the number of pathogens that are entirely sequenced approaches 100 and as access to these data improves. Epitope-driven vaccines that are designed and optimized, based on our current knowledge and understanding of the mechanics of immunogenicity and immunodominance, are now approaching testing in clinical trials in humans.

## ACKNOWLEDGMENT

Epiimmune's algorithms are available to the academic and industrial community on a collaborative basis ([asettte@epimmune.com](mailto:asettte@epimmune.com)). EpiMatrix and associated algorithm Conservatrix were licensed from Brown University in 1998 and have been further developed by EpiVax ([annied@epivax.com](mailto:annied@epivax.com)). EpiMatrix is also available on-line for use with HIV sequences at <http://tbhiv.biomed.brown.edu/>. Additional resources available on-line include the predictive matrix algorithm independently developed by Parker et al. [http://bimas.dert.nih.gov/molbio/hla\\_bind/](http://bimas.dert.nih.gov/molbio/hla_bind/) and one by Rammensee et al. <http://syfpeithi.bmi-heidelberg.com/Scripts/MHC-Server.dll/Info.htm>.

## The Challenge of Inducing Protection in Very Young Infants

Claire-Anne Siegrist

University of Geneva, Geneva, Switzerland

### I. INTRODUCTION

Currently used infant vaccines and schedules mostly induce protection after several vaccine doses, i.e., only at several months of age. As result of this delayed induction of protection, whooping cough still annually results in 360,000 infant deaths despite administration of three doses of diphtheria–tetanus–pertussis vaccine to 80% of children before their first birthday [1], and infants too young to have yet completed their three-dose vaccination schedule remain at a significant risk of pertussis [2]. At a global level, more than 2.5 million infant deaths annually result from acute respiratory and diarrheal infections, which could be prevented by immunization against a relatively limited number of viral and bacterial pathogens [3]. However, to prevent these infant deaths, vaccines and immunization strategies would have to safely induce protective responses more rapidly after birth, prior to pathogen exposure, which frequently occurs very early in life. The challenge, which will also have to be met by novel vaccines against major later killers, such as tuberculosis, malaria, and HIV, is thus to induce early protection despite the immaturity of the neonatal immune system and the presence of antibodies of maternal origin. The objective of this chapter is to review the current understanding of the determinants that may either limit or support the induction of vaccine responses in neonates and very young infants, and to highlight areas in which further research is needed.

### II. CHALLENGES FOR THE INDUCTION OF ANTIBODY RESPONSES IN EARLY LIFE

#### A. Limitations of Early Life Antibody Responses

##### 1. Limited Infant Responses to Polysaccharide Antigens

Infant and toddler responses to most bacterial capsular polysaccharides (PS) are markedly limited, which contributes to their high susceptibility to infections with encapsu-

lated bacteria such as *Haemophilus influenzae* (HIB), *Streptococcus pneumoniae*, and *Neisseria meningitidis*. The same limitations affect most polysaccharide vaccines, which remain poorly immunogenic before the age of 2 years and exhibit an age-dependent increase in vaccine efficacy between 2 and 10 years of age [4]. Factors that limit infant responses to PS include (1) low complement activity, which limits the deposition of C3d on bacterial PS; (2) weak expression of surface C3d-receptors (CD21) on infant B lymphocytes, limiting synergy between B cell receptor and complement receptor-mediated activation; and (3) structural immaturity of the splenic marginal zone [5] to which C3d-bound PS preferentially localizes in adults. Altogether, these factors limit the capacity of marginal zone B cells and B1 cells to rapidly respond to particulate bacterial antigens [6]. The recognition of this limitation, intrinsic to infant and toddlers, led to the development of glycoconjugate vaccines that attach bacterial PS to a carrier protein. Processing and presentation of carrier peptide fragments at the surface of antigen-presenting-cells (APC) recruits CD4<sup>+</sup> T cells, which provide costimulation to infant B cells and thus induce immunogenic and protective responses in young infants. Despite the strong immunogenicity of glycoconjugate vaccines, the magnitude of IgG antibody responses they elicit does depend on age at administration: As an example, a single dose of HIB-conjugate vaccine elicits progressively higher serum anticapsular antibody concentrations when administered at 2–3, 4–6, or 8–17 months [7].

##### 2. Limited Early Life Antibody Responses to Protein Antigens

The magnitude of IgG antibody responses that may be elicited by protein antigens, whether in subunit or live attenuated vaccines, is also directly related to age at immunization (Table 1). The influence of immune immaturity on currently available protein-based vaccines (such as combined diphtheria–tetanus–pertussis or hepatitis B vaccines) may not be directly assessed, as these vaccines do not induce significant antibody responses to a single vaccine dose even

**Table 1** Characteristics of Early Life Compared to Adult Responses to Conventional Vaccines<sup>a</sup>

Characteristics	Duration
Magnitude of antibody responses	
age-dependent limited induction of IgG responses to protein Ag	≤12–24 months
limited persistence of IgG Ab responses	≤12 months (?)
age-dependent limited induction of IgG responses to most polysaccharides	≤18–24 months
efficient induction of memory B cells	At birth (?)
Quality of antibody responses	
age-dependent limited IgG2 responses	≤12–18 months
age-dependent limitation of IgG repertoire	≥8–12 months (?)
limited avidity of IgG antibodies compared to adult	(?)
Antigen-specific T cell responses	
efficient T cell priming	At or before birth
age-dependent limited primary IFN-γ responses	≥12 months (?)
age-dependent limited CTL responses	≥9–12 months (?)
adulthlike IL-12 production by dendritic cells	≥12 months (?)

<sup>a</sup>Schematic comparison of main characteristics, although notable exceptions may exist.

(?) Limited data available; notable influence of antigen/vaccine type.

in adults. Although early rapid vaccination schedules (i.e., immunization at 2–3–4 months of age) elicit lower antibody titers and lower seroconversion rates than immunization at 2–4–6 or 3–5–12 months of age [8], this not only reflects immune immaturity but also the shorter time period available for affinity maturation of vaccine-induced B cells. In contrast, the stepwise increase of antibody concentrations following measles [9–11] or mumps [12] immunization when immunization is delayed from 6 to 9, 12, or 15 months of age directly reflects the influence of age at immunization.

The mechanisms that limit early life antibody responses to protein antigens, whether included in protein, subunit, inactivated, or live attenuated vaccines, are not yet fully understood. Recent studies assessing the influence of age on antibody responses to human vaccines in neonatal, infant, and adult mice yielded observations very similar to those of human infants, providing that immunization was initiated ≥7 days of age (rather than in the immediate neonatal period) to compensate for the greater immaturity of newborn mice (reviewed in Ref. 13). Studies assessing the various stages of antigen-specific B cell differentiation in these preclinical models of early life immunization demonstrated that the weaker antibody responses to alum-adjuvanted protein vaccines (tetanus, pertussis) reflect a delayed and weaker induction of primary antibody-secreting-cells (ASC) in infant mice [14]. This could reflect immaturity of neonatal B cells, CD4<sup>+</sup> T cells, or APC, as well as that of additional determinants such as the postnatal development of the microarchitecture of lymphoid organs. The definition of the relative contribution of each of these factors to the limited capacity of inducing early life B cells to differentiate into ASC, and the identification of strategies likely to circumvent such immaturity-associated limitations, require additional studies.

### 3. Limited Duration of Early Life Antibody Responses

Another challenge for early life immunization is that the strong antibody responses that are eventually elicited after several doses of immunogenic vaccines (such as tetanus or acellular pertussis vaccines) are of a shorter duration than those elicited >12 months of age. This rapid decline of IgG antibodies within 6–12 months requires repeat vaccine administration already in the second year of life, a strategy that is difficult to implement in many countries of the world. A similar finding is that early (<12 months) immunization could similarly be associated with waning immunity against measles, which is not observed following immunization at an older age [15]. The shorter persistence of IgG antibodies elicited in infancy is likely to reflect a limited *in vivo* half-life of plasma cells generated in early life, which is believed to depend on their developmental history, their homing capacity, as well as the supporting capacity of their environment. In mice, long-lived plasma cells are essentially located in the bone marrow. Our recent observation of a limited establishment of the bone marrow pool of long-lived plasmocytes in early life is thus of significant interest [14]. Should a similar limited homing of plasmocytes toward the bone marrow occur in infants, it would explain the shorter kinetics of their early life antibody responses. This can hardly be studied directly in humans, and studies in preclinical models will be required to eventually identify the contributing factors/molecules.

### 4. Does Early Life Immunization Limit the Quality of Antibody Responses?

Whether early life immunization results in antibodies of a different quality is an important question. Infant vaccines

preferentially elicit IgG antibodies regardless of age at administration [16]. However, infant immunization mainly elicits IgG1 and IgG3 isotypes, and IgG2 antibodies remain weak during the first 18 months of life [17] even for vaccines that induce preferential IgG2 responses in adults (Table 1).

The relative capacity to induce high-avidity antibodies in early life is of significant concern, as avidity is a direct marker of functional efficacy. Infants indeed produce Ab of a significantly lower avidity (with absent bactericidal activity) following *N. meningitidis* infection as compared to older children and somatic hypermutation of Ig genes in infant B cells slowly increases between 2 and 10 months of age, with evidence for selection only from 6 months onward [18,19]. In infant mice, studies with hapten-conjugated antigens had demonstrated years ago that the capacity to enter into an efficient antibody maturation process was age-related. All together, this generated the concern that early life immunization may be associated with induction of antibodies of a weaker functional efficacy. However, we recently observed that in contrast to hapten-based vaccines, two human infant protein vaccines (tetanus and pertussis toxoids) induce an adult-like neonatal murine Ab avidity maturation process [20]. In accordance, several studies have now demonstrated that the affinity maturation machinery is already functional in the first year of life [21]. As studies in infant mice have shown that vaccines may differ in their capacity of inducing—or not inducing—an adultlike avidity maturation process, clinical studies comparing avidity maturation following immunization of infants and unprimed children/adults are required to define the relative capacity of inducing high-avidity antibodies in early life and identify its determinants.

### B. Does Early Immunization Induce Neonatal Tolerance or Priming of Memory Cells?

Inducing tolerance by neonatal immunization is a concern that has originated from many murine studies. However, in contrast to newborn mice and their profoundly immature immune system, human neonatal immunization induced either enhanced or conserved subsequent infant responses. There are only few reports of hyporesponsiveness to subsequent vaccine doses following neonatal immunization with whole-cell pertussis vaccines, PRP-OMPc, or *N. meningitidis* group C polysaccharides (MenC PS). In contrast, neonatal immunization generally induces early priming of memory cells. This is best illustrated by neonatal immunization with oral polio and hepatitis B vaccines: Despite limited antibody responses to the priming dose (<10% seroconversion), secondary response patterns are clearly observed following boosting at 1 month of age (reviewed in Ref. 13). Thus as observed in murine models, certain vaccine antigens/delivery systems/adjuvants are clearly able to activate neonatal human B cells and trigger their differentiation into memory B cells, despite their limited capacity to drive B cell differentiation toward IgG-secreting plasmocytes. Surprisingly, neonatal administration of certain strongly immunogenic infant vaccines (such as tetanus toxoid vaccine) did not result into

enhanced responses to subsequent vaccine doses. Thus whether priming of memory cells may or may not be achieved by neonatal immunization currently cannot be predicted. As this is likely to prove essential for vaccine-mediated prevention in early life, through early prime–later boost immunization strategies, further studies are required so as to identify the determinants of neonatal priming.

### C. Influence of Maternal Antibodies on Early Life Antibody Responses

It has long been recognized that residual maternal IgG antibodies (MatAb) passively transferred during gestation may inhibit infant vaccine responses to measles and oral poliomyelitis vaccines, and more recently that they may also affect responses to nonlive vaccines (reviewed in Ref. 13). The main determinant of MatAb-mediated inhibition of antibody responses was identified as the titer of MatAb present at the time of immunization or rather as the ratio between vaccine antigen and MatAb [22–24]. Indeed, reducing MatAb titer at time of immunization or enhancing the dose of vaccine antigen may both circumvent the inhibition of infant antibody responses, in human and murine infants. This is best explained by the fact that following introduction of a vaccine antigen into a host with preexisting passive antibodies, MatAb readily bind to specific B cell vaccine epitopes, preventing access of infant B cells to the same determinants. If the vaccine antigen/MatAb ratio is low, this prevents access of infant B cells to B cell epitopes and therefore inhibits their differentiation into antibody-secreting cells. At a higher ratio, some B cell epitopes may remain unmasked by MatAb and thus available for binding by infant B cells and priming of B cell responses. Thus strategies to circumvent MatAb inhibition of vaccine antibody responses currently mainly include delayed vaccine administration, awaiting decline of MatAb or use of higher vaccine doses. Whether slow-release vaccines or certain delivery systems could better shield B cell epitopes from MatAb is an interesting possibility that awaits confirmation. In theory, mucosal vaccines should prove better able at escaping from MatAb inhibition, as concentrations of MatAb reaching infant mucosae are significantly lower than those reaching their serum. However, this may only be the case for immune responses directly elicited at the mucosal surface and not into the draining lymph nodes where MatAb concentration is higher.

### D. Perspectives for Enhancing Early Life Antibody Responses

In neonatal and infant murine models of immunization, certain adjuvant formulations are able to significantly enhance early life vaccine responses, whereas others fail to do so despite their strong adjuvanticity in adult animals (reviewed in Ref. 13). However, none of the adjuvant formulations tested so far proved capable of correcting the limitation of early antibody responses elicited following neonatal compared to adult immunization. This might unfortunately also be the case in human infants. Recently, coadministra-

tion of bacillus Calmette–Guerin (BCG) at time of neonatal hepatitis B immunization was shown to strongly enhance (50-fold) HBsAg antibody titers after the third vaccine dose compared to control infants [25], an influence likely to reflect the known maturation influence exerted by BCG on dendritic cells (DC). This observation thus suggests that enhancing DC/T cells/B cells interaction may have a positive influence on the magnitude of antibody responses elicited in neonates. Unfortunately, antibody responses to the first neonatal dose of HbsAg were only marginally enhanced by BCG coadministration. Although it cannot be excluded that this reflects in part the relatively weak immunogenicity of a single dose of hepatitis B vaccine even in adult hosts with mature DC, several months and/or vaccine doses were required for BCG to mediate its enhancing influence on neonatal antibody responses. This is similar to observations gathered with a large panel of adjuvants in murine models (review in Ref. 26) and may indicate that some limiting factors are not corrected by enhanced DC/T cells/B cells activation.

Novel antigen delivery systems, such as DNA vaccines, have not yet been tested in human neonates but were extensively studied in neonatal animal models. DNA vaccines induced similar antibody responses in newborn and adult mice (reviewed in Ref. 26) but failed to induce stronger early life antibody responses than those elicited by conventional protein/subunit/live attenuated vaccines. Accordingly, DNA immunization of newborn/infant nonhuman primates against hepatitis B, HIV, or influenza also resulted in weak antibody responses [27], and sequential bleeding indicated lack of antibody responses prior to 4 or 8 weeks of age, after 2 or 3 vaccine doses [28]. Thus vaccine formulations/delivery systems capable of rapidly inducing strong antibody responses in early life have not yet been identified. This calls for a better understanding of the limiting factors that they should be able to circumvent. Indeed, although early priming–later boosting strategies are currently the most promising strategies for enhancing early life antibody responses, time required for completion of such strategies is likely to be a limiting factor against pathogens for which exposure occurs very early in life.

### **III. CHALLENGES TO THE INDUCTION OF STRONG T CELL RESPONSES IN EARLY LIFE**

#### **A. Characteristics of Early Life CD4<sup>+</sup> and CD8<sup>+</sup> T Cell Responses**

In contrast to the slow maturation of antibody responses, acquisition of antigen-specific T cell responses is an early event, as shown by in utero priming of fetal T cell responses to allergens. However, the age-dependent maturation and differentiation of Th1 (IFN- $\gamma$  secreting) and Th2 (IL-4, IL-5, IL-13 secreting) T cell responses is yet poorly characterized (Table 1). T cell proliferative responses following BCG were stronger when administration was delayed from birth until 2–6 months of age in some studies, whereas adultlike IFN- $\gamma$  responses to neonatal BCG were reported in *The Gambia*

[29]. In contrast, Gambian infants showed defective IFN- $\gamma$  responses during the primary phase of the response to oral polio vaccine [29a] as compared to adults. Analyses of T cell responses to measles and mumps vaccines indicated similar antigen-specific T cell proliferative and IFN- $\gamma$  responses in infants immunized at 6, 9, or 12 months of age, but lower infant responses than those of adult controls [12,30]. Infant T cells also showed a limited capacity to increase their IFN- $\gamma$  release in response to IL-12 supplementation [30]. A limitation of these MMR/OPV/BCG studies is that they could not include previously unprimed naive adult controls. Thus to precisely define the influence of immune immaturity on T cell differentiation awaits additional clinical evidence.

Little is yet known on the maturation of human infant CD8<sup>+</sup> cytotoxic responses (CTLs) responses. Although infection-induced CTLs may be detected within the first weeks of life, CTL responses could also be age- and vaccine-dependent [31–33]. As an example, CTLs were recovered in infants following influenza infection, but not following immunization with a live influenza vaccine, suggesting that a certain immunogenicity threshold had only been reached in infected infants [32]. Thus it seems likely that the maturation of CD8<sup>+</sup> cytotoxic responses will prove age and vaccine type dependent in human as in mice, although far more studies are required to clarify this important issue.

#### **B. Which Are the Factors Limiting Early Life T Cell Responses?**

Studies assessing the determinants of early life T cell responses are currently limited to murine models of early life immunization. They indicate that antigen-specific T cell responses may be readily elicited at an early stage, but that early immunization is associated with lower IFN- $\gamma$  responses (and higher IL-5, IL-4, and IL-13 responses) to most conventional vaccines (reviewed in Ref. 13). Early life murine immunization results in limited induction of Th1-driven IgG2a antibodies and of CTL responses. Altogether, these observations suggest a preferential differentiation of early life murine T cell responses to viral/protein vaccines toward the Th2 pathway, as a “default” developmental pathway (reviewed in Ref. 34). This is considered as reflecting suboptimal APC–T cell interactions. Evidence that neonatal APC function (assessed by IL-12 production) may be immature has indeed been provided in mice, and recently also in human cord blood monocyte-derived cells [35]. Available data suggests that a limited IL-12/IFN- $\gamma$  release capacity may persist during the first year of life [36]. Suboptimal APC–T cell interactions could also result from deficient T cell costimulation, and transient differences in CD40L/CD154 expression between neonatal and adult T cells have indeed been reported both in mice and humans. Studies should now better define the relative influence of the immaturity of neonatal APC, neonatal T cells, and/or of the microenvironment in which APC–T cell interactions take place, so as to indicate potentially effective immunomodulation strategies.

### C. Influence of Maternal Antibodies on Neonatal CD4<sup>+</sup> and CD8<sup>+</sup> Vaccine Responses

In contrast to the inhibiting influence of maternal antibodies (MatAb) on infant antibody responses, it was recently demonstrated that MatAb leave CD4<sup>+</sup> and CD8<sup>+</sup> T cell responses largely unaffected. This was first observed in mice, under experimental conditions in which high titers of MatAb completely abrogated antibody responses but did not affect either CD4<sup>+</sup> T cell proliferative and cytokine responses [23,24] nor CTL responses [24,37,38]. In human infants, measles and mumps immunization also leaves infant CD4<sup>+</sup> T cell proliferative and INF- $\gamma$  responses unaffected despite inhibition of antibody responses by MatAb that present at immunization [10,12,30]. Accordingly, measles-specific T cell responses were measured in 86.8% of 6-month-old infants immunized in the presence of MatAb, whereas antibody responses were only observed in 36.7% [39]. This inhibition of B cell but not of T cell responses is best explained by the efficient uptake of antigen–antibody immune complexes by APC. Following processing, vaccine-derived antigenic peptides are thus presented at the APC cell surface, allowing priming of CD4<sup>+</sup> and CD8<sup>+</sup> T cells to independently occur of the inhibition of B cell responses. This early T cell priming is likely to explain the reduced measles morbidity and mortality observed in vaccinated infants who failed to seroconvert because of the presence of maternal antibodies. It could also significantly facilitate early prime–later boost strategies in early human life, as shown in mice [24].

### D. Perspectives for Enhancement of Early Life CD4<sup>+</sup> and CD8<sup>+</sup> Vaccine Responses

Studies in mice have clearly demonstrated that adultlike T cell responses may be induced already in the neonatal period by novel delivery systems and/or adjuvants. This has been repeatedly achieved by DNA immunization against a panel of vaccine antigens (reviewed in Ref. 26) and the induction of adultlike CD4<sup>+</sup> and CD8<sup>+</sup> T cell responses appears as a generic property of most DNA vaccines. This could result in part from prolonged antigenic exposure, allowing both prolonged immune stimulation and ongoing immune maturation to occur. However, induction of adultlike neonatal Th1 and CTL responses was also achieved by certain adjuvants, including by oligonucleotides containing immunostimulating CpG motifs [40,41], which are present in DNA plasmids, as well as by certain nonpersistent novel delivery systems.

The current understanding is that neonatal T cells may have greater requirements than adult T cells for costimulatory signals, such that the induction of Th1 and CTL neonatal responses essentially reflects the relative capacity of vaccines to activate neonatal APCs to thresholds sufficient—or not sufficient—for optimal T cell activation to occur. In mice, mimicking (IL-12 supplementation) or triggering (CD40) optimal APC activation is sufficient to induce adultlike IFN- $\gamma$  and CTL neonatal responses. Recently, the novel MF-59 adjuvant was reported as increasing human

lymphoproliferative responses to recombinant HIV gp120 following immunization at birth, 2 weeks, 2 months, and 5 months of age [42]. Although cytokine responses were not measured, it seems reasonable to expect that certain adjuvant formulations or delivery systems may prove capable of enhancing early life Th1 responses, representing a major progress in the control of early infections with intracellular pathogens. However, the recent observation that neonatal BCG enhanced both Th1 and Th2 responses to coadministered HbsAg antigens despite its strong Th1-driving capacity [25] calls for much more detailed investigations of the capacity of modulating neonatal T cell responses.

## IV. CONCLUSION AND PERSPECTIVES

The rapid induction of strong antibody responses in very early life is yet an unmet challenge both in preclinical and clinical studies, calling for a better understanding of the determinants of this important limitation. However, immune immaturity may not prevent early induction of memory B cells that may be recalled by subsequent boosting. The limited capacity for early life INF- $\gamma$  and CTL responses appear to essentially result from suboptimal APC–T cell interactions, and thus might be overcome by use of specific adjuvants or delivery systems enhancing such interactions. As the optimal immunogenicity/reactogenicity balance of these new vaccine formulations will have to be defined in very young populations, specific ethical and regulatory considerations should be rapidly addressed.

## Vaccination and Autoimmunity

**Paul-Henri Lambert**

### I. INTRODUCTION

Diseases encompassing manifestations caused by an autoimmune process are not infrequent and are known to appear in age groups that are often selected as targets for vaccination programs. Therefore, in the context of a rapidly increasing number of vaccination events, it is not surprising that the question of a potential interaction between vaccines and autoimmune diseases is being raised with increasing insistence.

It is estimated that as much as 5% of the population in Western countries suffer from autoimmune diseases [1]. These disorders represent a growing burden for health budgets as their incidence has significantly increased over the last few years, as documented for type I diabetes [2] and multiple sclerosis [3]. It is generally assumed that autoimmune disorders result from complex interactions between genetic traits and environmental factors. Indeed, although there is a frequent concordance of autoimmune diseases among monozygotic twins [4], the concordance rate is lower than expected. Similarly, changes in the incidence of type I diabetes and multiple sclerosis when children from a given population migrate from one region to another [5,6] strongly suggest a critical role for environmental causes in addition to genetic predisposition. In most autoimmune diseases the trigger has not been formally identified, leaving room for hypotheses and allegations not always substantiated by facts. Mechanisms leading to autoimmune responses and to their occasional translation into autoimmune diseases are now better understood. Autoimmune responses result from the combined effects of antigen-specific stimulations of the immune system and of an antigen-nonspecific activation of antigen-presenting cells in the context of a genetically determined predisposition. Most often such responses are not followed by any clinical manifestations unless additional events favor disease expression, e.g., a localized inflammatory process at tissue level.

The role of infections has been occasionally demonstrated either as an etiologic factor or as a triggering event in autoimmune diseases. Well-known examples are the post-streptococcal heart disease or the Guillain–Barré syndrome that follows *Campylobacter jejuni* infections. Such observations have emphasized the multifactorial immunological pathogenesis of secondary autoimmune pathology. First, there is a potential role of antigenic similarities between some microbial molecules and host antigens (antigenic mimicry). Second, infection-related signals that trigger innate immunity appear to play an essential role in enhancing the immunogenicity of host antigens or of host-mimicking epitopes, and in possibly overcoming regulatory mechanisms that limit autoimmune responses. It should be stressed that post-infectious autoimmune responses are not infrequent, whereas associated autoimmune diseases remain rare events and often require additional infection-related inflammatory processes.

It is on the basis of such observations that questions are raised regarding the potential risk of autoimmune responses and of autoimmune diseases following vaccination. Is there a significant risk that some vaccines may induce autoimmune responses through the introduction of microbial epitopes that cross-react with host antigens? Can adjuvant-containing vaccines trigger the clinical expression of an underlying autoimmune process through a “nonspecific” activation of antigen-presenting cells and the release of inflammatory cytokines? Until now, answers to these questions have been largely based on epidemiological studies, with limitations due to the difficulty in assessing the frequency of relatively rare events during clinical trials or post-marketing surveillance. When considered as a whole, autoimmune diseases affect up to 5% of the general population in industrialized countries, but many specific autoimmune diseases have a relatively low natural incidence. Whereas diseases such as rheumatoid arthritis may reach 1% prevalence, others such

as multiple sclerosis or SLE are less frequent (around 0.1%) and many others are relatively rare diseases. Therefore, for most of these clinical entities, only very large epidemiological studies or huge clinical trials would allow for a consistent assessment of the relative risk of vaccine-related effects.

Understanding the mechanisms by which autoimmune responses are generated and how they may or may not lead to autoimmune diseases is of paramount importance in defining the real risk of vaccine-associated autoimmune reaction. During the course of vaccine development, it is now becoming conceivable that a comprehensive and multidisciplinary approach would help to reduce to a minimum the risk that a new vaccine would induce autoimmune manifestations. Later, once the new vaccine is largely used in public health programs, systems should be in place to readily assess observations or allegations of unexpected autoimmune adverse effects. Although in the last few years, there has been a dramatic increase in the number of such allegations, it is somewhat reassuring to see that autoimmune adverse effects were only demonstrated in very few instances.

## II. INFECTIOUS AGENTS AS TRIGGER OF AUTOIMMUNE DISEASES

The prototype of autoimmune disease of infectious origin is rheumatic fever. It is caused by an anti-streptococcal immune response that cross-reacts with cardiac myosin [7]. Another well-documented example is the Guillain–Barré syndrome occurring in the course of *C. jejuni* infection, which is mediated by anti-bacterial lipopolysaccharide antibodies that cross-react with human gangliosides [8]. Similarly, antibodies directed against the Tax protein of the human T-lymphotropic virus type 1 (HTLV-1) and cross-reacting with the heterogeneous nuclear ribonucleoprotein-A1 (hnRNP-A1) self-antigen were demonstrated in HTLV-1-associated myelopathy/tropical spastic paraparesis [9]. Although cross-reactivity between viral peptides and self-antigens was documented in type I diabetes and multiple sclerosis and despite circumstantial observations linking the overexpression of these diseases to previous viral infections, a clear-cut relation between the onset of organ-specific autoimmunity and viral infection has not been firmly established, except for type 1 diabetes in the context of congenital rubella [10–12]. In systemic autoimmune diseases, the role of viruses is also suspected, especially in systemic lupus erythematosus. However, such a role has only been clearly demonstrated in mixed cryoglobulinemia, a disease associated with hepatitis C [13].

It has also been suggested that some long-term complications of infections might be of autoimmune origin. This is the case for reactive arthritis consecutive to infection with intracellular bacteria, including *Chlamydia*, *Salmonella*, *Shigella*, *Borrelia*, and *Yersinia* species. In these diseases there is evidence of a persistent pathogenic immune response involving T lymphocytes, but whether such T-cell responses are directed against cross-reactive self-antigens or maintained by persistent bacterial antigens is still an open question [14,15]. In Lyme arthritis, the identification of an immuno-

dominant epitope of the outer surface protein A of *Borrelia burgdorfi* (Osp A) displaying significant homology with human LFA-1, an adhesion molecule of the  $\beta 2$  integrin family, provided convincing evidence for an autoimmune mechanism [16]. Indeed, cross-reactive T-cell responses to OspA and LFA-1 were observed in blood and synovial fluid of patients with antibiotic-resistant chronic Lyme arthritis [16].

The role of infections as etiological agents of human autoimmune disease has been demonstrated in only a few instances. However, their involvement in the exacerbation of a pre-existing autoimmune disorder is rather well established. For example, in multiple sclerosis, epidemiological data strongly suggest that relapses of the disease can be triggered by both bacterial and viral infections [17,18]. Several vaccine-preventable infections are well known to negatively influence the course of defined autoimmune diseases. Vaccination in such cases is highly recommended (e.g., influenza vaccination in patients with multiple sclerosis) [19] because no exacerbation has been recorded following the use of any of the current vaccines.

## III. MECHANISMS OF AUTOIMMUNITY INDUCED BY INFECTIOUS AGENTS

It is generally assumed that activation and clonal expansion of autoreactive T lymphocytes represent critical steps in the pathogenesis of autoimmune diseases. Infections might be responsible for these key events through several non-mutually exclusive mechanisms including molecular mimicry, enhanced presentation of self-antigens, bystander activation, and impaired T-cell regulation [15].

### A. Molecular Mimicry

The molecular mimicry hypothesis is based on sequence homologies between microbial peptides and self-antigen epitopes. At the T-cell level, this concept was initially established in an experimental model in which immunization with a hepatitis B virus polymerase peptide containing a six amino-acid sequence of rabbit myelin basic protein (MBP) elicited an anti-MBP T-cell response leading to autoimmune encephalomyelitis [20]. The demonstration that a viral infection in itself can lead to autoimmune pathology caused by molecular mimicry was established in a murine model of herpes simplex keratitis, in which pathogenic autoreactive T-cell clones were shown to cross-react with a peptide from the UL6 protein of the herpes simplex virus [21]. Indeed, a single amino acid mutation in the UL6 T-cell epitope was sufficient to limit the capacity of the mutant virus to induce autoimmune corneal lesions [22]. Conclusive evidence that a viral infection can induce pathogenic autoreactive T cells was also provided in a model of Theiler's murine encephalomyelitis virus encoding a mimicking peptide [23]. Molecular mimicry at the level of epitopes recognized by CD8<sup>+</sup> T lymphocytes may also be involved in autoimmunity. This was shown in a model of inflammatory bowel disease induced in immunodeficient mice by CD8<sup>+</sup> T-cell clones directed against my-

cobacterial heat shock protein hsp60, which cross-react with hsp60 self antigen [24].

B cell epitope mimicry also occurs. Functional mimicry of host proteins is quite widespread, as it allows pathogens not only to evade an immune response but also to use cellular receptors as port of entry. Such functional mimicry of human glycosphingolipids by lipopolysaccharides (LPS) from several *Neisseria* species and from *Haemophilus influenzae* may have evolved to serve this function [25]. Structural homology with autoimmune implications has been identified. A tetrasaccharide of the LPS core of the gastrointestinal pathogen *C. jejuni* can induce antibodies to human gangliosides and may be causally implicated in the autoimmune Guillain–Barré syndrome [26]. In contrast, it is well known that Lewis-like polysaccharide antigens from certain *Helicobacter pylori* strains induce antibodies that cross-react with gastric mucosa antigens and appear to contribute to atrophic gastritis in man [27].

## B. Enhanced Presentation of Self-Antigens

Infection can promote processing and presentation of self-antigens by several mechanisms. First, cellular damage locally induced by viral or bacterial infection can result in the release of sequestered self-antigens that stimulate auto-reactive T cells. This was clearly demonstrated in autoimmune diabetes induced by coxsackievirus B4 infection in mice [28]. Second, the local inflammatory reaction elicited in tissues by microbial products can trigger dendritic cell maturation, which represents a key step in the induction phase of immune responses. Microbial products that engage Toll-like receptors on dendritic cells can induce the up-regulation of membrane expression of MHC and costimulatory molecules and the secretion of cytokines, particularly interleukin (IL)-12, which promote T-cell activation [29]. Third, a T-cell response directed toward a single self-peptide can “spread” to other self-epitopes during an inflammatory reaction. This process of “epitope spreading” has been well-documented in murine models of encephalomyelitis [15].

## C. Bystander Activation

The release of cytokines such as IL-12 can promote bystander activation of memory T cells and occasionally trigger autoimmune reactions when such autoreactive cells do pre-exist. Using murine models of encephalomyelitis, Shevach et al. demonstrated that quiescent autoreactive T cells could differentiate into pathogenic Th1 effectors in the presence of microbial products that induce IL-12 synthesis [30,31]. Likewise, Fujinami demonstrated that IL-12-inducing viral infections could elicit relapses of autoimmune encephalomyelitis, in a nonantigen-specific manner, in myelin-primed animals [32]. A salient feature of bystander activation is its limited duration. In order to observe an exacerbation of EAE one should provide the triggering signal within a relatively restricted window of time after the aetiological stimuli that “primed” the animal for disease. In addition, disease exacerbation occurs within weeks after bystander activation and is not usually seen after longer delays [32].

## D. Regulatory T Cells

There is growing evidence that regulatory T cells are instrumental in controlling autoreactive T cells both in neonates and adults [33,34]. Indeed, depletion of regulatory CD25<sup>+</sup> T cells promotes autoimmunity although in adult animals this maneuver is not sufficient by itself and requires administration of self-antigen [34]. It is likely that infectious agents could have profound influences, either positive or negative, on regulatory T cells. This represents an increasingly important area of investigation that will probably deserve attention during the course of vaccine development.

## IV. THE RISK OF VACCINE-ASSOCIATED AUTOIMMUNITY

There exist no general criteria for diagnosing vaccine-related autoimmune disease and this question has to be analyzed on a case-by-case basis. In general, appropriate epidemiological studies are essential before seriously considering that a particular autoimmune clinical condition might be associated with a given vaccination. This can then be followed by the determination of known biological markers of the identified autoimmune disease in other vaccinees. However, it is always relevant to compare the level of vaccine-related risk to that associated with the corresponding natural infection, for the population at large or for specific subgroups to be identified.

Criteria underpinning vaccine adverse event causality assessment have been established by WHO [35]. Some of these criteria particularly apply to autoimmune diseases and may be summarized as follows:

- (1) Consistency. The association of a purported autoimmune event with the administration of a vaccine should be consistent, i.e., the findings should be replicable in different localities, by different investigators not unduly influencing one another, and by different methods of investigation, all leading to the same conclusion(s).
- (2) Strength of the association. The association should be strong in the magnitude of the association (in an epidemiological sense).
- (3) Specificity. The association should be distinctive and the adverse event should be linked uniquely or specifically with the vaccine concerned, rather than its occurring frequently, spontaneously, or commonly in association with other external stimuli or conditions. An adverse event may be caused by a vaccine adjuvant or additive, rather than by the active component of the vaccine. In this case, it might spuriously influence the specificity of the association between vaccine and adverse event.
- (4) Temporal relation. There should be a clear temporal relationship between the vaccine and the adverse event, in that receipt of the vaccine should precede the earliest manifestation of the event or a clear exacerbation of an ongoing condition. The timing is important: long delays (over 2 months)

are not the rule. Indeed, the induction or the acceleration of autoimmune tissue lesions that have been observed following some acute infections (e.g., *C. jejuni* or influenza) has always occurred within weeks of the infectious event.

Therefore an association between vaccine administration and an autoimmune adverse event is most likely to be considered strong when the evidence is based on:

1. Well-conducted human studies that demonstrate a clear association in a study design that is determined a priori for testing the hypothesis of such association. Such studies will normally be one of the following, in descending order of probability of achieving the objective of the study: randomized controlled clinical trials, cohort studies, case control studies, and controlled case-series analyses. Case reports, however numerous and complete, do not fulfil the requirements for testing hypotheses. When autoimmune events appear attributable to a vaccine, it is important to determine whether there is a predisposed set of subjects (by age, population, genetic, immunological, environmental, ethnic, sociological, or underlying disease conditions). Such predisposition is most likely to be identified in case-controlled studies.
2. An association that is demonstrated in more than one human study and consistent among the studies. The studies would need to have been well conducted, by different investigators, in different populations, with results that are consistent, despite different study designs.
3. Pathology similarities: In the case of future vaccines against infections known to be associated with autoimmune complications (e.g., post-group A streptococcal rheumatic heart disease), vaccine-associated autoimmune adverse events should closely resemble these infection-associated complications.
4. A nonrandom temporal relationship between administration and the adverse incident.

There should be a strict definition of the autoimmune adverse event in clinical, pathological, and biochemical terms, as far as that is achievable. The frequency in the non-immunized population of the adverse event should be substantially different from that in the immunized population.

#### A. Vaccine-Attributable Autoimmune Diseases

It is only in a few rare cases that autoimmune pathology has been firmly considered as attributable to the use of modern vaccines. For example, a form of Guillain–Barré Syndrome (GBS, polyradiculoneuritis) was found associated with the 1976–1977 vaccination campaign against swine influenza using the A/New Jersey/8/76 swine-flu vaccine [36]. The estimated attributable risk of vaccine-related GBS in the adult population was just under one case per 100,000 vaccinations and the period of increased risk in swine-flu vaccinated versus nonvaccinated individuals was concentrated

primarily within the 5-week period after vaccination (relative risk: 7.60). Although this original Centers for Disease Control study demonstrated a statistical association and suggested a causal relation between the two events, controversy has persisted for several years. The causal relation was reassessed and confirmed in a later study focusing on cases observed in Michigan and Minnesota [37]. The relative risk of developing Guillain–Barre syndrome in the vaccinated population of these two states, as compared to swine-flu nonvaccinated individuals, during the 6 weeks following vaccination was 7.10, whereas the excess cases of Guillain–Barre syndrome during the first 6 weeks attributed to the vaccine was 8.6 per million vaccinees in Michigan and 9.7 per million vaccinees in Minnesota. The pathogenic mechanisms involved are still unknown. With subsequent influenza vaccines, no significant increase in the development of Guillain–Barré syndrome was noted [38] and it is currently assumed that the risk of developing the Guillain–Barré syndrome following vaccination (one additional case per million persons vaccinated) is substantially less than the risk for severe influenza and influenza-related complications [39].

Another example of confirmed autoimmune adverse effect of vaccination is idiopathic thrombocytopenia (ITP) that may occur after measles-mumps-rubella (MMR) vaccination [40–44]. The reported frequency of clinically apparent ITP after this vaccine is around 1 in 30,000 vaccinated children. In one study [40], the relative incidence in the 6-week post-immunization risk period has been estimated at 3.27 (95% CI: 1.49 to 7.16) when compared to the control period. In about two thirds of the patients, platelet counts under 20,000 have been recorded. The clinical course of MMR-related ITP is usually transient but it is not infrequently associated with bleeding and, as shown in a study conducted in Finland, it can occasionally be severe [45]. In this latter study, there was an increase in platelet-associated immunoglobulin in 10 out of 15 patients whereas circulating antiplatelet autoantibodies, specific for platelet glycoprotein IIb/IIIa, were detected in 5 out of 15 patients. These findings are compatible with an autoimmune mechanism triggered by immune response to MMR vaccination. However, it should be noted that the risk for thrombocytopenia following natural rubella (1/3000) or measles (1/6000) infections is much greater than after vaccination [39]. Patients with a history of previous immune thrombocytopenic purpura are prone to develop this complication and in these individuals the risk of vaccination should be weighed against that of being exposed to the corresponding viral diseases [46].

#### B. Vaccine-Related Allegations of Autoimmune Adverse Effects

The advent of new vaccines and the increasing number of highly publicized reports that claim a link between certain immunizations and autoimmune disease have led to public concern over the risk of inducing autoimmune disease by immunization. For example, in France there has been concern over the potential association of multiple sclerosis with hepatitis B vaccination. Similarly, the influence of childhood vaccination on type 1 diabetes has been questioned in the United States. Such allegations, even if they are not con-

firmed, may have detrimental effects on vaccination programs at a global level and therefore require a very particular attention.

### C. Hepatitis B and Multiple Sclerosis

The possible association of hepatitis B (HB) vaccination with the development of multiple sclerosis (MS) was primarily questioned in France, following the report of 35 cases of primary demyelinating events occurring at one Paris hospital between 1991 and 1997, within 8 weeks of recombinant HB vaccine injection [47–49].

The neurological manifestations were similar to those observed in MS. There were inflammatory changes in the cerebrospinal fluid and high signal intensity lesions were observed in the cerebral white matter on T2-weighted MR images. After a mean follow-up of 3 years, half of them became clinically definite MS. These neurological manifestations occurred in individuals considered at higher risk for MS: a preponderance of women, mean age near 30 years, overrepresentation of the DR2 HLA antigen, and a positive family history of MS. These observations rapidly called the attention of the French pharmaco-vigilance system and from 1993 through 1999, several hundred cases with similar demographic and clinical characteristics were identified. It is essential to note that this episode occurred in a very special context. In France, close to 25 million people received the HB vaccine during this period, of which 18 million were adults, and this represented about 40% of the population of the country. No cases were reported in children under 3 years

of age. Since these initial reports, at least 10 studies aiming at defining the significance of such observations have now been completed. They are summarized in Table 1. There was no significant association between hepatitis B vaccination and the occurrence of demyelinating events or MS in any of these studies. However, a common feature was an insufficient statistical power to definitely exclude such an association. Two studies are particularly illustrative of the difficulty in interpreting these data. First, a retrospective, hospital-based case-control study was carried out on patients experiencing the first episode of CNS demyelination during the 2-year period from January 1994–December 1995 [50] (121 cases and 121 matched controls). Adjusted odds ratios (OR) obtained from conditional logistic regression between a CNS demyelination and HB vaccine exposure during the previous 60 days were 1.7 (CI 95%, 0.5–6.3) and, during the previous 61–180 days, 1.5 (CI 95%, 0.5–5.3). Second, a population-based case-control study using the general practice database in the United Kingdom analyzed 360 cases with incident MS and 140 cases of central demyelination. Each case was matched with up to six controls [51]. The OR for exposure to HB vaccine in the 0–12-month period was 1.6 (CI 95%, 0.6–4.0).

However, two recent studies bear particular weight in confirming the lack of a significant association between hepatitis B vaccination and the occurrence of MS. Confavreux et al. [52] conducted a case-crossover study in patients included in the European Database for Multiple Sclerosis who had a relapse between 1993 and 1997. The index relapse was the first relapse confirmed by a visit to a neurologist and

**Table 1** Clinical Studies of the Association Between Multiple Sclerosis or Demyelinating Diseases with Hepatitis B Vaccination

Analysis	Study site	RR/OR (time interval)	CI 95%	Ref.
MS, first episode	USA	0.7 (24 months) 0.9 (any time)	0.3–1.8 0.5–1.6	[53]
MS, relapses	Europe	0.71 (2 months)	0.4–1.3	[52]
Acute demyelination	France	1.7 (2 months) 1.5 (2–6 months)	0.5–6.3 0.5–5.3	[50]
MS, first episode	Canada	5/288657 ( <i>pre-vaccination period, 1986–1992</i> ) 9/289651 ( <i>post-vaccination period, 1992–1998</i> )		[54]
MS, first episode	USA	1.3 (6 months) 1.0 (12 months) 2.0, 0.9 (36 months)	0.4–4.8 0.3–3.0 0.4–2.1	[55]
Acute demyelination	United States	1.09	0.7–1.7	[56]
MS, relapses	France	0.6/year ( <i>incidence before vaccination</i> ) 0.5/year ( <i>incidence after vaccination</i> )		[57]
Acute demyelination	France	1.05 (2 months, expected 102.7 vs. observed 108/7.18 million vaccinees)		[58]
MS, first episode and acute demyelination	UK	1.6 (12 months)	0.6–4.0	[59]
Acute demyelination	US	0.6 (2 months)	01–4.6	[60]

RR = Relative risk, OR = odds risk.

preceded by a relapse-free period of at least 12 months. Exposure to vaccination in the 2-month risk period immediately preceding the relapse was compared with that in the four previous 2-month control periods for the calculation of relative risks. Of 643 patients with relapses of multiple sclerosis, 2.3% had been vaccinated during the preceding 2-month risk period as compared with 2.8% to 4.0% who were vaccinated during one or more of the four control periods. The relative risk of relapse associated with exposure to any vaccination during the previous 2 months was 0.71 (95% CI, 0.40 to 1.26). There was no increase in the specific short-term risk of relapse associated with hepatitis B.

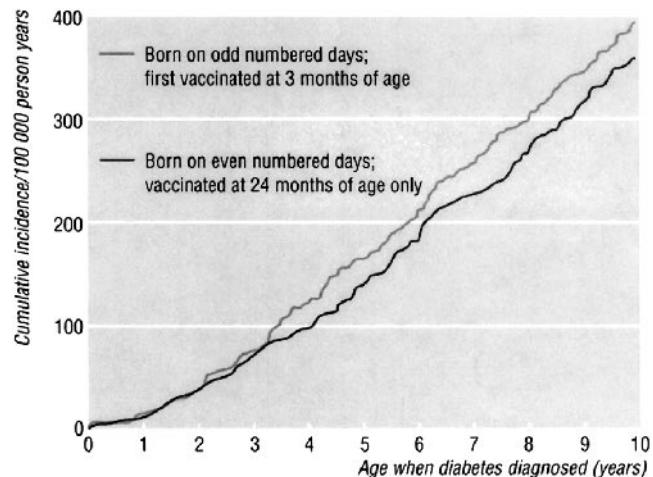

Another recent study [53] also excluded a possible link between hepatitis B (HB) vaccine and multiple sclerosis. These authors conducted a nested case-control study in two large cohorts of nurses in the United States: those in the Nurses' Health Study (which has followed 121,700 women since 1976) and those in the Nurses' Health Study II (which has followed 116,671 women since 1989). For each woman with multiple sclerosis, five healthy women and one woman with breast cancer were selected as controls. The analyses included 192 women with multiple sclerosis and 645 matched controls. The multivariate relative risk of multiple sclerosis associated with exposure to the hepatitis B vaccine at any time before the onset of the disease was 0.9 (95% CI, 0.5 to 1.6). The relative risk associated with hepatitis B vaccination within 2 years before the onset of the disease was 0.7 (95% CI, 0.3 to 1.8). The results were similar in analyses restricted to women with multiple sclerosis that began after the introduction of the recombinant hepatitis B vaccine.

These reassuring data are consistent with the fact that, since the integration of hepatitis B vaccine into national childhood immunization schedules in over 125 countries, it has been used in more than 500 million persons and has proved to be among the safest vaccines yet developed.

#### D. Vaccination and Diabetes

Type 1 diabetes [formerly known as insulin-dependent diabetes mellitus (IDDM) or juvenile diabetes] results from autoimmune destruction of pancreatic  $\beta$ -cells in genetically susceptible individuals exposed to environmental risk factors. The incidence is particularly high in some geographic areas, e.g., Finland and Sardinia, where it can reach 40 cases per 100,000. During the last decades, there has been a regular increase of the incidence of type 1 diabetes in most countries of the world. In a recent European multicenter study covering the period 1989–1994, the annual rate of increase in incidence was found to be 3–4%, with a particularly rapid rate of increase in children under 4 years of age (6.3%) [61].

In this context, it is not surprising that the potential role of childhood vaccines as triggering event for this disease has been questioned. This possibility has been evaluated in a few epidemiologic studies. A case-control study conducted in Sweden in the mid-1980s did not observe any significant effect of vaccination against tuberculosis, smallpox, tetanus, Pertussis, rubella on odd-risk for diabetes [62]. However, some authors [63,64] have hypothesized that the timing of vaccination may be of importance and that certain vaccines

**Figure 1** Cumulative incidence of type 1 diabetes per 100,000 person years in Finnish children aged 10 years or under. Comparison of children vaccinated first at the age of 3 months with children vaccinated at the age of 24 months only [65]. There was no statistically significant differences between these two groups (relative risk: 1.01).

(e.g., *Haemophilus influenzae* type b, Hib), if given at 2 months of life or later, may increase the risk of type 1 diabetes. This was not confirmed by a 10-year follow-up study of over 100,000 Finnish children involved in a clinical trial of Hib vaccine (Fig. 1). There was no increased risk of diabetes when comparing children who had received four doses of vaccine at 3, 4, 6, and 14 to 18 months of age with children who received only one dose at 24 months of age [65].

A recent study conducted in four large health maintenance organizations (HMOs) in the USA did not observe any association between administration of routine childhood vaccines and the risk of type 1 diabetes. There was no influence of the timing of hepatitis B or Hib vaccination on the diabetes risk [66].

Therefore, at this stage, there are no serious indications of any significant influence of current childhood vaccines on the occurrence of type 1 diabetes.

#### V. NEW GENERATION VACCINES AND AUTOIMMUNITY: APPROACHES TOWARD EARLY RISK ASSESSMENT

During the course of vaccine development, only a comprehensive and multidisciplinary strategy may help to reduce the theoretical risk that a new vaccine would induce autoimmune manifestations. First, one should question whether clinical manifestations of an autoimmune nature are known to be associated with the infectious disease that will be the target of the new vaccine. If such events have been reported, e.g., for group A streptococcal diseases, attention should be given to avoid reproducing the natural disease pathogenic process. This may include the identification and the exclusion of naturally pathogenic epitopes. Second, potential

molecular and immunological mimicry between vaccine antigens and host components should be extensively and critically analyzed through an intelligent combination of bio-informatics and immunological studies. One should keep in mind that, by itself, an identified mimicry is of little pathogenic significance. Information should be gathered on the relative ability of such epitopes to bind to human MHC molecules, to be processed by human antigen-presenting cells, and to be recognized by autoreactive T cells. Molecular mimicry in itself is not sufficient to trigger autoimmune pathology and other factors intrinsic to infections such as tissue damage and long-lasting inflammatory reaction might be required as well. For example, a recently developed Lyme disease vaccine was shown to contain an immunodominant epitope of the outer surface protein A of *Borrelia burgdorfi* (Osp A) displaying significant homology with human LFA-1, an adhesion molecule of the  $\beta 2$  integrin family. Although this raised concern about the safety of this vaccine, there was no evidence for an increased incidence of arthritis in individuals having received the Lyme vaccine [39]. Third, indicative information can be obtained through the use of ad hoc experimental models of autoimmune diseases. Different vaccine formulations and adjuvants can be compared regarding their potential capacity to induce or enhance the expression of pathology in relevant models. For example, there are models of experimental allergic encephalitis which are sensitive to the administration of IL-12 inducing microbial products and can help to compare the nonspecific effects of different adjuvants or vaccine formulations [32]. Fourth, appropriate immunological investigations (e.g., autoimmune serology) may be systematically included in phase I–III clinical trials. On an ad hoc basis, clinical surveillance of potential autoimmune adverse effects may have to be included in the monitoring protocol. Such surveillance will have to be extended through the postmarketing stage if specific rare events have to be ruled out.

## VI. CONCLUSION

Isolated case reports and increased attention in the media to possible side effects of vaccines have dramatically modified the perception by the medical community and the public of the risk of autoimmunity elicited by vaccination, despite the lack of epidemiological support for such a concern. Although available data are reassuring, we must remain vigilant as the risk of autoimmunity associated with some of the new generation vaccines might be increased as compared to current vaccines. A number of new adjuvants that are being developed aim at inducing strong Th1-type immune responses against viruses or other intracellular pathogens. Such effects may occasionally favor the expression of underlying autoimmune diseases or induce autoimmune responses in exceptional cases when the vaccine antigens contain immuno-dominant epitopes that cross-react with self-antigens. Special attention should be given to adjuvants acting as strong inducers of IL-12 synthesis [27,28]. Cancer vaccines based on dendritic cells pulsed with tumor antigens might also carry a significant risk of autoimmunity induction [39,40].

Finally, it is of paramount importance to keep in mind that the mere occurrence of autoimmune markers (auto-reactive antibodies or T cells) is a frequent phenomenon in a normal population and that pathological expression, i.e., the development of an autoimmune disease, is by far much less frequent.

## Adjuvants for the Future

**Richard T. Kenney**

*Iomai Corporation, Gaithersburg, Maryland, U.S.A.*

**Robert Edelman**

*University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.*

In 1925, Ramon demonstrated that it was possible to artificially increase antigen-specific levels of diphtheria or tetanus antitoxin by the addition of bread crumbs, agar, tapioca, starch oil, lecithin, or saponin to the vaccines [1]. Since then, aluminum hydroxide has become the dominant reagent used and is the only adjuvant currently used in licensed vaccines in the United States. The field has become much more sophisticated in the past decade with the introduction of numerous new adjuvants and new concepts regarding the mechanisms of action. In this brief chapter, we review the modern adjuvants administered to enhance a variety of experimental vaccines in humans. After a more general discussion of adjuvants, including their definition, mechanisms of action, and safety, we will discuss clinical trials of investigational adjuvants. For additional study of this complex subject, including a historical perspective, the reader is referred to recent published reviews of vaccine adjuvants (Refs. [2–5] and references therein).

Interest in vaccine adjuvants is growing rapidly for several reasons. First, dozens of new vaccine candidates have emerged over the past decade against infectious agents, cancer, fertility, and allergic and autoimmune diseases; many of these candidates require adjuvants. Second, the Children's Vaccine Initiative (CVI), initiated in 1990 [6], and the Global Alliance for Vaccines (GAVI), initiated in 1999 [7], have helped to energize political and public health interest in vaccine adjuvants by establishing ambitious goals for enhancing present vaccines and for developing new ones. Finally, refinements in the fields of analytical biochemistry, macromolecular purification, recombinant technology, and improved understanding of immunological mechanisms and disease pathogenesis have helped to improve the technical basis for adjuvant development and application.

### I. DEFINITIONS

The term “adjuvant” (from the Latin *adjuvare*, meaning *to help*) was coined in 1926 by Ramon for a substance used in combination with a specific antigen that produces more immunity than the antigen used alone [8]. The enormous diversity of compounds that increase specific immune responses to an antigen and thus function as vaccine adjuvants makes any classification system somewhat arbitrary. Adjuvants can be loosely categorized in terms of their physical nature as 1) mineral salts; 2) mycobacterial, bacterial, and plant derivatives; 3) surface-active agents and microparticles; 4) polymers, cytokines, vitamins, and hormones; and 5) synthetic constructs. Those listed in Table 1 are examples of immunopotentiators used during the past 25 years. They are grouped according to origin rather than mechanism of action because the mechanisms for most adjuvants are incompletely understood. Agents in Table 1 are reported to augment specific antigens; nonspecific enhancers of the immune response that principally stimulate innate immunity are largely excluded. A comprehensive list of adjuvants, beyond the scope of this chapter, is available and updated by the NIAID [9].

A “carrier” is an immunogenic protein to which a hapten or a weakly immunogenic antigen is bound [10]. A carrier may also be a living organism (or vector) bearing genes for expression of the foreign hapten or antigen on its surface. A naked DNA vaccine is a carrier in the sense that it entails injection into the host of a plasmid-based DNA vector that encodes the production of the protein antigen [11]. Carriers increase the immune response by providing T-cell help to the hapten or antigen.

A “vehicle” provides the substrate for the adjuvant, the antigen, or the antigen–carrier complex. Unlike the carriers

**Table 1** Classes of Modern Vaccine Adjuvants, Carriers, and Vehicles

Adjutants		Polymers	
Mineral salts	Mycobacterial, bacterial, and plant derivatives	Surface-active agents and microparticles	
Aluminum hydroxide (Alhydrogel; Rehydragel®), aluminum, and calcium phosphate gel	Complete Freund's adjuvant (killed <i>M. tuberculosis</i> ), DETOX™ (MPL plus cell wall skeleton of <i>Mycobacterium phlei</i> ), Bacillus Calmette Guérin (BCG), muramyl dipeptides and tripeptides, dipalmitoyl phosphatidylethanolamine-MTP (MTP-PE), monophosphoryl lipid A (MPL®), gamma inulin/alum (Algammulin), <i>Klebsiella pneumoniae</i> glycoprotein, <i>Bordetella pertussis</i> , <i>Corynebacterium parvum</i> , cholera toxin, cholera B subunit, <i>E. coli</i> heat-labile toxin (LT)	Saponin (Stimulon™ QS-21, Quil-A), immune-stimulating complexes (ISCOMS™), Avridine®, nonionic block copolymers (CRL1005, Pluronic® L121), virosomes, dimethyl dioctadecyl-ammonium bromide (DDA)	Dextran, double-stranded polynucleotides (Poly rA:Poly rU), acetylated polymannose (Acemannan), sulfopolysaccharide, polymethyl methacrylate (PMMA), acrylic acid-allyl sucrose (Carbopol), polyphosphazene (Adnumer™), β-glucan (Pleuran, Algal Glucan)
Cytokines, vitamins, and hormones	Synthetic constructs	Carriers	Vehicles
GM-CSF, IFN-α, IFN-γ, IL-1β, IL-2, IL-6, IL-7, IL-12, cytokine-containing liposomes, vitamin A, D <sub>3</sub> (Calcitriol), E, human growth hormone, dehydroepiandrosterone (DHEA)	Imidazo-quinolines (Imiquimod, S-28463), glycolipid bay R1005, stearyl tyrosine, DTP-GDP (Imm Ther™), DTP-DPP (Theramide™), threonyl-MDP 7-allyl-8-oxoguanosine (Loxoribine), multiantigen peptide (MAP) system, linear polymerization of haptic peptides, peptide linkage to T-cell or B-cell epitopes	Bacterial toxoids (tetanus, diphtheria, pseudomons A, pertussis), meningococcal outer membrane proteins (proteosomes), fatty acids, Ty viruslike particles, nucleic acid vaccines, living vectors (vaccinia virus, adenovirus, canary pox, polio virus, BCG, attenuated <i>Salmonella</i> , <i>Vibrio cholerae</i> , and <i>Shigella</i> ), protein cochleates	Mineral oil (IFA, Montanide®; Specol) and vegetable oil (peanut, olive, sesame) emulsions, squalene and squalane emulsions (MF59, SAF, SPT), lipid-containing vesicles (liposomes [DMPC, DMPG], Sendai proteoliposomes, virosomes [IRIV]), biodegradable polymer microspheres (lactide and glycolide polymers (PLGA, PGA, PLA), proteinoid microspheres (PODDS™), polyphosphazene, protein cochleates, edible plants

listed in Table 1, vehicles are not themselves immunogenic. Like carriers, most vehicles can enhance antigens alone and so sometimes are considered to be another class of adjuvants, although their immunostimulatory effects are often augmented by the addition of conventional adjuvants to constitute “adjuvant formulations.” Thus, an “adjuvant formulation” is composed of an adjuvant in a suitable vehicle. Many examples of such adjuvant formulations have been tested in humans [12–15] (cf. Table 2).

## II. MECHANISMS OF ACTION

Adjuvants can select for or modulate humoral or cell-mediated immunity and they can do this in several ways. First, antigen processing can be modulated, leading to vaccines that can elicit both helper T cells and cytotoxic lymphocytes (CTLs) (reviewed in Refs. [16–18]). Second, depending upon the adjuvant, the immune response can be modulated in favor of type 1 or type 2 immune responses [16,17,19]. For example, complete Freund’s adjuvant and the QS-21 adjuvant can elicit DTH and MHC class I CTL responses when mixed with protein antigens, peptides, or inactivated viruses [20]. Many other adjuvants, such as aluminum salts [19] and nonionic block polymers [3] elicit principally antibody responses when combined with protein antigens or inactivated organisms, perhaps by activating APCs by an IL-4-dependent mechanism [21]. Third, adjuvants can modulate the immune response by preferentially stimulating Th1 or Th2 CD4<sup>+</sup> T-helper cells [22]. The Th1 response is accompanied by secretion of interleukin-2 (IL-2), interferon-gamma (IFN-γ), and TNF-β leading to a CMI response, including activation of macrophages and CTLs and high levels of IgG2a antibodies in mice. The Th2 response is modulated by secretion of IL-4, IL-5, IL-6, and IL-10, which provide better help for B-cell responses, including those of IgG1, IgE, and IgA isotypes in mice. Aluminum salts principally stimulate the Th2 response [23], whereas the Th1 response is stimulated by many adjuvants, such as muramyl dipeptide, monophosphoryl lipid A, and QS-21 [16,24,25].

Vaccine adjuvants can modulate antibody avidity, specificity, quantity, isotype, and subclass against epitopes on complex immunogens [26–29]. For example, only certain adjuvants, vehicles, and adjuvant formulations can induce the development of the protective IgG2a antibody isotype against *Plasmodium yoelii* [28]. The ability of adjuvants to influence so many parameters of the immune response greatly complicates the process of finding an effective adjuvant, because our knowledge of how any one adjuvant operates on a cellular level is insufficient to support a completely rational approach for matching the vaccine antigen with the proper adjuvant. Consequently, many investigators advocate an empirical approach for antigen selection based on the balance between toxicity and adjuvanticity in animals. Unfortunately, no validated animal models exist that can substitute for comparing adjuvants directly in humans [30,31]. Decades of experimental studies in laboratory mammals have shown that successful predictions about the safety, potency, or efficacy in humans of a

particular adjuvant cannot be reliably made in these models. The effect of adjuvants are modulated strongly by 1) the nature and dose of the immunogen; 2) the nature and dose of the adjuvant, carrier, or vehicle in the formulation; 3) the stability of the formulation; 4) the immunization schedule; 5) the route of administration; 6) the species of animal; and 7) the genetic and other biological variations within species, including their immune status.

## III. SAFETY

During the past 75 years many adjuvants have been developed, but they were never accepted for routine vaccination because of their immediate toxicity and fear of delayed side effects. The current attitude regarding risk benefits of vaccination favors safety over efficacy when a vaccine is given to a healthy population of children and adults. In high-risk groups, including patients with cancer and AIDS, and for therapeutic vaccines an additional level of toxicity may be acceptable if the benefit of the vaccine was substantial. Unfortunately, the absolute safety of adjuvanted vaccines, or any vaccine, cannot be guaranteed, so the risks must be minimized. Undesirable reactions can be grouped as either local or systemic.

The most frequent local adverse effects are tenderness and swelling, with the most severe ones involving the formation of painful abscesses and nodules at the inoculum site. The mechanisms for such severe local reactions include the following: 1) contamination of the vaccine at the time of formulation with reactogenic chemicals and microbial products; 2) instability of the vaccine on storage with breakdown into reactogenic side products; 3) formation of inflammatory immune complexes at the inoculation site by combination of the adjuvanted vaccine with preexisting antibodies resulting in an Arthus-type reaction; and 4) poor biodegradability of the adjuvanted vaccine resulting in prolonged persistence in the tissues and reactive granuloma formation. Such local reactions are of special concern for depot-type adjuvants, such as aluminum salts, oil emulsions, liposomes, biodegradable polymer microspheres, and living vectors such as BCG.

Severe local reactions in humans followed subcutaneous injections of incomplete Freund’s adjuvant (IFA), a mineral oil emulsion, using early formulations made with a manmade monooleate stabilizer that contained free fatty acid impurities. However, these lesions did not occur with IFA injected intramuscularly and that contained the stabilizer without impurities (reviewed in Refs. [30,32]). IFA has been administered to more than a million people worldwide [32–35]. Despite the apparent long-term safety of this adjuvant [36], the risk/benefit ratio is felt to be too high for commercial use.

To date, vaccine adjuvants have caused few severe acute systemic adverse effects. More theoretical risks include the induction of autoimmunity or cancer. Fortunately, in 10-, 18-, and 35-year follow-up studies, the incidence of cancer and autoimmune and collagen disorders in 18,000 persons who received oil-emulsion influenza vaccine in the early 1950s was not different from that in persons given aqueous

vaccines [33,36–38]. It requires decades of expensive and time-consuming follow-up for such low-incidence reactions to be identified, and, at present, a mechanism for the systematic, active follow-up of vaccinees given experimental adjuvants is not available [39]. Anterior chamber uveitis has been reported with *N*-acetylmuramyl-L-alanyl-D-isoglutamine (MDP) and several MDP analogues in rabbits [40] and monkeys [41], and has been systematically sought in at least one adjuvant vaccine study involving 110 volunteers, but it was not found there [42]. Adjuvant-associated arthritis [43,44] has not been reported in humans, even after long-term follow-up [34,36,45]. Anaphylactic reactions, angioedema, urticaria, and vasculitis have been described following the administration of the majority of vaccines, although severe events are rare [31]. Finally, a syndrome known as macrophagic myofasciitis (MMF), characterized by diffuse arthromyalgias and fatigue in connection with muscle infiltration by macrophages and lymphocytes, was recently linked to alum-containing vaccinations in France [46], although a causal association has not been established.

#### IV. REGULATORY ISSUES

In concert with the progress of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH), worldwide regulatory guidance on the development and testing of vaccines has expanded significantly in the last few years. Documents covering nearly every aspect of drug and biological development are being created and revised in an effort to enhance and standardize the quality, safety, and efficacy of pharmaceutical products (<http://www.ich.org>, <http://www.fda.gov/cber/guidelines.htm>, <http://www.emea.eu.int>). However, advice directed specifically at the development of adjuvants is lacking. It is important to note that as a rule adjuvants are not licensed on their own. Because each combination of one or more antigens with an adjuvant has its own unique safety and efficacy profile, they are licensed and regulated as individual products in combination.

#### V. EXPERIMENTAL ADJUVANTS IN HUMANS

The number of commercially feasible adjuvants tested in animals and humans (Table 1) is too large to review in this short chapter. Instead, a smaller number of modern adjuvants or adjuvant formulations used to enhance a variety of experimental vaccines in humans (Table 2) will be considered. The development of experimental adjuvants has been driven principally by the failure of aluminum compounds to 1) enhance many vaccines in man [32], 2) enhance subunit vaccine antigens in animals [30,47,48], and 3) to stimulate cytotoxic T-cell responses [19]. In many instances, several adjuvants have been combined in one adjuvant formulation hoping to obtain a synergistic or additive effect.

##### A. Emulsion-Based Formulations

Two basic concepts have emerged in the manufacture of aqueous and oil combinations that describe the dispersion of

one liquid as particles within a second liquid that is continuous [49]. Surfactants, which are compounds that contain both polar and nonpolar groups, are added to stabilize the emulsions. Their hydrophilic/lipophilic balance determines the state of the emulsion that forms. Water-in-oil (W/O) emulsions that Freund used were initially very unstable and viscous and caused strong local reactions, yet they are very efficient at inducing an immune response to weak antigens. Newer oils and surfactants are now used that allow the development of stable fluid emulsions that are safer [49].

Mineral oils in W/O emulsions, such as IFA, stay at the injection site and are slowly eliminated by macrophages or metabolized to fatty acids, triglycerides, phospholipids, or sterols [50]. Protein antigens are released very slowly from this matrix. Proprietary, highly refined emulsifiers from the mannide monooleate family in a natural metabolizable oil solution were developed by SEPPIC (Paris, France), named Montanide ISA 51 and ISA 720. Both Montanide adjuvants induce a strong immune response, but severe local reactions may limit their use.

Oil-in-water (O/W) preparations containing small particles of oil dispersed in an aqueous continuous phase are more easily cleared from the injection site. The droplets with antigen can be endocytosed by APCs or readily pass from the injection site to lymphatics [51]. A major part of the effort to develop immunostimulators as vaccine adjuvants has been devoted to the characterization of mycobacterial cell wall components and their analogues as additions to these preparations [32,52,53]. The most studied component of the cell wall has been the muramyl dipeptide, MDP. Three promising derivatives of MDP were developed because of MDP's residual toxicity and pyrogenicity; they include a butyl-ester derivative (Murabutide<sup>TM</sup>) [54,55], threonyl-MDP [56,57], and muramyl tripeptide dipalmitoyl phosphatidylethanolamine (MTP-PE) [48,57]. Because MDP in water provides only a modest adjuvant effect in mice [58,59] and in humans [54], threonyl-MDP and MTP-PE have been administered in oil emulsion vehicles in attempts to improve potency.

The Syntex adjuvant formulation (SAF) preparation (Syntex Research, Palo Alto, CA) is an oil-in-water emulsion vehicle. The vehicle contains 5% squalane, 2.5% Pluronic<sup>®</sup> L121, and 0.2% polysorbate 80 (Tween<sup>®</sup> 80) in phosphate-buffered saline, pH 7.4 [14,51]. Squalane, used in several modern adjuvant emulsions, is a metabolizable oil used in many over-the-counter drugs and cosmetics. Pluronic<sup>®</sup> 121 is a nonionic block copolymer discussed below. SAF elicits both cell-mediated (lymphocyte blastogenic) and humoral responses. MTP-PE, which is often added to SAF, probably acts by inducing immunoregulatory cytokines, whereas the emulsion vehicle and Pluronic<sup>®</sup> L121 facilitate presentation of antigens to responding lymphocytes. In humans, SAF and SAF + threonyl-MDP have been compared to other adjuvanted HIV gp120 vaccines; the results showed SAF preparations to be immunogenic but highly reactogenic.

In addition to the inclusion of MF-59 in various experimental and licensed vaccines in Europe [57,60–62], several other oil-in-water emulsions are under development by SmithKline Beecham in Rixensart, Belgium. AS02 (formerly known as SBAS2) is a proprietary O/W emulsion containing

**Table 2** Selected Clinical Trials of Experimental Adjuvanted Vaccines

Vaccine	Vehicle, adjuvant, or formulation	Vaccine	Vehicle, adjuvant, or formulation
<b>Viral</b>		<b>Parasitic</b>	
HIV-1 env2-3	MTP-PE/squalene emulsion [15] MTP-PE/MF59 [124]	Leishmania peptides Inactivated <i>L. major</i> Malaria CS, RTS,S	MDP (Murabutide®) [150] BCG bacteria [151,152] Interferon-alpha [117,153] Interferon-gamma [117] DETOX™ [12,84] MPL®/liposomes + alum [13,154] MPL® + alum [87] QS-21 + alum [155] AS02 [63,64]
HIV-1 gp120/gp160	Alum [125] MF59 + MDP-PE, MTP-PE [126,127] MF59 ± Alum [60] SAF + threonyl-MDP, QS-21, MPL®, Liposome/MPL ± alum [42]		
HIV p17/p24	Ty-VLP [128]

<i>S. pyogenes</i> M prot.	MDP (Murabutide®) [147]	Antifertility hCG peptide	Nor-MDP/squalene [164,165]
<i>Borrelia</i> OspA	Alum [148] rBCG [149]		
<i>S. pneumoniae</i>	MPL ± alum [78]		

monophosphoryl lipid A (MPL®) and QS-21 that causes strong antibody responses as well as Th1 and CTL cellular responses. Phase 1/2 studies have been conducted in malaria, most recently with RTS,S, a circumsporozoite (CS) subunit antigen fused to the hepatitis S antigen [63]. RTS,S with AS02 demonstrated efficacy in a Phase 2b field trial in the Gambia [64]. Similar emulsions have been studied with human papilloma virus (HPV)-induced genital warts in a therapeutic setting [65], with hepatitis BsAg [66], and with multiple HIV vaccine formulations [67].

### B. Monophosphoryl Lipid A (MPL®)

The adjuvant effect of lipopolysaccharide (LPS) was described in 1956 [68]. Most of the adjuvanticity and toxicity of LPS are associated with the lipid A region of the molecule [69]. The LPS of *Salmonella minnesota* R595 has been detoxified without destroying its adjuvant activity by exposing the LPS to mild hydrolytic treatment [70]. The resultant monophosphoryl derivative of lipid A, called MPL® by

Corixa Corporation (Hamilton, MT), is a highly adaptable molecule that can be used effectively in many adjuvant formulations [24,71]. Such formulations include antigen in saline [72], oil-in-water emulsions [72,73], aluminum salts (a combination also called AS04) [66,74], and in liposomes [13]. The immunopotentiating nature of MPL® may be associated with its capacity to induce cytokines, such as IL-12 [24], IFN-γ, IL-1, and IL-2 in mouse and human macrophages [75,76]. MPL® promotes antigen-specific DTH and a predominant murine IgG2a immunoglobulin response characteristic of TH1 help [77]. Numerous animal and human studies testify to the utility of MPL® as an adjuvant, used alone or combined effectively with other adjuvants and vehicles for capsular polysaccharide, protein, and peptide antigens [24,71,78]. In the past decade, many clinical studies have utilized MPL® or DETOX™ (MPL® plus cell wall skeleton of *Mycobacterium phlei* in a squalane-in-water emulsion vehicle) as vaccine adjuvants in volunteers [12,13,66,67,74,79–92] (Table 2). The DETOX™ adjuvant formulation has been used as therapeutic vaccines for mel-

anoma [80,81], ovarian cancer [82], and breast cancer [83] with modest clinical success.

### C. Exotoxins

The bacterial ADP-ribosylating exotoxins (bAREs) represent a potent group of proteins that have been studied as enteric, nasal, and topical adjuvants for decades, and this category includes both licensed and experimental vaccines. Cholera toxin B subunit is used to enhance the mucosal immune response in a licensed whole-cell cholera vaccine (Dukoral, PowderJect Pharmaceuticals, PLC, Oxford, UK) that contains  $10^{11}$  killed *V. cholerae* O1 organisms including classical and El Tor Inaba and Ogawa strains [93]. The vaccine afforded a high level of protection (85%) against both classical and El Tor strains in the first 6 months [94]. However, the efficacy against El Tor waned by 36 months, particularly in young children [95]. The addition of the cholera toxin B subunit also provides short-lived efficacy (67% at 3 months) against traveler's diarrhea associated with heat-labile toxin (LT) producing enterotoxigenic *E. coli* (ETEC) [93,96].

In addition to its use in a licensed intranasal virosomal influenza vaccine (see earlier), recombinant LT, which is one of the most potent mucosal adjuvants [97], was recently shown to be safe and immunogenic by transcutaneous immunization (TCI) in humans [98]. LT-specific IgG and IgA antibodies were present in both stool and urine, implying the induction of a strong mucosal immune response. The potent activation of epidermal Langerhans cells allows LT to adjuvant the response to a coadministered antigen as well [99]. Serological and antibody-secreting cell (ASC) responses to the LT and the *E. coli* surface antigen CS6 were comparable to those seen following a protective oral challenge, suggesting that TCI can potentially elicit effective immunity similar to natural infection with ETEC [99]. Other groups are using detoxified mutants of LT to explore the potential for oral or nasal vaccination [100–102].

### D. Saponins

Saponins are triterpene glycosides that can be isolated from the bark of the *Quillaja saponaria* Molina tree, a species native to South America [25]. A partially purified saponin, Quil A, has been used widely as an adjuvant in veterinary vaccines [103]. Quil A is a heterogeneous mixture of glycosides. Analysis by HPLC reveals at least 24 peaks that vary in their adjuvanticity and toxicity in mice [104]. Quil A has also been tested extensively as part of immune-stimulating complexes (ISCOMs), which are cage-like, 40-nm particles consisting of antigen, cholesterol, phospholipids, and Quil A [105]. Despite their potent adjuvanticity, ISCOM vaccines have only recently been administered to humans because of the local and systemic toxicity of Quil A in mice [105,106]. An influenza ISCOM vaccine for humans containing a less toxic saponin fraction is under development that shows a strong cellular immune response [107].

QS-21 (Stimulon™) is one of at least 24 structurally distinct triterpene glycosides isolated from Quil A. QS-21 was chosen for development by the Antigenics, Inc. (Fra-

mingham, MA), because it demonstrated the proper balance of low mouse toxicity and maximum adjuvanticity, and it eliminated the problem of lot-to-lot variation characteristic of Quil A. QS-21 is novel in that it can improve the immunogenicity of protein, and polysaccharide antigens [108] in a variety of small animals, dogs, or primates. It also uniquely stimulates both humoral and cell-mediated immunity, including potent class I-restricted cytotoxic T-lymphocyte responses to subunit antigens [109].

### E. Nonionic Block Copolymers

The copolymer adjuvants are simple linear chains or blocks of polymers of hydrophobic polyoxypropylene, flanked by two chains of hydrophilic polyoxyethylene. A large number of copolymer adjuvants have been synthesized by varying the constituent chains [110]. Nonionic block copolymers are currently used commercially in over-the-counter products, including shampoos, mouthwashes, and cosmetics. Copolymers are adhesive molecules that bind antigens to hydrophobic surfaces, such as oil drops or cells [111]. Evidence suggests that proteins bound to copolymer are held firmly in a condensed fashion and retain much of their native B-cell epitope confirmation when presented to macrophages and dendritic cells for immune processing [111]. The activation of complement by contact with the copolymer surface augments the adjuvant effect. A block polymer of ethylene oxide and propylene oxide (Pluronic® L121) has been used in humans as a component of the Syntex adjuvant formulation. Several preparations of block polymers developed by Vaxcel, Inc. (Norcross, GA) are awaiting clinical trial [110,112].

### F. Cytokines

The use of cytokines as vaccine adjuvants has been encouraged by better understanding of cytokine mechanisms and by the commercial availability of recombinant (IFN- $\gamma$ ) and granulocyte-macrophage stimulating factor (GM-CSF). Many cytokines (e.g., IL-3, IL-6, IL-11, GM-CSF) are capable of enhancing various immune responses when administered repeatedly. The cytokines with the greatest potential are those administered in a single dose at or near the time of antigen injection; cytokines administered in this practical way include IFN- $\alpha$ , IFN- $\gamma$ , IL-1, IL-2, IL-12, and GM-CSF. The adjuvant effects of these cytokines in animals or humans have been reviewed in detail [113–115]. Trial results to date have failed to document a strong adjuvant effect for cytokines in humans [116]. It appears that cytokines have not reached their potential, because the in vivo functions of cytokine networks are complex and incompletely understood. A cytokine can enhance, inhibit, or have no effect, depending on the dose, timing, and animal species, and which of these effects predominates is not always predictable [117,118].

### G. Immunostimulatory Oligonucleotides: CpGs

Just as bacterial DNA can activate immune cells, synthetic oligodeoxynucleotides (ODNs) containing unmethylated CpG dinucleotides in particular base contexts (CpG motifs) stimulate the innate immune system to induce protection in

mice and primates [119,120]. Either alone or in combination with a vaccine, they can activate human B cells, DC, and NK cells [121] and trigger an immune cascade that includes the production of cytokines, chemokines, and IgM to protect against infection. CpG ODN are extremely efficient inducers of Th1 immunity and CTLs, and can allow a 10- to 100-fold reduction in the dose of antigen, presumably because of the increased efficiency of antigen presentation by DC [122]. Preliminary reports from human studies indicate safety should be expected in allergenic, cancer, and infectious vaccine applications, even at high doses [123].

## VI. SUMMARY AND CONCLUSION

Every adjuvant has a complex and often multifactorial immunological mechanism, usually poorly understood *in vivo*. Adjuvant safety, including the real and theoretical risks of administering vaccine adjuvants to humans, is a critical component that can enhance or retard vaccine development. In addition to the problem of safety, at least four other issues impede the orderly development of adjuvanted vaccines. These include inconsistent immunopotentiation by candidate adjuvants, the unreliability of reference aluminum adjuvants, marked variation in response to the same adjuvant by different animal models, and the inability to consistently predict protective efficacy by immunoassays.

The most studied experimental adjuvants in man include aluminum compounds, oil-based emulsions with or without muramyl dipeptide, monophosphoryl (detoxified) lipid A, the triterpene glycoside QS-21, nonionic block copolymers, and several cytokines. In preclinical studies of adjuvants and vaccines, the same adjuvant can enhance, inhibit, or have no effect at all. The more important determinants of immunogenicity include the nature and dose of the immunogen, the stability of the adjuvant formulation, the schedule and route of immunization, and the animal species and strain studied. In addition to immunological enhancement without toxicity and successful protection against challenge, choice of adjuvant for a clinical trial may depend upon cost and commercial availability. Future vaccine development will focus increasingly on unique synthetic antigen constructs, DNA, and live-vector vaccines to avoid administration of extraneous chemical or biological adjuvants to humans. Until those are broadly available, the rational development of classical and novel adjuvants will continue to be one of the most important challenges for the vaccinologist.

## MF59 Adjuvant Emulsion

**Audino Podda and Giuseppe Del Giudice**

*Chiron S.r.l., Siena, Italy*

### I. INTRODUCTION

Most of the existing vaccines share two general characteristics; with very few exceptions, they are parenterally administered. In addition, they are formulated together with adjuvants with the aim of enhancing their immunogenicity. The need for the use of adjuvants is particularly evident for highly purified recombinant or subunit antigens, which are generally very poorly immunogenic when delivered as such. Adjuvants can significantly influence the outcome of the immune response to vaccine molecules, both quantitatively and qualitatively. As a consequence, the use of inappropriate adjuvants may adversely affect the development of new vaccines either by the conventional approach to antigen selection or by the emerging genomic approach [1].

Major efforts have been made in the past decades to develop new vaccine adjuvants; a very long list of adjuvants has been proposed and several of them have even been tested in humans in association with a variety of vaccines or vaccine candidates [2]. Despite all these efforts, aluminum salts, the first vaccine adjuvants introduced during the 1920s, remain the standard adjuvants admitted worldwide for human use. Several reasons have determined this negative outcome in adjuvant research. For sure, safety has represented one of the major limiting factors in the introduction of new adjuvants. On the other hand, not all adjuvants are equally effective for all vaccine constructs. For example, it is well known that aluminum salts fail to exert appropriate adjuvanticity for influenza vaccines, for some Hib conjugate vaccines, and for some recombinant antigens and synthetic peptides [2].

In 1997, the MF59 adjuvant emulsion was the first new adjuvant to be licensed for human use 70 years after the introduction of aluminum salts and remains the only adjuvant licensed for human use in addition to alum. MF59 was licensed after the successful outcome of a long-lasting pre-clinical experience and an extensive clinical testing that yielded a database of more than 20,000 subjects, 12,000 of which were immunized with one or more doses of the influenza adjuvanted vaccine. Today MF59 is licensed in most European countries and its safety has been supported

by more than ten million doses of vaccine distributed so far. In this chapter, we will briefly summarize the characteristics of the MF59 adjuvant; we will go through the animal testing with various vaccines and comment on the immune response induced; finally, we will give some details on the extensive clinical experience not only with the licensed influenza vaccine, but also with other investigational vaccines, safely and efficiently tested in different age groups.

### II. THE MF59 ADJUVANT

MF59 is an oil-in-water emulsion consisting of small (< 250 nm in diameter), uniform, and stable microparticles made by a drop of oil surrounded by a coat of water droplets held onto the oil by surface detergents. The oil is the natural and fully metabolizable squalene. This oil is obtained from shark liver and is also found in humans as a natural metabolite of cholesterol and is a normal component of cell membranes. Squalene droplets are stabilized by addition of two emulsifiers, a water-soluble surfactant, the polyoxyethylene sorbitan monoleate (Tween 80), and an oil-soluble surfactant, sorbitan trioleate (Span 85) [3].

For manufacturing of stable and uniform emulsions, a key point is to keep the number of large particles down to a minimum because large particles act as nucleation sites for further aggregation during storage, potentially leading to phase separation. Indeed, emulsions tend to be thermodynamically unstable systems, subject to flocculation and coalescence during storage. For MF59, the reduction in the number of large particles is achieved by microfluidization and filtration of the emulsion through a 0.22- $\mu\text{m}$  membrane. This procedure removes 99.5% of particles larger than 1.2  $\mu\text{m}$ , so that particles of this size are < 0.1% in the final bulk. The mean particle size, the squalene concentration, and the pH remain unchanged from initial values for at least 3 years at 4°C, providing an excellent stability to vaccine formulations adjuvanted with MF59. Importantly, the number of large particle per milliliter of MF59 also remained stably very low during the same period of time.

A wide variety of vaccine antigens have been formulated with MF59, either premixed in a single container or in separate vials to be mixed just before use. It is interesting to note that antigens successfully formulated in a single container with MF59 can have quite diverse physical-chemical characteristics. Some are fully soluble antigens, such as the HSV-2 gD protein; others are hydrophobic, representing proteins with an intrinsic ability to self-associate or to associate with lipid bilayers or emulsions, such as the influenza HA. Finally, other proteins are particulate antigens, such as HBsAg containing the preS region. All this shows the large versatility of the MF59 as a stable vaccine adjuvant.

### III. MECHANISM OF ADJUVANTICITY OF MF59 AND QUALITY OF IMMUNE RESPONSE INDUCED

Although vaccine adjuvants have been used for more than 70 years, very little is known on the exact mechanisms behind their biological effect. The depot effect postulated for aluminum salts and other adjuvants cannot explain, by itself, all the immunological phenomena that are triggered by vaccine adjuvants, and that bring the activation and recruitment of professional antigen-presenting cells (APC), which, in turn, induce the activation and expansion of antigen-specific T cell and then B cell populations.

During the past few years, a big explosion of research has been experienced in the field of innate immunity [4]. This has brought the recognition of several molecules and their relevant ligands important in the first line of defense against invading microorganisms. These findings are turning out to be instrumental in the understanding of the mechanisms of adjuvanticity of several substances, mainly those derived from bacterial components. The family of the Toll-like receptors (TLR), first described in *Drosophila*, is emerging as a key player in the delivery of initial signals not only by invading pathogens, but also by some of their ingredients, which can be used as vaccine adjuvants. Activation of cells by lipopolysaccharides (LPS) requires the presence on APC of an intact TLR4: This will induce the expression of inflammatory cytokines and of costimulatory molecules [5]. In addition to LPS, TLR4 is also implicated in the recognition of the heat shock protein of 60 kDa (hsp60) [6] and of lipoteichoic acid [7], which have been known for a while for their adjuvant activity [2]. By forming heterodimers with TLR1 and TLR6, TLR2 recognizes several microbial components, such as peptidoglycan, bacterial lipoproteins, and zymosan [8,9]. It is likely that the strong adjuvant activity of complete Freund's adjuvant, which contains mycobacteria, and of monophosphoryl lipid A (MPL), derived from the bacterial cell wall, may be at least partly explained by the interaction with TLR2. Finally, the strong immunostimulatory effect of unmethylated CpG DNA oligonucleotides, which leads to the strong induction of Th1-type response, has been shown to be mediated by a specific recognition of TLR9 by these motifs [10]. This leads to the activation of macrophages and dendritic cells (DC), upregulation of major histocompatibility complex (MHC) class I molecules and of costimulatory molecules, and to the production of pro-inflammatory (Th1-type) cytokines.

The MF59 does not contain any microbial component. Thus there is no indication that its mechanism(s) of action may be mediated by interactions with Toll-like receptors. The fine mechanisms of MF59 adjuvanticity are still unknown. Studies conducted with fluorescent-labeled MF59 have shown that 4 hr after intramuscular (i.m.) administration, 36% of the injected adjuvant was in the muscle and that the peak of localization in the draining lymph nodes was maximal 2 days after injection. It is noteworthy that the presence of the adjuvant did not influence the distribution of the coadministered antigen (HSV-2 gD), which was cleared from the site of injection independently of MF59. Using the same technology, it was shown that 2 days after i.m. injection, MF59 localized inside cells that had all the characteristics of APC, mainly of mature macrophages. Administration of MF59 clearly induced a significant influx of macrophages at the site of injection, which was significantly suppressed in mice deficient for the chemokine receptor 2 (CCR2) [11,12].

Irrespective of its mechanism(s) of action, the available data strongly support the notion that MF59 predominantly induces Th2-type immune responses, as evidenced by the immunoglobulin isotypes and by the cytokines induced after immunization in mice. Indeed, mice immunized with MF59-adjuvanted influenza vaccine exhibited significant increase in the levels of IL-5 and IL-6 (but not of IFN- $\gamma$ ) [13,14], which peaked already 3–12 hr after immunization [13]. A more pronounced IL-4 and IL-5 induction was also observed in mice immunized with the HSV-2 gD2 antigen given together with MF59 [15]. In agreement with the cytokine data, mouse receiving MF59-adjuvanted flu vaccine [14], HSV-2 gD2 antigen [15], or *Neisseria meningitidis* outer membrane proteins [16] produced higher titers of antigen-specific IgG1 than IgG2a. An in-depth knowledge of the mechanism(s) behind the adjuvanticity of MF59 will shed light on the propensity of this adjuvant to preferentially induce Th2-type immune responses.

### IV. THE PRECLINICAL EXPERIENCE WITH MF59-ADJUVANTED VACCINES

MF59 has been utilized by several groups, both inside and outside Chiron Corporation, to evaluate the enhancement of the immunogenicity and of the efficacy of several vaccine constructs in various animal models. In several cases, as with influenza vaccine, HSV-2 antigens, human immunodeficiency virus (HIV) antigens, hepatitis C virus (HCV) antigens, etc., these studies have been instrumental to move to clinical studies in humans. The clinical experience with MF59 is now so wide, also in consideration of the existence of licensed MF59-adjuvanted vaccines, that we will only give an overview of the preclinical experience with this adjuvant limited to a few model vaccines to give more emphasis to the clinical studies at all ages, from elderly people to newborns, which have confirmed in humans some of the findings obtained in animals. Those readers interested in a detailed description of the animal studies performed with MF59-adjuvanted vaccines and appeared in literature up to now (Spring 2002) are referred to in Table 1, which provides an almost comprehensive list of the published papers.

**Table 1** Summary of the Major Studies Carried Out in Animals with Immunogens Adjuvanted with MF59

Microorganism	Antigen(s)	Animal species	Comments	Ref.
HSV-2	gD2 gB2, gD2	Hartley guinea pigs NZW rabbits	Therapeutic efficacy of the vaccine against recurrent genital disease. Periodocular (subconjunctival) therapeutic immunization in HSV-1-infected rabbits induces an 8–60-fold increase in antibody titers and reduction of viral shedding.	[23] [25]
	gD1, gD2	NZW rabbits	Therapeutic efficacy with reduced recurrence of herpetic keratitis after periocular immunization. With gD1 reduced viral shedding.	[28]
	gB2, gD2	NZW rabbits	Prophylactic efficacy against HSV-1 infection (conjunctivitis, iritis) after periocular, but not after systemic immunization.	[27]
	gB2, gD2	NZW rabbits	Therapeutic efficacy after periocular, but not after systemic immunization: less viral shedding and specific IgA in the tears.	[26]
Influenza virus	gd2 gd2 gd2 Subunit vaccine Split vaccine	BALB/c mice BALB/c mice Hartley guinea pigs BALB/c mice BALB/c mice, Syrian hamsters, Hartley guinea pigs, NZW rabbits, Beagle dogs, goats	More pronounced Th2-type immune response than PLG High serum IgG titers and high neutralizing antibody titers Protection against intravaginal challenge Pronounced Th2-type profile of serum cytokines Very strong enhancement of the antibody response. Tested with and without MTP, which gives little increase in antibody response.	[15] [57] [24] [13] [17]
HIV-1	gp120	BALB/c mice BALB/c mice Chimpanzees	Significant enhancement of the antibody response in old mice, and in old mice previously infected with influenza virus. Pronounced Th2-type immune response.	[14]
	gp120	BALB/c mice BALB/c mice Chimpanzees	Protection against intranasal challenge, long-lasting Intranasal administration for priming and boosting One animal fully protected against homologous challenge. The other animal with transient infection.	[18] [58] [29]
	gp120	Chimpanzees	After priming with adenovirus and boost with MF59, three out of four animals had neutralizing antibodies and were protected. Antibodies and protection persisted.	[30]
	gp120	Rhesus monkeys Rhesus monkeys	Heterologous boosting does not protect. Three out of four with full protection against challenge with SHIV. In the fourth monkey, transient infection.	[59] [31]
HBV	gp120, p24 HbsAg + preS2	BALB/c mice, baboons Baboons	Together with PLG, enhancement of antibody and cellular responses. Stronger and faster induction of protective antibody titers (>10 mIU/mL) that alum adjuvanted vaccine and than commercially available vaccines	[60] [19]
HCV	E1–E2	Chimpanzees	Full protection against homologous challenge with the highest antibody titers, or milder disease	[20]
HPV-16b	E7	DBA/2, BALB/c mice	Induction of specific CD8+ CTL similar to that achieved with vaccinia virus	[61]
HPV-6b	VLPs	BALB/c mice	Strong serum IgG response.	[62]
<i>H. influenzae</i> b, <i>N. meningitidis</i> C	Conjugate vaccine (oligosaccharide + CRM197)	Baboons	In 1–4 months old animals, 7-fold enhancement of the antibody response and 5–10-fold increase of bactericidal antibody titers. Induction of strong B cell memory	[32]
<i>N. meningitidis</i>	Outer membrane complexes	BALB/c mice	Enhancement of IgG antibody and of bactericidal antibody titers.	[16]
<i>E. coli</i>	FimH adhesin	Cynomolgus monkeys	After bladder challenge, three out of four protected against bacteruria and pyuria.	[34]
<i>Plasmodium falciparum</i>	MSP1	Aotus monkeys	Lower antibody responses than with Freund's; no protection against challenge.	[63]

### A. Influenza Virus

It is commonly accepted that influenza vaccine is mainly recommended for elderly people who are at higher risk of contracting serious and life-threatening complications following influenza infection. Unadjuvanted, split, and subunit vaccines are commonly available. However, there is a general agreement on the need to enhance the immunogenicity and the efficacy of these vaccines, especially at the elderly age when the ability of the immune system to mount strong and efficacious responses generally decreases. It is known that aluminum salts do not work as adjuvants for these vaccines.

A very large experience has been acquired in the past 10 years on the use of MF59 as a strong adjuvant to enhance the immunogenicity of the influenza vaccine in several animal species, including old mice. Indeed, MF59 was proved to strongly enhance the immunogenicity of flu vaccines in mice, hamsters, guinea pigs, dogs, and goats inducing antibody titers 5 to >100 times higher than those obtained in the absence of adjuvants [17]. It is noteworthy that old mice responded very poorly to immunization with a conventional (nonadjuvanted) subunit vaccine, as compared to young, fully immune competent mice. However, when old mice were immunized with the same vaccine admixed together with MF59, antigen-specific antibody titers increased at levels normally encountered in young animals [14]. Importantly, this enhancement of the immune response to the vaccine was not affected by a preexisting immunity to the virus, because post-immunization antibody titers remained high in mice that had been previously infected with a homologous viral strain [14]. These data are of particular importance because vaccination against influenza is routinely carried out every year, and a preexisting immunity can negatively affect the efficacy of subsequent vaccinations. Additional studies very clearly showed that the use of the adjuvant MF59 permitted to decrease the amount of vaccine to be used per dose to induce a strong immune response, to significantly decrease the viral load in the lungs of mice, and to significantly protect against an infectious challenge, even 126 and 200 days post immunization [18].

### B. Hepatitis B Virus and Hepatitis C Virus

A dramatically strong adjuvanticity was exerted by MF59 in baboons for a CHO-derived hepatitis B virus (HBV) vaccine containing the preS2 component [19]. As compared to a similar vaccine adjuvanted with aluminum hydroxide, or with two commercially available vaccines, the MF59-adjuvanted vaccine generated protective levels of antibodies (i.e., >10 mIU/mL) in a larger number of animals, with antibody titers higher than up to 127-fold than those obtained with conventional vaccines. These very high protective antibody titers were still persisting several months after the third immunization. These results have been, then, successfully confirmed in humans vaccinated with the MF59-adjuvanted HBV vaccine (see below).

If vaccines against HBV exist, although their effectiveness can be ameliorated, vaccines against HCV are not available. Using the E1–E2 envelope glycoproteins derived

from an eukaryotic expression system, it was shown that immunization together with MF59 (plus MTP) induced a strong antigen-specific antibody response. The animals with the highest antibody titers were fully protected against an infectious challenge with the homologous virus, whereas the two vaccinated monkeys that became infected exhibited an infection and a disease milder than those observed in control monkeys [20]. It was subsequently shown that such protection could have been mediated by antibodies able to specifically inhibit the binding of the E1 glycoprotein to its cell receptor [21]. This finding was instrumental in the discovery of CD81 as the receptor for HCV [22].

### C. Herpes Simplex Virus and Human Immunodeficiency Virus

The efficacy of MF59-adjuvanted vaccines was also demonstrated in experimental models of infection with herpes simplex virus (HSV) and HIV. Immunization with the gD2 recombinant proteins along with MF59 efficiently protected guinea pigs against recurrent genital disease both therapeutically [23] and prophylactically [24]. In addition, periocular (subconjunctival) immunization of rabbits with gB and gD proteins efficiently prevented HSV-1 infection in the eye (conjunctivitis, iritis) [25–28]. The same procedure exhibited therapeutic efficacy against herpetic keratitis [25–28].

Most of the chimpanzees immunized with recombinant gp120 given with MF59, either as such [29] or as a boost to a primary immunization provided with adenoviruses expressing the gp120 [30], were protected against a challenge with homologous HIV. Similar good levels of protection were achieved in immunized rhesus monkeys subsequently challenged with SHIV [31].

### D. Bacterial Vaccines

An important objective for future vaccines or vaccination strategies will be to anticipate the timing of immunization to confer protection right after birth, mainly for those diseases, such as meningitis, which have a particularly high morbidity during the very first months of life. Using infant baboons as an experimental model, it was shown that MF59 significantly enhanced the protective (bactericidal) antibody response to bacterial capsular polysaccharides of *Haemophilus influenzae* type b and of group C *N. meningitidis*, when they were given as conjugate vaccines [32]. As compared to the conventional alum-adjuvanted vaccines, the vaccine containing MF59 induced five to seven times higher titers of bactericidal antibodies, which still persisted at these high levels 31 weeks after the third immunization.

Uropathogenic *Escherichia coli* is the major cause of urinary tract infections. FimH is an adhesin crucial in the colonization of the urinary bladder mucosa [33]. Immunization of cynomolgus monkeys immunized three times with recombinant FimH plus MF59 induced a strong and sustained antigen-specific antibody response. Very importantly, three out of four monkeys were protected against bacteriuria and pyuria from a challenge with an infectious uropathogenic *E. coli* isolate [34].

## V. CLINICAL EXPERIENCE

Extensive clinical research programs have been carried out for the development of several MF59-adjuvanted vaccines, mostly against viral diseases. The clinical experience spaced across all age groups; depending on the type of vaccine, clinical trials with MF59-adjuvanted vaccines have been performed in elderly subjects, younger adults, adolescents, children, and even newborns in some cases.

### A. Adult Immunization

#### 1. Influenza Virus Vaccine

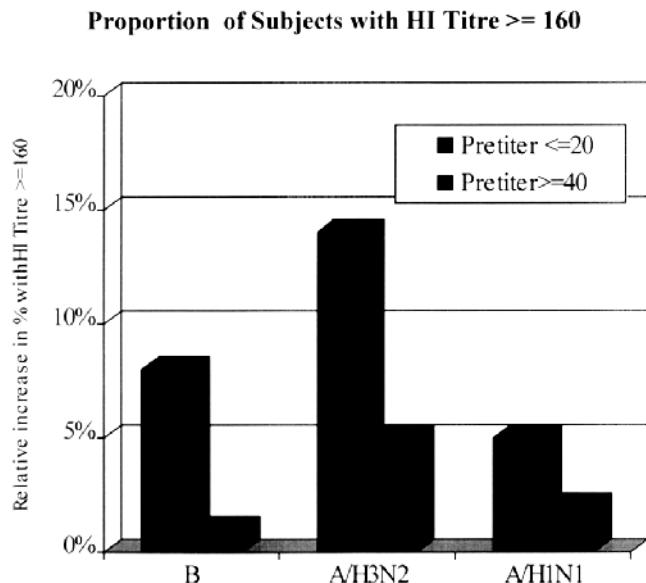

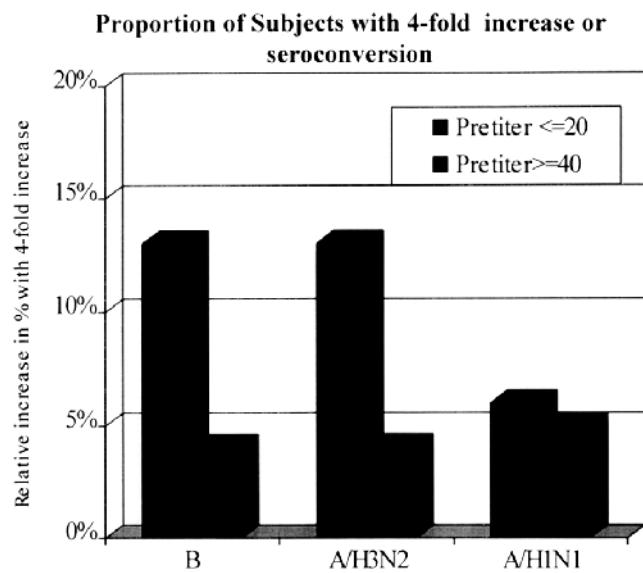

Conventional influenza vaccines are highly effective (70–90%) in young adults, particularly when the vaccine composition closely matches the epidemic influenza strain [35–37]. However, their efficacy considerably drops in elderly subjects. More specifically, conventional vaccines have a limited efficacy to protect the elderly from an influenza infection, as shown in a review of influenza vaccine effectiveness in elderly subjects, which reports a reduction in mortality of 74% and 47% (institutionalized and noninstitutionalized subjects, respectively), but a prevention of clinical illness in only 33% and 5% of the subjects [38]. The reduced immunogenicity of influenza vaccines in elderly subjects [39,40] is one of the factors that might explain the decreased efficacy of conventional influenza vaccines in this age group [38,41,42]. As shown in the preclinical studies, MF59 significantly increases the response to influenza vaccination in aged mice with depressed antibody and cellular immune response, as well as altered cytokine response [3,14]. Therefore the preclinical data and the medical need to

develop more immunogenic vaccines for the elderly have targeted the clinical development of this adjuvanted vaccine for the elderly age group. This is the reason why the great majority of the over 20,000 subjects evaluated in the clinical development program of the MF59-adjuvanted influenza vaccine were elderly subjects [43].

Most of these clinical trials were aimed to compare the safety and immunogenicity of the new vaccine with that of nonadjuvanted conventional vaccines. Influenza vaccines, because of the frequent change in their antigenic composition, are normally administered every year; therefore it is extremely important to evaluate the profile of any new influenza vaccine also after repeated administrations. This approach was followed in the clinical development of the MF59-adjuvanted vaccine whose safety and immunogenicity profiles were evaluated after repeated immunization during three consecutive influenza seasons [44,45].

**Safety.** In elderly subjects, MF59-adjuvanted influenza vaccine is safe and very well tolerated. Because of the presence of the adjuvant, the rates of local adverse reactions, particularly local pain, were increased in the recipients of the MF59 vaccine; however, most of the reactions were mild in nature, of short duration, and qualitatively similar to those induced by control vaccines [43–47]. Additionally, the repeated immunization of elderly subjects with the adjuvanted vaccine across subsequent influenza seasons did not exhibit any increased reactogenicity [44,45]. More clinically relevant adverse events, also monitored during the clinical trials, were rare and quantitatively similar to those induced or temporally associated with control vaccines [43].

**Immunogenicity.** The immune response to immunization was assessed by standard and validated procedures

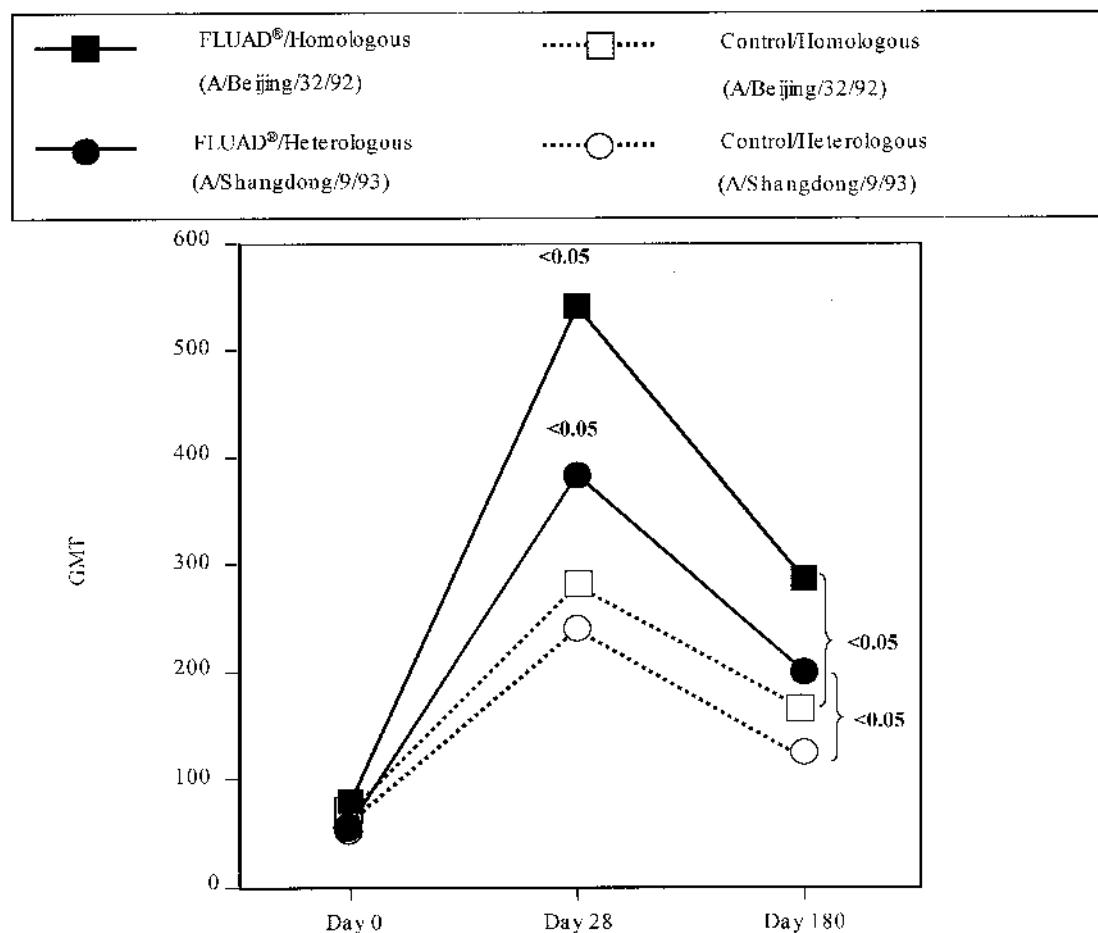

**Figure 1** Increased adjuvant effect in elderly subjects susceptible to influenza. The MF59 adjuvant effect on the immunogenicity of subunit influenza antigens is enhanced in elderly subjects with low preimmunization titer. Both the proportion of subjects with fourfold increase or seroconversion and that of subjects with highly protective postimmunization titers (i.e.,  $\geq 160$ ) are significantly higher in subjects with low preimmunization titers (i.e.,  $\leq 20$ ). (From Ref. 43.)

(haemagglutination inhibition assay), which are known to correlate with clinical protection [48–52]. The statistical analyses were based on several immunogenicity measures, including geometric mean titers and ratios, proportions of subjects with seroconversion and proportions of subjects achieving accepted thresholds of protection [i.e., 40 (PL50) and 160 (PL90)] after immunization [53].

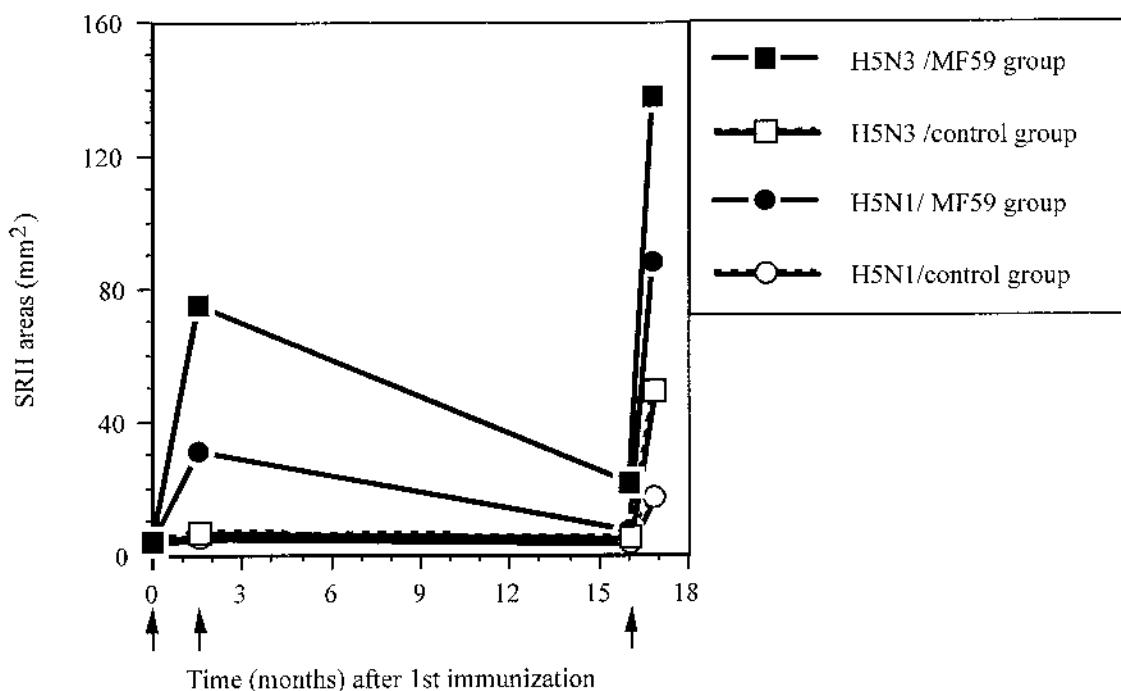

The adjuvant effect of MF59, resulting in an increased immunogenicity compared to conventional vaccines, particularly for the A/H3N2 and B strains, was a consistent finding of clinical trials in elderly [43–47]. This enhanced immunogenicity of MF59-adjuvanted flu vaccines was also observed after repeated immunization [44,45]. Additional analyses were performed and helped to better characterize the immunogenicity profile of the new vaccine. More specifically, the adjuvant effect of MF59 was greater in the subsets of the elderly population, which are more likely to develop influenza and the most serious complications of the disease. As a matter of fact, an increased adjuvant effect was shown in elderly subjects with a low titer of specific antibodies before

immunization (Figure 1) and in subjects affected by chronic underlying conditions, such as respiratory and cardiovascular diseases and/or diabetes mellitus [43]. Another important finding from immunogenicity analyses was the increased immunogenicity against heterovariant strains of influenza viruses. This phenomenon might be important in case of flu outbreaks caused by strains that do not entirely match those included in the vaccine available for immunization [44,45] (Figure 2).

**Influenza Pandemic Vaccines.** The prepandemic alert consequent to the A/H5N1 outbreak in Hong Kong in 1997, prompted public health authorities to focus on pandemic preparedness plans. In these plans, the availability of effective pandemic vaccines is always considered as one of the key tools to be made available to face these potentially catastrophic events. In this context, the role of MF59 as a primary ingredient of a pandemic influenza vaccine was considered and clinically explored. A study performed in young adults, immunized with increasing concentrations of A/H5N3 antigen with and without MF59, clearly showed

**Figure 2** Increased immunogenicity against heterologous influenza strains. The addition of MF59 increases the immune response of subunit influenza antigens not only against the vaccine homologous H3N2 strain (i.e., A/Beijing/32/92), but also against an heterologous H3N2 strain (i.e., A/Shangdong/9/93). The difference between the two vaccines is still significant 6 months after immunization. (From Ref. 45.)

**Figure 3** Increased immunogenicity against potentially pandemic influenza strains. The addition of MF59 dramatically increases the immunogenicity against potentially pandemic influenza strains in naive young volunteers and determines a more potent booster response in subjects previously primed with the same vaccine. (From Ref. 55.)

that conventional nonadjuvanted subunit vaccines are very poorly immunogenic against the homologous vaccine strain A/H5N3 and even less against the heterologous wild A/H5N1 Hong Kong strain [54]. By contrast, the addition of MF59 elicited high titers of protective antibodies, even with a reduced antigen concentration (7.5 µg/dose in a two-dose schedule) [54]. A second trial demonstrated that a primary immunization with a MF59 vaccine not only allows a better priming, but also determines a longer persistence of protective antibody titers and a better booster response up to 16 months after the primary immunization [55] (Figure 3). In light of the expected severe consequences of an influenza pandemic, these data are very relevant and underline the major role that an innovative adjuvant like MF59 can play in a public health emergency in terms of both increased clinical protection and greater availability of vaccine doses.

## 2. Hepatitis B Virus Vaccine

Safe and immunogenic vaccines for the prevention of hepatitis B are already available. However, also in this case, there is the need for improvement, particularly with regard to the schedule of immunization, currently requiring three doses at 0, 1, and 6 months, and to the immunogenicity of the vaccine in some high-risk populations, who should be offered an earlier and more complete protection. Because of the very promising preclinical data obtained in baboons [19] with a PreS2 + S hepatitis virus vaccine, produced in CHO cells and adjuvanted with MF59, this vaccine has also been evaluated in seronegative human healthy volunteers.

Vaccines received either the adjuvanted vaccine or a licensed, alum-based vaccine according to three different immunization schedules (i.e., 0 and 2 months; 0 and 6 months; and 0, 1, and 6 months). Despite a higher rate of local reactions, the adjuvanted vaccine was overall well tolerated. After the first immunization, 89% of recipients of the adjuvanted vaccine had protective (10 mIU/mL) anti HBs antibodies compared to 12% of subjects immunized with the licensed vaccine; additionally, more than 50% had a post-immunization titer 10-fold higher than the protective threshold [56] (Table 2). The geometric mean titer after the first dose was more than 100-fold greater than that of the licensed vaccine. The difference between the two vaccines was still statistically significant 6 months after a single dose

**Table 2** The Addition of MF59 Enhances the Response to HBV Vaccine. A Protective Titer of Anti-HBsAg Antibody (i.e., > 10 mIU/mL) Is Obtained in 89% of the Recipients of MF59 Adjuvanted HBV Vaccine Already After the First Dose Compared to 12% in the Control Group Immunized with an Unadjuvanted HBV Vaccine

Anti-HBs antibody titers (mIU/mL)	HB vaccine + MF59	Comparator
> 10	89%	12%
> 100	52%	6%
> 1000	10%	2%

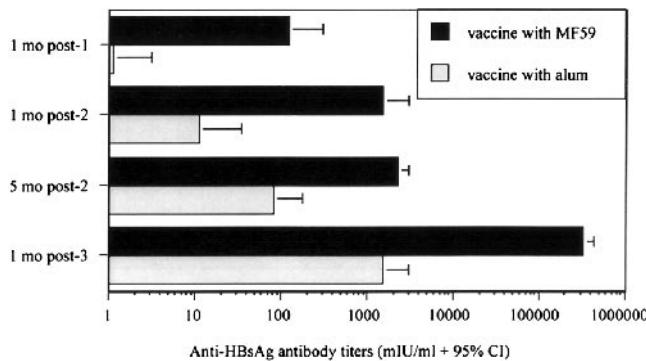

Source: Ref. 56.

in terms of both seroprotection rate (94% versus 69%) and GMT (161 mIU/mL versus 11 mIU/mL) [56]. Antibody responses following the second and third immunizations were still significantly higher in the MF59 group compared to the licensed vaccine (Figure 4). In particular, it was clinically important that all subjects in the MF59 group, after the second dose, regardless of its timing (1, 2, or 6 months after the first dose), had titers 10-fold greater than the protective threshold of 10 mIU/mL. Additionally, two doses of the MF59 vaccine (given at 0 and 1 month) elicited the same level of antibody titers as three doses of the licensed vaccine given at 0, 1, and 6 months [56] (Figure 4). In summary, the clinical experience with the PreS2 + S hepatitis B virus vaccine adjuvanted with MF59 highlights the adjuvant effect of MF59, which, with a very reasonable safety profile, increases the immunogenicity of the vaccine, allows the use of a two-dose schedule over a short period of time, and might be considered for a better prophylaxis of hypo- or nonresponders to the current vaccine.

### 3. Herpes Simplex Virus Vaccine

A very large clinical experience has been acquired with an experimental recombinant HSV vaccine formulated with MF59 adjuvant and given to adult volunteers. The vaccine consists of the two recombinant glycoproteins gD2 and gB2, which represent the target of specific antibodies with neutralizing activity. Three immunizations with these proteins together with MF59 was shown to be very well tolerated. In HSV-seronegative subjects, this vaccine induced specific neutralizing antibody titers and T cells at frequencies equal or higher than those obtained in naturally infected individuals. Also in HSV-seropositive subjects, the antibody response induced by vaccination was higher than that acquired with natural infection [64], suggesting a boosting effect of the vaccine on the immune response primed by the natural infection [65]. Interestingly, intramuscular vaccination also induced high titers of gD2- and gB2-specific IgA and IgG antibodies in the cervical secretions of vaccinated women [66].

Tested in phase III trials in more than 2000 HSV-2-seronegative individuals, this vaccine was shown to reduce

**Figure 4** Increased immunogenicity against HbsAg. The immunogenicity of the MF59-adjuvanted vaccine is significantly higher after each of three doses administered at 0, 1, and 6 months. (From Ref. 56.)

the acquisition rate of HSV-2 by 50% during the first 5 months of the trial, as compared to placebo, but not on the overall follow up of the study. In addition, the vaccine did not influence the duration of the first nor of the subsequent HSV-2 genital episodes [67]. In HSV-2-seropositive individuals, immunization with this vaccine did not affect the frequency of the recurrence of the genital lesions, but significantly reduced the duration and the severity of the first clinically confirmed herpes lesion [65].

## B. Pediatric Immunization

Vaccination early in life can have different advantages over conventional pediatric immunization, including those of reducing morbidity and disease transmission in the first months of life. However, the peculiarities of the neonatal immune system [68] impose the need for particular vaccination strategies acceptably safe and sufficiently strong to induce protective immunity. The MF59 adjuvant has been tested in toddlers and infants using candidate vaccines against cytomegalovirus (CMV) and HIV.

### 1. Cytomegalovirus Vaccine

The safety and immunogenicity of a recombinant CMV gB protein from CHO cells was extensively tested in adult volunteers. Following three immunizations over a period of 6 months, seronegative subjects mounted a strong and sustained antibody response, which was higher than that induced by the same protein formulated with aluminum hydroxide and that commonly found in naturally CMV infected patients [69,70]. Interestingly, lower doses of the vaccine (5–30 µg) induced better responses than higher doses. Furthermore, immunization with this vaccine induced gB-specific mucosal IgG and IgA antibodies [71] and good and sustained production of IFN-γ upon in vitro restimulation of peripheral blood mononuclear cells with the gB protein [72].

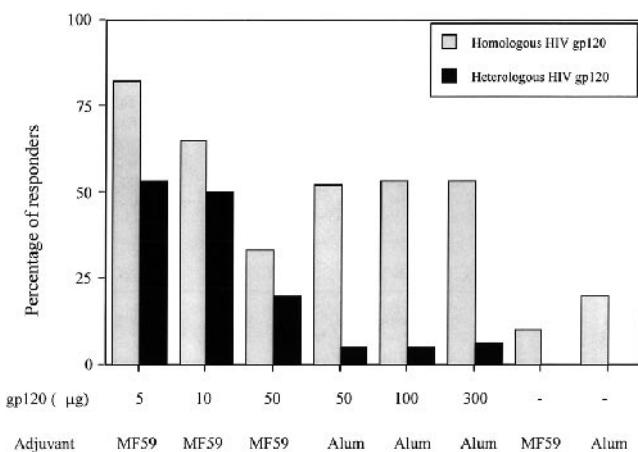

Child-to-child transmission of CMV is very common and children may represent the source of infection for their parents. Thus early vaccination against CMV may contribute to prevent congenital infection. The safety and immunogenicity of the gB recombinant vaccine adjuvanted with MF59 was tested in seronegative toddlers aged between 12 and 35 months [73]. After three doses (20 µg each), the MF59-adjuvanted gB-based vaccine exhibited a very high immunogenicity. Vaccine-specific antibody titers were >100 times higher than those observed after the first dose, at least six times higher than those normally found in the adults immunized with the same vaccine, and higher than those found in adults naturally infected with CMV. Thus such a vaccine may represent a tool to reduce CMV transmission among infants and to reduce congenital CMV by providing maternal immunity against primary maternal infection.

### 2. Human Immunodeficiency Virus

A recombinant HIV vaccine construct consisting of the gp120 from HIV-SF2 adjuvanted with MF59 has been investigated for its safety and immunogenicity in adults before being tested in infants at birth. Indeed, at doses

ranging between 25 and 100 µg and after three doses given over a period of 6 months, followed by one or two booster doses, the MF59-adjuvanted vaccine was very well tolerated, both in adult American and Thai volunteers [74–77]. Moderate to severe side effects were observed only when the formulation contained MTP-PE [75,76]. Interestingly, after three immunizations, all the vaccinated individuals developed strain-specific neutralizing antibodies, and about two-third of them exhibited antibodies that cross-neutralized other HIV strain (e.g., HIV-MN) [74,75,77]. Also, a very strong antigen-specific proliferative response was consistently observed in these trials in adults.

Vaccination against HIV at birth of infants born from HIV-infected mothers may offer the advantage of preventing the infection. However, the presence of maternal antibodies may indeed limit the efficacy of a vaccine given so early. The recombinant gp120-SF2 protein formulated with MF59 was shown to be totally safe when given at doses of 5, 15, or 50 µg at birth (within the first 72 hr of life) and then 4, 12, and 20 weeks later [78]. This vaccination schedule (or even shorter) induced specific antibody responses in 87% of the infants [79]. Interestingly, the MF59-adjuvanted gp120-SF2 vaccine was much stronger than an alum-adjuvanted gp120-MN vaccine in inducing cell proliferative responses when administered at birth [80]. Indeed, very low doses (e.g., 5 µg) of the MF59-adjuvanted vaccine induced strong proliferative responses to the homologous gp120 protein in about 80% of the infants, and in 50% of the infants even to an heterologous protein, thus largely exceeding the results obtained with the alum-adjuvanted vaccine containing the recombinant protein at doses ranging from 30 to 300 µg per dose (Figure 5). These results are in full agreement with those obtained in adults with the pandemic influenza vaccine showing that the use of MF59 as an adjuvant can induce stronger responses with lower doses of the vaccine.

**Figure 5** Increased responses against homologous and heterologous HIV gp120. Percentages of vaccine recipients with positive cell proliferative responses to homologous and heterologous HIV antigens are significantly greater compared to an alum adjuvanted vaccine. (From Ref. 80.)

## VI. CONCLUSIONS

After extensive studies in different preclinical models, MF59, as part of an influenza vaccine, is now one of the few vaccine adjuvants already licensed for human use. Additionally, MF59 is under clinical investigation as adjuvant of several other vaccines, both bacterial and viral. Although currently licensed for use in elderly, the results in toddlers and infant studies with candidate vaccines against CMV and HIV have shown that this adjuvant can be safely used for vaccination also in the youngest age groups. This may pave the way to the neonatal use of vaccines for prevention of infections that peculiarly affect this age (e.g., pertussis) or for prevention of neonatal transmission of pathogens such as CMV and HIV. In addition, the results obtained with the pandemic flu vaccines and with the HIV candidate vaccine clearly show that the use of MF59 can allow a significant reduction of the amount of antigens required to induce strong and protective immune responses; the same data have also shown that a better response is achieved not only against homologous, but also heterologous, strains of the targeted infectious agent. In conclusion, the experience with MF59 suggests that this adjuvant can play an important role to strengthen and broaden the immune response against several pathogens and can be used, with a very good safety profile, in all age groups, from elderly to children and even newborns.

## ACKNOWLEDGMENTS

The authors are grateful to Anne-Marie Duliège for insights on pediatric immunization with MF59-adjuvanted vaccines and to Maria Bernadotte for assistance in manuscript preparation

### I. INTRODUCTION

The goal of vaccination is to provide protection against a particular infection. Vaccines induce protection through a variety of immune mechanisms. Understanding the immune mechanisms, often referred to as “immune correlates of protection,” can facilitate the rational design of vaccines. The humoral immune response through the production of antibodies appears to be the immune correlate by which a majority of current vaccines induce protection, most notably against viral or bacterial infections. For many other infectious diseases, however, the cellular immune response through CD4<sup>+</sup> and CD8<sup>+</sup> T cells is also important for immune protection. Indeed, a major impediment to the development of successful vaccines against HIV, malaria, and *Mycobacterium tuberculosis* infection has been the failure to induce and sustain long-term cellular immune responses sufficient to mediate protection. Thus, in considering vaccine design, especially for the aforementioned infections in which cellular immune responses might be critical in mediating protection, attention should be given not only to maximizing the magnitude of the immune response but also to the qualitative aspects of the immune response.

The immune response can be segregated into two major compartments designated the innate and adaptive immune systems. The innate response relies on immediate recognition of antigenic structures common to many microorganisms by a selected set of immune cells [1–3]. The adaptive immune response is made up of B and T lymphocytes that have unique receptors specific to various microbial antigens.

The goal of vaccination is to enhance the number of antigen-specific B and T cells against a given pathogen sufficient to provide protection following an infectious challenge. Recently, there have been several exciting discoveries showing that the innate immune response has an additional important role in regulating the adaptive immune response, especially the cellular immune response. Innate immune recognition of infectious pathogens is mediated by pattern recognition receptors, called Toll-like receptors [4–6], which are expressed on various cells of the innate immune response including the major antigen-presenting cells (APCs) (macrophages, dendritic cells [DCs], and B cells) responsible for T-cell activation. This innate recognition pathway leads to an increase in APC function that can strongly influence the initial adaptive immune response generated by immunization. These observations of how innate immune responses can affect adaptive immunity have tremendous importance for vaccine design, especially when cellular immune responses are required as discussed below.

T cells comprise a major part of the adaptive immune response. CD4<sup>+</sup> T cells recognize antigens that have been processed through the exogenous pathway by APC expressing MHC class II histocompatibility molecules. CD4<sup>+</sup> T cells become activated, and differentiation can occur into functional subsets termed T helper 1 (Th1)-and T helper 2 (Th2)-type cells. Th1 cells produce the cytokine IFN- $\gamma$ , whereas Th2 cells produce the cytokine IL-4 [7,8]. Th1 cells, through their production of IFN- $\gamma$ , mediate killing for a variety of intracellular infections and will be critical in generating a vaccine against *M. tuberculosis* as well as other intracellular infections. CD8<sup>+</sup> T cells recognize antigens

processed and presented by cells expressing MHC class I molecules and have a critical role in mediating protection in many infections including HIV and malaria. While all currently licensed vaccines (killed/inactivated, whole-cell, recombinant protein, or live attenuated) generate humoral immune responses, a potential shortcoming of nonlive vaccines is their relative inefficiency in generating cellular immune (Th1 or CD8<sup>+</sup> T cell) responses. Although live attenuated vaccines allow for efficient MHC class I presentation of antigen that can stimulate CD8<sup>+</sup> T-cell responses, the use of live attenuated vaccines may be precluded for several intracellular infections due to safety and/or manufacturing concerns.

Together, these findings have prompted investigation into how cellular immune responses can be generated using nonlive antigens. In this regard, there has been a focus on using specific immune adjuvants to induce such responses. At present, aluminum adjuvants (alum) are the only approved adjuvants for use in humans in the United States. Although alum enhances antibody production, it has little effect on influencing cellular immune responses and in fact may facilitate a type of cellular immune response (Th2) that would provide no protective efficacy against intracellular infections [9]. As the cellular and molecular mechanisms of immune activation for both humoral and cellular responses are more clearly understood, it is now possible to use immunomodulators as vaccine adjuvants with a cellular and molecular basis for how they work. The focus of this chapter will be to review how cytokines, costimulatory molecules, and cytosine phosphate guanosine (CpG) oligodeoxynucleotides (ODNs) can be used as vaccine adjuvants to induce long-term humoral and cellular immune responses sufficient to mediate protection against infectious and neoplastic disease.

## II. CYTOKINES AS IMMUNE ADJUVANTS

Much of the early work using cytokines as vaccine adjuvants or treatments in neoplastic disease was done with recombinant proteins delivered systemically. As most cytokines are small proteins with very short half-life in vivo, recent work has focused on using plasmid DNA encoding specific cytokine genes given with DNA encoding an antigen as a potential method to deliver the cytokine to the same site as the antigen. This would potentially mitigate side effects associated with giving high doses of cytokine proteins systemically. In addition, cytokine DNA might allow for more sustained persistence in vivo, albeit at lower levels than what would be achieved by giving cytokine protein. The majority of studies have used plasmid DNA vaccines encoding cytokines codelivered with the DNA encoding the antigen in the same inoculation. This is clearly the most practical regimen for use. One notable exception is the use of a plasmid DNA encoding a fusion protein for IL-2 [10,11]. In this instance, optimal induction of immune responses occurred when the cytokine DNA was given 2 days following DNA encoding the antigen. This might be explained by the kinetics of T-cell activation. The optimal effect of IL-2 would occur once T cells were activated and expressed the IL-2 receptor  $\alpha$  chain.

This might indeed take 1 or 2 days and would explain the importance of the kinetics for this particular cytokine. These data raise an important point: the timing and even the ratio of cytokine to DNA encoding the antigen should be carefully studied in experimental models to determine the best way to administer the vaccine for optimizing an immune response. This information can then be used as the basis to develop a usable and practical regimen in humans.

Cytokines have been shown to be effective immune modulators at several key points within the generation and maintenance of the immune response. First, depending on the type of immune response required, a potentially important issue would be to target the vaccine toward a specific APC. In this regard, cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF) (see Table 1) or FLT-3 ligand [76] have been shown to be potent stimulators of DC and have been used as proteins and/or plasmid DNA as vaccine adjuvants with varying efficacy in mice, primates, and humans. It is important to note that there is substantial heterogeneity in the type and function of DCs that can markedly effect the immune response generated [77]. Thus, while the targeting of DC for vaccination is a burgeoning area of vaccine research for a variety of diseases (infectious, autoimmune, neoplastic), the maturation and specific type of DC is an additional and important consideration when using such a targeted approach. Second, cytokines can act directly on T cells to facilitate T-cell proliferation. IL-2 is the most intensively studied cytokine for clinical use in humans for both infectious and neoplastic diseases and is a potent inducer of both CD4<sup>+</sup> and CD8<sup>+</sup> T-cell proliferation. Recently, IL-15 has been shown to be a critical factor in sustaining CD8<sup>+</sup> memory T cells [78] and is currently being studied as a vaccine adjuvant to enhance the maintenance of CD8<sup>+</sup> T-cell responses. Finally, cytokines can influence the qualitative aspects of the immune response. For CD4<sup>+</sup> Th responses, IL-12 is the most potent inducer of Th1 responses, while IL-4 induces Th2 responses [79,80]. Thus, in instances where the immune correlates of protection are known, it is possible to choose a cytokine regimen to specifically induce the immune response to achieve the desired effect.

A summary of studies using such an approach is shown in Table 1. For CD4<sup>+</sup> T helper responses, coinjection of IFN- $\gamma$ , IL-12-, or IL-18-encoding plasmids has been shown to enhance induction of Th1 responses, while cytokines IL-4, IL-5, IL-10, and IL-13 have generated a predominantly Th2 response. Other cytokines encoding plasmids, such as TGF- $\beta$  and IL-10, have been shown to decrease T-cell proliferative responses and have been used to downregulate the immune response [40,70]. In this regard, IL-10 and TGF- $\beta$  might be useful in vaccines against specific autoimmune diseases in which the goal is to inhibit proinflammatory immune responses or generate T regulatory cells. The use of cytokines to both augment and inhibit immune responses for infections and autoimmune diseases, respectively, raises an important issue. Thus, induction of long-term cellular immune responses required for protection against infection is balanced by the risk of autoimmune disease due to the presence of a persistent cellular immune response. For CD8<sup>+</sup> T-cell

**Table 1** Effects of Cytokine DNA on Humoral and Cellular Immune Response

Cytokine adjuvant	Antibody	Cellular response	CTL	References
IL-1	↑ IgG ↑ IgG2a	↑ CTL ↑ IFN-γ	↑ Proliferation	12–14
IL-2	↑ IgG ↑ IgG2a ↑ IgG1 <sup>a</sup>	↑ Proliferation ↑ IFN-γ	↑ CTL	14–27

responses, a broad array of cytokines (e.g., IL-2, IL-12, IL-15, IL-18, and GM-CSF) have been shown to increase such responses.

### III. COSTIMULATORY MOLECULES AS IMMUNE ADJUVANTS

Initiation of an immune response involves recognition of antigen in the context of MHC class II and class I for activation of CD4<sup>+</sup> and CD8<sup>+</sup> T cells, respectively. In addition, several accessory or costimulatory molecules that exist on T cells and APC allow for enhanced activation and expansion of T-cell responses and can further increase the functional capacity of APCs. Several of these adhesive and costimulatory ligand/receptor molecules have been exploited as potential vaccine adjuvants for both T and APC activation.

The most widely studied costimulatory molecules for plasmid DNA vaccines have been CD80, CD86, and CD40 ligand (Table 2). In the course of initial T-cell activation, CD80 and CD86, through interaction with CD28 on the T cell, augment T-cell activation. Plasmid DNA encoding either CD80 or CD86 has been used with varying efficacy to augment cellular immune responses, notably CD8 responses. Another costimulatory molecule, CD40 ligand, is induced upon T-cell activation and interacts with B cells, DC, and macrophages expressing its cognate ligand CD40. This interaction is critical for both B-cell activation and immunoglobulin (Ig) class switching and enhances DC activation, resulting in upregulation of CD80 and CD86 production of cytokines such as IL-12. Studies using CD40 ligand DNA have demonstrated striking increases in antibody production as well as induction of Th1 responses and enhancement in CTL responses. This immune enhancement fits well with a profile for a vaccine adjuvant to induce a broad immune response that can be used in a variety of

infectious diseases and cancer models. A final approach is to direct antigen directly to APCs to improve immunogenicity. To this end, plasmid encoding a fusion protein of CTLA-4, a ligand for CD80 and CD86 antigen would target the antigen to APCs by binding to CD80 or CD86 on the APC. A brief summary of these studies is provided in Table 2.

### IV. CHEMOKINES

In addition to the exciting developments in understanding the role of cytokines and costimulatory molecules in the immune response and their role in vaccines, a very active area of recent research is the role and function of chemokines and chemokine receptors. Chemokines were initially shown to be important in mediating leukocyte extravasation and navigation (with selectins and integrins). In addition, flexible regulation of chemokine receptors is seen during activation and differentiation of lymphocytes. Thus, chemokines can selectively induce, modulate, and prevent cellular immune interactions and conceivably will find therapeutic application. Several studies using molecules from the chemokine superfamily have shown that codelivery of these chemokines not only modulates immune responses but also impacts protection from disease. Of particular interest is a study using plasmid DNA encoding CCR7 ligands SLC and ELC as immunoregulators [95]. CCR7 is a homing receptor for DC into secondary lymphoid organs. Consequently, provision of SLC and ELC can influence migration of DC into lymphoid tissue and increase the efficiency of immune induction. Data from this study suggest that coimmunization with CCR7 ligands increased antibody production, T-cell-mediated immunity (antigen-specific CD4 T-cell proliferation and CD8 cytolytic activity), and the number of DCs in secondary lymphoid tissues. Table 3 is a brief summary of the immune responses seen in studying the effects of chemokine DNA in vivo.

## V. IMMUNE ENHANCING CpG SEQUENCES

### A. Mechanisms of CpG Sequences and Their Effects on Immune Response

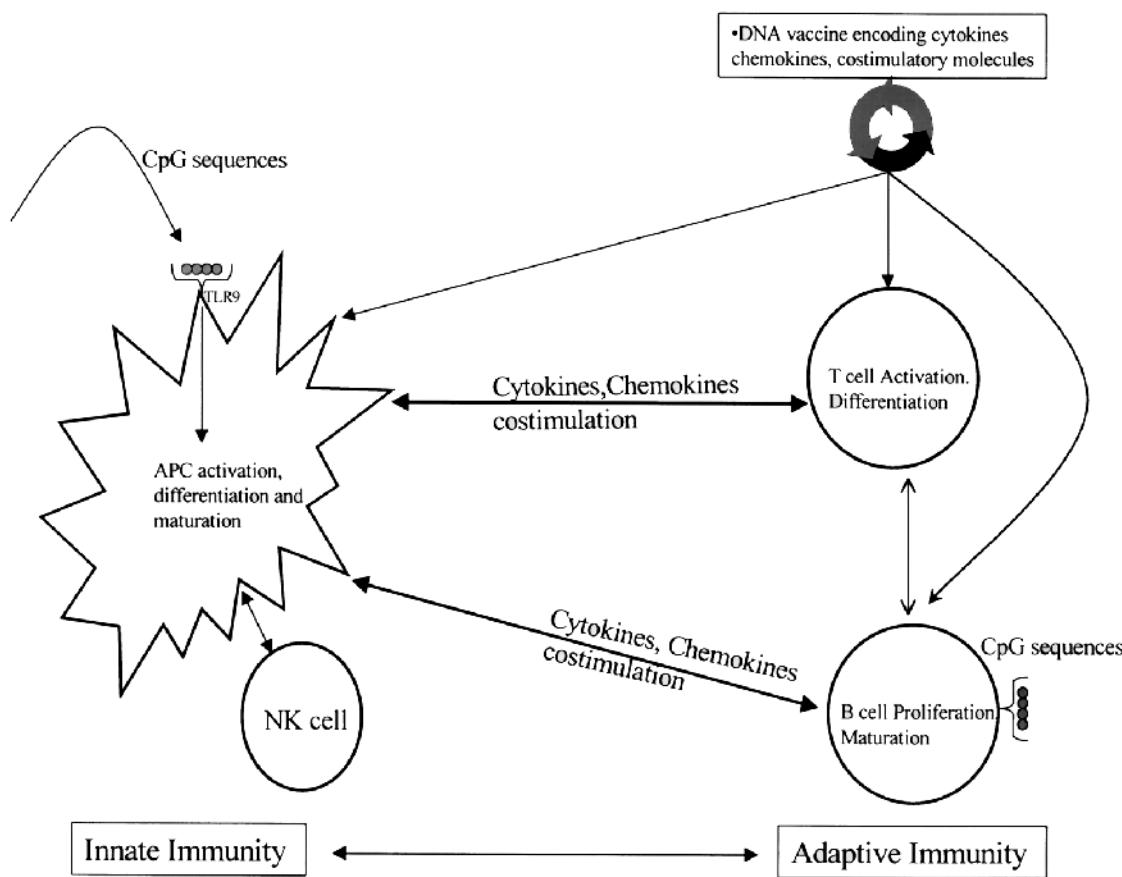

Yamamoto and his colleagues made the seminal observation that synthetic ODNs with sequences patterned after those found in bacterial DNA were immunostimulatory. They reported that purified bacterial DNA and synthetic ODNs expressing palindromic sequences could activate natural killer cells to secrete IFN-γ [104,105]. Subsequently, studies by Krieg et al. and Klinman et al. showed that the critical immunostimulatory motif consisted of an unmethylated CpG dinucleotide with appropriate flanking regions. In mice, this CpG should be flanked by two 5' purines and two 3' pyrimidines [106,107]. Such motifs are 20-fold more common in microbial than mammalian DNA, due to differences in the frequency of use and the methylation pattern of CpG dinucleotides in prokaryotes vs. eukaryotes [108,109].

CpG motifs have been shown to directly activate B cells to proliferate and secrete antibody [106]. CpG ODNs also directly trigger professional APCs (DCs, macrophages) to differentiate, mature, and/or secrete cytokines [107,110,111]. Most recently, Hemmi and his colleagues established that Toll-like receptor 9 is involved in recognition of CpG motifs in mice [112], a finding confirmed for the human response to CpG DNA [113]. As noted above, Toll-like receptors are pattern-recognition receptors that are expressed on various cells including the major APCs (macrophages, DCs). Acti-

vation of APCs via Toll-like receptor 9 has been shown to improve APC function both by enhancing expression of activation and costimulatory molecules on APCs and by induction of proinflammatory cytokines and chemokines such as IL-6, IL-12, tumor necrosis factor alpha (TNF-α), IFN-α, MIP1-β, and MIP-1α [107,114–116]. In turn, these activated APCs can enhance the activity of natural killer cells and induce both Th1 and CTL responses. The enhancement of natural killer and T cells provides a striking example of how CpG ODNs, through their effect on APCs, influence the innate and adaptive immune response, respectively (Figure 1). Together, this broad-based immune enhancement profile has generated considerable interest in harnessing the immunostimulatory properties of CpG motifs for use as vaccine adjuvants for vaccines in which humoral and cellular immune responses are required.

### B. The Role of CpG Motifs in Mediating Immune Responses by DNA Vaccines

Over the past 10 years, a growing body of literature has demonstrated that plasmid DNA vaccination can induce broad cellular immune responses in rodents and nonhuman primates. Early work has shown that some of the potency of DNA vaccines is due to the presence of CpG motifs within the backbone of the plasmid itself. First, these plasmids mimic the ability of bacterial DNA and CpG ODN to stimulate the host immune response [117]. For example, in

**Figure 1** Role of CpG ODN and/or plasmid DNA in linking innate and adaptive immune responses. Innate immune recognition of bacterial DNA or CpG motifs is mediated by Toll-like receptor 9 (TLR9) expressed on APCs (DCs, macrophages, and B cells). Activation through TLR-9 can lead to enhancement in APC function, through secretion of cytokines and chemokines and an increase in costimulatory molecules leading to activation of both natural killer cells and T cells. CpG motifs can also directly stimulate B cells via TLR9 to enhance B-cell activation and antibody production. Plasmid DNA encoding specific cytokines, chemokines, or costimulatory molecule genes can be codelivered with plasmid DNA encoding specific antigens. These immunostimulatory DNA enhance APC function (e.g., GM-CSF, CD40L), T-cell activation (e.g., IL-2, CD80, and CD86), CD4<sup>+</sup> T-cell differentiation (e.g., IL-12, IL-4), B-cell activation (e.g., IL-2, CD40L), and immune cell trafficking (e.g., chemokines).

vitro studies involving murine spleen cells show that bacterial DNA plasmids (with or without protein-encoding inserts) trigger a five-to-eightfold increase in the number of lymphocytes secreting IgM, IL-6, IL-12, and IFN- $\gamma$ . This is similar to the level of immune stimulation elicited by bacterial DNA or CpG ODN. Second, when these CpG motifs in the plasmid backbone are methylated using Sss-I CpG methylase, the plasmid's ability to trigger this cytokine and IgM production is concomitantly reduced [115,117]. Third, the nature of the immune response elicited by coadministration of CpG ODNs and protein antigens is similar to the response elicited by DNA vaccine encoding the same antigen (*in vivo* mimics the pattern induced by a CpG-dominated response) [118–120]. Specifically, DNA vaccines preferentially stimulate the production of antigen-specific IFN- $\gamma$  and IgG2a antibodies. Compared with the response elicited against the same protein in Freund's adjuvant, the levels of IFN- $\gamma$  and IgG2a production induced by a DNA vaccine is

greater than threefold higher, whereas production of IL-4 and IgG1 antibodies may actually be reduced [121].

Based on these findings, researchers examined whether the activity of a DNA vaccine could be improved by increasing the number of CpG motifs present in the plasmid backbone. In this regard, substituting a CpG-containing ampR gene for a kanR-selectable marker in a  $\beta$ -gal-encoding plasmid elicited a higher IgG antibody response, more CTL, and greater IFN- $\gamma$  production than did the original vector [115]. The same effect was observed when CpG motifs were added elsewhere in plasmid backbone by other groups [117,121–126]. In general, adding CpG motifs to a DNA vaccine either increases the magnitude of the resultant *in vivo* response or decreases the amount of vaccine required to induce a significant response [117,121–126]. Further evidence of the contribution of CpG motifs to the immunogenicity of a DNA vaccine derives from studies in which synthetic CpG ODNs were coadministered with DNA plas-

mids. Mice primed and boosted with DNA vaccine plus CpG ODNs developed antigen-specific IgG and IFN- $\gamma$  responses up to an order of magnitude greater than those in animals receiving DNA vaccine alone [117,127]. The magnitude of this CpG effect was greatest when mice were immunized with low doses of DNA vaccine, presumably because CpG motifs in the vector served the same function at high plasmid concentrations. It should also be noted that sequences present in mammalian DNA can block immune activation by bacterial CpG sequences [126]. This may account for the inability of mammalian DNA, which contains some unmethylated CpG motifs (albeit at a lower frequency than bacterial DNA), to persistently stimulate the host immune system; however, an excess of control ODNs can inhibit uptake of CpG ODNs [128]. This inhibition abrogated the ability of CpG DNA to induce immune stimulation, interfering with cytokine production and stress kinase activation [128,129]. Recent work by Krieg et al. [126] confirmed that the immunostimulatory activity of CpG ODNs could be blocked by certain non-CpG motifs. They found that eliminating such suppressive motifs (tandem repeats of GpC) from the plasmid backbone of a DNA vaccine improved vaccine immunogenicity by up to threefold [122]. Alternatively, while eliminating suppressive motifs might enhance the immunogenicity of a plasmid, these observations suggest that adding stimulatory CpG motifs to a plasmid could significantly improve the resultant DNA vaccine's ability to induce a protective immune response; however, in using this approach, CpG motifs appear to be limited in their ability to augment antibody and cytokine production *in vivo*. In one study, introducing 16 additional CpG motifs into the plasmid backbone improved the humoral immune response of a DNA vaccine, whereas introducing 50 such motifs was detrimental [122]. Not only the number but the placement and sequence of CpG motifs may be important. Efforts are under way to determine whether different motifs can preferentially induce specific types of immune response and to identify regions in the plasmid where addition of CpG motifs provides the greatest benefit. These efforts are likely to yield vectors with significantly improved immunostimulatory capacity for clinical use.

### C. The Role of Synthetic CpG ODNs as Vaccine Adjuvant

Several studies have examined the ability of CpG ODNs to boost the immune response elicited by a variety of protein antigens. Ovalbumin (OVA) was the model antigen widely used in early studies. Normal mice immunized with soluble OVA generated a modest serum IgG anti-OVA response; addition of CpG ODNs to the OVA increased the resultant antibody response by approximately fourfold [121]. It was quickly recognized that the immunogenicity of the ODN–antigen combination might be improved if these components were prevented from diffusing away from the injection site. Thus, methods for linking ODN to the antigen were investigated, including coemulsifying them in incomplete Freund's adjuvant, coencapsulating them in liposomes, or coupling them together ionically or covalently [132]. In each case, the immune response elicited by the antigen–ODN

complex triggered an antigen-specific IgG response at least 10-fold greater than free antigen plus CpG ODN and > 50-fold higher than antigen alone [119,121,125,132]. Throughout these studies, control ODN (lacking the critical CpG dinucleotide) had no significant effect on immunogenicity, demonstrating that the adjuvant effect was CpG dependent. Consistent with results from studies of DNA vaccines, combining CpG ODN with antigen significantly altered the isotype profile of the subsequent immune response. For example, OVA alone primarily elicits an IgG1 response (IgG1:IgG2a ratio ranging from 6 to 9), whereas inclusion of CpG ODN increases production of IgG2a antibodies [119,121,125,132]. The enhanced ratio of IgG2a:IgG1 in mice is correlative with a Th1 response and is consistent with studies showing that protein plus CpG ODN indeed induces potent Th1 responses [130,133]. In addition to enhancing antibody and Th1 responses, CpG ODNs have also been shown to activate DCs, leading to presentation of soluble proteins to class I-restricted T cells, and to induce CTL responses [134–136].

Moreover, physically conjugated antigen and CpG ODN has been shown to enhance uptake by DC in mice [137] and to induce substantially higher CTL responses than protein and CpG given together but not conjugated [136,138]. These observations in mouse models have potential importance in human studies in allowing a protein-based vaccine to induce both Th1 and CD8/CTL responses, which in the case of CD8 responses are normally limited to live attenuated vaccines. Subsequent studies have established that CpG ODNs could boost the response to other protein- or peptide-based vaccines [119,121,125,130,131]. This includes evidence that the antibody, T cell, and protective responses of normal mice to agents—including the gp33 glycoprotein-derived peptide from lymphocytic choriomeningitis virus [139], tetanus and diphtheria toxoids [140], and proteins from HIV, influenza, herpes, brucella, and hepatitis—were all increased by coadministration of CpG ODNs [141–144].

As above, optimal adjuvanticity required that the ODN be given in the same immunization with the antigen. Under such conditions, improved immune responses were induced when the CpG ODN–antigen mixtures were administered by a variety of routes including intramuscular, intranasal, oral, and subcutaneous [141].

### D. CpG ODNs Have Different Immune-Stimulating Properties Based on Sequence

Because of evolutionary divergence in CpG recognition between species, CpG ODNs that are highly active in rodents are poorly immunostimulatory in primates and vice versa [121,145–148]. Several groups succeeded in identifying CpG ODNs capable of stimulating human B cells [147–150], natural killer cells [151], and/or macrophages/monocytes to proliferate, mature and/or secrete [147,151,152]. These were subsequently used in preclinical and clinical studies evaluating the activity and safety of these agents *in vivo*. Recent studies show that human peripheral blood mononuclear cells recognize and respond to two distinct types of

CpG ODNs [147,153]. K-type ODNs have phosphorothioate backbones, encode multiple TCGTT and/or TCGTA motifs, and primarily stimulate B cells and macrophages to proliferate and produce IgM and/or IL-6 [147]. D-type ODNs have phosphodiester backbones and contain a single hexameric purine/pyrimidine/CG/purine/pyrimidine motif flanked by self-complementary bases that form a stem-loop structure capped at the 3' end by a poly G tail [147]. D-type ODNs trigger maturation of APCs and preferentially induce secretion of IFN- $\alpha$  and IFN- $\gamma$ . These findings raise the intriguing possibility that CpG ODNs may be tailored to activate specific cell types and thus support precisely the type of immune response required to provide maximal protection against a specific target pathogen [147,150].

Because rodents respond poorly to the motifs that strongly activate human peripheral blood mononuclear cells, preclinical studies evaluated the response of nonhuman primates to these ODNs. Results from several laboratories show that peripheral blood mononuclear cells from rhesus macaques, Aotus monkeys, and chimpanzees recognize and respond to the same D-and K-type ODNs that are active in humans [147,148,150,153–155]. Based on previous studies in mice, the adjuvant activity of CpG ODNs was tested in primates using the model antigen OVA. Rhesus macaques were immunized and boosted with OVA plus D-type, K-type, or control ODN. Alum was used to cross-link ODNs to the antigen. Monkeys immunized with D ODN plus OVA increased their IgG anti-OVA response by nearly 500-fold after primary and secondary immunization [156]. By comparison, K ODN boosted the IgG antibody response by sevenfold after primary and 35-fold after secondary immunization. Further studies established that CpG ODN could boost the in vivo response of primates to protein- or peptide-based vaccines. For example, the antigen-specific serum IgG response of Aotus monkeys immunized with a synthetic malaria peptide vaccine was significantly increased by inclusion of an ODN expressing multiple CpG motifs [154,155]. Control ODN had no effect on peptide immunogenicity. Similarly, nonhuman primates vaccinated with the hepatitis B antigen plus CpG ODN developed 15-fold higher antihepatitis antibody titers than did animals immunized with the vaccine alone [157]. One study established that the protective efficacy of a leishmanial protein was improved by coadministration of CpG ODN. Rhesus macaques were immunized and boosted with alum-adsorbed heat-killed leishmania vaccine (HKLV) plus K or D ODN. In this model system, generation of antigen-specific IFN- $\gamma$  production is strongly associated with parasitic control. When these animals were challenged with *L. major* metacyclic promastigotes, animals vaccinated with HKLV-alum plus D ODN developed smaller lesions than those of controls [156].

## VI. SAFETY

The use of DNA vaccines, plasmid-encoded immunomodulators, and CpG motifs as vaccine adjuvants raises several safety concerns, particularly because newborns, children, and healthy adults are common vaccine recipients. Concerns

include the possibility that potent immunostimulatory activity may 1) enhance the immunogenicity of self-proteins, thereby triggering development of autoimmune disease or 2) stimulate production of cytokines that alter the subsequent host response to pathogens or other vaccines [158].

These concerns are supported by evidence that bacterial DNA can induce production of anti-double-stranded-DNA autoantibodies in normal mice and accelerate development of autoimmune disease in lupus-prone animals [159–161]. Furthermore, CpG motifs present in bacterial DNA and CpG ODN have been shown to stimulate production of IL-6 and block the apoptotic death of activated lymphocytes, both functions that predispose to the development of systemic lupus erythematosus by facilitating persistent B-cell activation [162–167]. These findings led several groups to investigate whether systemic autoimmune disease was induced or accelerated by the CpG motifs [168]. Results show that shortly after CpG DNA treatment, the number of IgG anti-DNA-secreting B cells rises by two-to threefold [169]. This is accompanied by a 35% to 60% increase in serum IgG anti-DNA antibody titer. This modest rise in autoantibody level did not, however, cause disease in normal mice or accelerate disease in lupus-prone animals [168–171]. The situation is somewhat more complex for organ-specific autoimmune disease, whose induction is promoted by the type of Th1 response preferentially triggered by CpG motifs. In an IL-12-dependent model of experimental allergic encephalomyelitis, animals treated with CpG DNA and then challenged with myelin basic protein developed autoreactive Th1 effector cells that caused experimental allergic encephalomyelitis [172]. In a molecular mimicry model, CpG motifs acted as potent immunoactivators, inducing autoimmune myocarditis when coinjected with *Chlamydia*-derived antigen [173]. These findings indicate that CpG motifs may trigger deleterious autoimmune reactions under certain circumstances.

In addition to concerns with regard to autoimmunity, potential safety concerns also arise from vaccines/adjuvants that can elicit potent or persistent stimulation of the host immune system. An important component of immune homeostasis is balance in the production of Th1 cytokines (which promote cell-mediated immunity) and Th2 cytokines (which facilitate humoral immune responses or counter-regulate Th1 responses). Overproduction of one type of cytokine can disrupt immune homeostasis, altering the host response to other vaccines, susceptibility to infection, and predisposition to develop autoimmune disease. In this regard, mice treated repeatedly with CpG ODN develop a statistically significant twofold increase in serum IgM levels and in the number of spleen and lymph node cells secreting IL-6 and IFN- $\gamma$  in vivo. They also showed a modest decrease in the number of cells actively secreting IL-4 [174]. These effects persist for the duration of ODN therapy but return to baseline by 1 month after cessation of treatment. Several reports indicate that CpG ODN can be toxic if administered with lipopolysaccharide or D-galactosamine [175]. Finally, while the use of cytokine-encoding plasmids is growing in popularity, relatively little information is available on their long-term safety. Although no serious side effects have been reported following the administration of cytokine-encoding

plasmids in animals [176], it is unclear whether systematic efforts to detect such events were undertaken.

Despite concern that DNA vaccines/CpG ODN might have adverse effect on the host, there is no evidence that even multiple doses of CpG ODN are directly toxic under normal conditions. Moreover, major toxicity has not been reported among the hundreds of normal human volunteers exposed to CpG motifs in plasmid DNA vaccines.

## VII. CONCLUSIONS

Identifying agents that boost antigen-specific immune responses is an important goal of vaccine research. Our increased understanding of the role of cellular immunity in mediating protection against a variety of infections, combined with a molecular basis for inducing long-term memory cellular immune responses, should provide a strong foundation for developing successful vaccines for a variety of diseases. The use of CpG ODNs and immunomodulators described above has generated much enthusiasm in moving toward this goal.

### I. INTRODUCTION

Vaccination remains one of the most cost-effective methods of medical intervention in the battle to reduce human morbidity and mortality from infectious disease in the 21st century. However, its use remains limited due to the existence of many challenging scientific and ethical issues including the high cost of development and licensing, public acceptance of new technologies used in the generation of such vaccines, and high cost of litigation that may result from vaccine failure or damage. Yet the potential for worldwide protection and, in some cases such as smallpox, complete eradication of disease has driven scientists to consider the generation and development of new, effective, cheap, and easy to administer vaccines. To this end, vaccines that induce high levels of protection following a single immunization would be of great benefit, especially if they could be administered without the use of needles. In addition, it is thought that the stimulation of protective immune responses at the natural site of infection is necessary to achieve high levels of efficacy against some infectious agents. This may result in not only the protection of the individual, but also the reduction of the circulation of pathogens in the community and enhancement of herd immunity. For these and other related reasons, there has been a consistent and continuing interest in the development of vaccines that can be delivered via mucosal surfaces (particularly oral and nasal vaccines) [1]. However, the fact that so few mucosal vaccines are in current use indicates that there are significant barriers to their development. These include the fact that most soluble antigens are poorly immunogenic when delivered directly to the host via mucosal surfaces. Even antigens such as tetanus toxoid that are potent immunogens when administered

parenterally are weak mucosal immunogens [2]. Stimulation of such responses is limited, as although these surfaces have evolved to deal with the threat of microorganisms and their toxic products, protective immunity has to be induced without simultaneously mounting inappropriate immune responses to food and harmless environmental antigens. Hence there is a sophisticated network of immune regulation operating at the surfaces of the body that control immune responses in an antigen-specific manner [3–5]. Unfortunately, despite intensive investigation, these regulatory mechanisms are currently poorly understood. However, we have known for many years that live pathogens can act as mucosal immunogens, stimulating local and, in some cases, systemic immune responses during infection [6]. Using this information, attenuated derivatives of pathogens and their close relations have been created that can stimulate protective immunity without causing disease. Such live mucosal vaccines are considered elsewhere in this volume.

Immune responses to such pathogens are dependent on the production of a number of pathogen-associated antigens that target host cells, often in a tissue-specific way. Some of these products, including some adhesions and toxins, have been shown to have the ability to act as mucosal immunogens in their native (cell binding) form [7–9]. Hence the mucosal immune system may have some capacity to recognize potentially dangerous antigens produced by pathogens and mount appropriate immune responses against them. Many immune cells express receptors that recognize degenerate pathogen products such as DNA, lipopolysaccharide, and other features distinct to microbes. These include the Toll receptors that lead to signal pathways associated with the activation of innate immune responses [10]. Many adjuvants have the capacity to activate innate immunity via Toll

receptors, although it is likely that many other mechanisms remain to be discovered.

Perhaps the most powerful mucosal immunogens identified to date are members of the bacterial enterotoxin family that includes cholera toxin (CT) and the different heat-labile toxins (LT) produced by *Escherichia coli*. Cholera toxin and labile toxin can stimulate potent local and systemic responses to themselves when delivered to the mucosal surfaces of a number of different animals [11]. In addition to being potent mucosal immunogens, LT and CT can activate local and systemic immune responses to uncoupled or (chemically or genetically) coupled antigens that are co-administered to the same mucosal surface in some animals (e.g., mice). Thus LT and CT act as potent mucosal adjuvants [11,12]. Cholera toxin and LT have relatively low toxicity in mice and can be readily used in microgram quantities to adjuvant immune responses to both nasally and orally co-administered proteins, polysaccharides, protein/polysaccharide conjugates, and even whole microorganisms [13,14]. However, in other species, including man, they are toxic and in their native form are not ideal for use as vaccine components [15].

## II. STRUCTURAL AND FUNCTIONAL RELATIONSHIPS BETWEEN LABILE TOXIN AND CHOLERA TOXIN

Cholera toxin and labile toxin belong to the AB class of bacterial toxins and share a high degree of homology in both their primary [16] (80% identity) and tertiary structures [17]. The toxins are hetero-oligomeric complexes each composed of an enzymatic A subunit (CT-A or LT-A) and five identical B subunits (CT-B or LT-B) [17,18]. The A subunit is responsible for toxicity, while the pentameric B oligomer binds to receptor(s) on the surface of eukaryotic cells. The A subunit contains an ADP-ribosyltransferase activity which is able to transfer an ADP-ribose group from NAD to host proteins, including the  $\alpha$  subunit of the GTP-binding protein Gs that activates adenylate cyclase in mammalian cells. The A subunit is associated with the B subunit via the A2 domain that forms an extended  $\alpha$  helix which enters the central cavity of the B subunit oligomer. This A2 domain differs between CT and LT, being nicked in CT but initially unnicked in LT [19]. The A subunit is also able to associate with other eukaryotic proteins, and although cAMP accumulation is thought to lead to toxicity, other factors may provide some contribution to this effect. The B oligomer of these toxins is a pentameric protein of  $\sim$  55 kDa, which contain five identical polypeptide monomers of  $\sim$  11 kDa. These monomers form a compact, protease, and pH-resistant structure, which forms spontaneously even in the absence of the A subunit. The receptor-binding activity of both CT-B and LT-B is specific for polysaccharide groups. Cholera toxin-B binds predominantly to ganglioside GM1, which is almost certainly the major toxin receptor [20]. Labile toxin-B is more promiscuous in that in addition to GM1, it also binds to other molecules including glycosphingolipids and glycoproteins [21–23]. When LT or CT binds to host cells via the B subunit,

they are rapidly internalized into vesicles that undergo retrograde trafficking to the Golgi rather than via the conventional endocytic pathway to lysosomes. During this transport, the A and B subunits remain associated; however, they eventually dissociate and the A subunit is transported via the Golgi to the endoplasmic reticulum and thence to the cytosol. In the cytosol, the A subunits interact with a number of proteins referred to as ADP-ribosylation factors or ARFs. ADP-ribosylation factors normally play a key role in vesicular membrane trafficking, but here, they contribute to the activation of the A subunits [24]. The NAD and ARF binding domains are believed to be distinct on both LT-A and CT-A [25]. When associated together, the A and B subunits form a tightly compact holotoxin structure, which is significantly resistant to denaturation, dissociation, and protease degradation. These characteristics may contribute to the longevity of the toxins at the mucosal surfaces of the body and may play a key contribution to the unique immunogenicity and potentially adjuvanticity of the molecules.

Labile toxin and cholera toxin can induce mucosal IgA and systemic Ig responses after mucosal administration both to themselves and to certain co-administered bystander molecules [26]. Thus they apparently activate immunocompetent cells at mucosal surfaces that are normally regulated to be nonresponders to mucosally delivered antigen. The mucosal immune system is highly organized, and many immune cells are located in specific lymphoid tissues such as those associated with the Peyer's patches of the intestine (the gut-associated lymphoid tissues or GALT). Despite the high degree of homology that exists between CT and LTs, most immunological studies indicate subtle differences in the adjuvant activity of these proteins, with CT-mediated adjuvanticity apparently accompanied by a preferential activation of T helper 2 (Th2) type CD4+ cell populations. In contrast, polarization of the response is less pronounced when LT is used as an adjuvant, with both Th1 and Th2 cells being activated [27]. These differences may reflect subtle differences that exist in the binding of the proteins to their receptors, inherent stability of the holotoxin molecule, trafficking and activation of secondary messengers within the cell, and the level of enzymatic activation once inside the cell. It is also important to recognize that there is considerable variation in the type of T cell immunity (Th1 vs. Th2) reported from different laboratories using LT and CT as mucosal adjuvants. Thus many factors such as toxin purity, animal health, and variations in local experimental practice may influence the type of immunity induced. Nevertheless, both CT and LT have been consistently shown to be potent mucosal adjuvants of both humoral and cellular immune responses in the mouse and other animals [28,29].

The potent mucosal adjuvant activity of LT and CT has attracted considerable interest from immunologists keen to investigate the mechanisms of mucosal adjuvanticity associated with defined molecules. However, despite much intensive investigation, we still do not understand how these enterotoxins act as mucosal adjuvants. One problem is the fact that the mechanism is likely to involve multiple steps in which different cell types operating in a strictly regulated environment are required to interact. Thus work *in vitro*

using purified cellular components and these toxins may provide potentially misleading clues about these mechanisms. Labile toxin and cholera toxin can induce both CD4- and CD8-associated immune responses to bystander antigens [30]. Cholera toxin can induce CD4 T cells secreting interleukin (IL)-4, IL-5, IL-6, and IL-10 which may provide help for antibody class switching to IgG and IgA [27]. Cholera toxin and labile toxin can induce the production of CD8 cytotoxic lymphocytes that can contribute to the protection against disease [31,32]. One area that could be of vital importance is antigen presentation. Treatment of both B cells and macrophages with CT and LT is known to influence the levels of expression of the B7-1 and B7-2 signal molecules, implicating B7/CD28 signaling in adjuvant activity [33]. CD40 may also play a role in adjuvanticity as LT and CT lose some adjuvant activity in CD40 gene knockout mice, although this defect has not been linked directly to CD40–CD40 ligand interactions [27]. Interestingly, CT, rather than LT, has been shown *in vitro* to reduce expression of CD40 on CD4 cells [34], which may help to explain the greater polarization of Th2 responses observed when CT rather than LT is used as an adjuvant. Cholera toxin and labile toxin can also influence antigen presentation by dendritic cells. Cholera toxin-treated dendritic cells upregulate HLA-DR molecule expression on their surface, increase B7-1 and B7-2 expression, and are able to prime naive T cells, driving the polarization toward Th2 [35]. Cholera toxin treatment also influences chemokine receptor expression [35]. Clearly, more work will be needed in this area if we are to define the immunological mechanisms underpinning this adjuvant activity.

### III. THE ADJUVANTICITY OF NONTOXIC MUTANT DERIVATIVES OF LABILE TOXIN AND CHOLERA TOXIN

A key question concerning the mechanism of mucosal antigenicity associated with CT and LT is whether toxicity is linked to adjuvanticity. Early studies using CT-B or LT-B purified by biochemical means from wild-type, fully toxic enterotoxins proved difficult to interpret because of the potential contamination of the nontoxic B subunits with small amounts of the fully toxic parent toxins. Controlled experiments showed that even very small levels of LT or CT toxin contamination could enhance significantly any adjuvant activity associated with the B subunits [36]. Hence investigators turned to the use of highly purified preparations of recombinant proteins produced by heterologous expression hosts that did not produce the wild-type toxins. Production and testing of these recombinant proteins have allowed us to clarify the contribution of the different characteristics and domains of LT and CT to the adjuvant activity of these proteins. Overall studies with the recombinant B subunits in different systems indicate that both LT-B and CT-B retain some ability to act as mucosal adjuvants. Most data indicate that both B subunits are weaker adjuvants than the holotoxins, although there is no universal agreement about this between different laboratories. Labile toxin-B appears to retain

a more potent adjuvant capacity than CT-B, possibly because LT-B is a more stable pentamer than CT-B [37]. Labile toxin-B may also have a more substantial effect on trafficking (vasculation and protein retention in vesicles) than CT-B, potentially influencing the length of time antigens are presented to the immune system [38].

A number of groups have generated mutations in the B subunit that obliterate or reduce the ability of this subunit to bind to its receptor. From these studies, it appears that receptor-binding activity contributes significantly to adjuvant activity [39,40], although this is not a consistent finding as some nonbinding mutants may retain some adjuvant activity particularly following nasal delivery [41] which is a more sensitive route than oral immunization. Recently, a novel B subunit mutant has been described which is able to bind GM1 and traffic to the Golgi but is unable to influence immunomodulation (by either the B subunit alone or the holotoxin if genetically created in this molecule). This mutant LTH57A [42], in which the histidine at position 57 of the B subunit has been changed for an arginine, is believed to result in a more rigid protein structure. It has been postulated that this reduction in flexibility prevents interaction with membrane proteins that are important in the activation of secondary signal pathways within the host cell, which are important for adjuvanticity.

In addition to work with the B subunits, many different site-directed mutants of LT and CT have been created, and these have been used to monitor the relationship between structure and function with respect to adjuvant activity [26]. Many mutations in the toxins generate mutant derivatives that are either unstable, unable to form AB complexes, or have properties indistinguishable from wild-type toxins [26]. However, some site-directed mutants are able to form stable AB complexes but exhibit either severely reduced or undetectable levels of toxicity or ADP-ribosyltransferase activity [43]. Of these mutants, LTK63, CTK63 (harboring inactivating lysine substitutions at position 63 of the respective A subunits), and CTE112K (harboring a lysine substitution at position 112 of the CT-A subunit) [44,45] have been studied in most detail. These molecules form stable holotoxinoid complexes but do not detectably direct the accumulation of cAMP in target cells. They do not appear to ADP-ribosylate host proteins and are nontoxic when incubated with cultured cells or evaluated in ligated intestinal loop assays [46]. LTK63 also retains the ability to interact with ARFs. The crystal structure of LTK63 has been solved and compared directly to the wild-type LT parental toxin. The two molecules show indistinguishable identity except for a bulge in the active site associated with the lysine at position 63 [47]. LTK63 has been consistently shown to retain significant adjuvant activity, capable of adjuvanting both CD4- and CD8-associated immune responses [30,31]. However, CTK63 is a poor mucosal adjuvant [48]. The adjuvant activity of LTK63 also appears to be consistently greater than LT-B in direct comparisons using identical bystander molecules [49]. CTE112K appears to exhibit similar properties to LTK63 in terms of the level of adjuvant activity [50]. Thus these experiments conclusively show that mutants of LT and CT with undetectable activity can retain adjuvant activity.

Several mutant derivatives have been created that have significantly reduced toxicity and enzymatic activity but retained some adjuvant activity. These include LTR72 [51] and CTS106 [48]. Both these molecules are excellent mucosal adjuvants with levels of activity approaching those of the wild-type toxins. Other mutant derivatives with reduced activity have been created by introducing mutations into the protease-sensitive loop of LT. LTG192 is perhaps best characterized by this class and has an arginine replaced by a glycine at position 192 of the A subunit [52] which reduces the efficiency of protease nicking associated with the A2 domain of the toxin. In vitro, the mutant is completely trypsin-resistant, however, in vivo, proteases other than trypsin can cleave the loop and activate the toxin, resulting in detectable toxicity [46]. LTG192 retains significant adjuvanticity [53], and ongoing human trials are expected to establish the safety profile of this adjuvant.

From the above studies, it appears that several characteristics of the LT/CT classes of enterotoxins contribute to adjuvant activity. Binding to receptors has been shown to be relevant for this activity, as has stability of the holotoxin structure. However, the fact that nontoxic mutants of both LT and CT retain greater adjuvant activity than the B subunit alone suggests that the formation of the holotoxin may contribute towards the increased activity of these proteins at immune-inductive sites in vivo. Generation of these mutants has allowed us to see that although enzymatic activity and toxicity are not essential for adjuvant activity, they contribute to it. A dose-response curve measuring the adjuvant activity of different LT derivatives at different immunization doses has shown that a few nanograms of LT-B or LTK63 have no obvious adjuvant activity when administered intranasally to mice with bystander antigens [51]. However, increasing the amount of LTK63 reveals adjuvant activity at concentrations lower than that required for showing similar levels of activity with LT-B. In contrast, wild-type LT exhibits adjuvant activity at much lower doses than either LTK63 or LT-B. However, the activity of LT increases in a dose-dependent manner, following the curve of LTK63, suggesting that the influence of enzymatic activity can become saturated. Interestingly, the mutant LTR72, which has reduced toxic activity, behaved in a manner intermediate to LTK63 and LT in these assays. Thus enzymatic activity acts in a dose-independent manner, whereas the nontoxic AB complex acts in a manner dependent on dose. The inactivated A subunit may enhance LT-B-associated activity by increasing the resistance of the complex to denaturing factors. Also, the LT-A subunit of LTK63 is still delivered via the Golgi to the cell cytosol, and the interaction of this subunit with host factors such as ARF may play important roles in adjuvanticity. Clearly, the mechanism of adjuvanticity is complex and is likely to be multifactorial.

Some investigations have been made comparing the immunological properties of LT and CT mutant derivatives to wild-type toxins. CTE112K retains a Th2-type activation profile associated with the upregulation of B7 on antigen-presenting cells [45]. LTK63 enhances a mixed Th1/Th2-type response, whereas LTK72 promotes a more Th2-type response [54]. LTK63 and LT-B apparently enhance IL-12 and

interferon  $\gamma$  production as well as NF $\kappa$ B activation levels comparable to both LT and LTR72 [55].

#### **IV. CLINICAL EVALUATION OF LABILE TOXIN AND MUTANT DERIVATIVES AS MUCOSAL ADJUVANTS**

Although many studies have now been performed in animal models using these adjuvants, very few have been conducted in human volunteers. In fact, most clinical studies to date have actually used the wild-type LT to evaluate the potential of this molecule as a mucosal adjuvant. Early studies with wild-type cholera-like enterotoxins in volunteers showed that microgram quantities could induce diarrhea when ingested orally [15]. Despite this observation, wild-type enterotoxins have been fed to volunteers as potential adjuvants. In one study, wild-type LT was used to immunize volunteers along with a recombinant urease from *Helicobacter pylori* [56]. Volunteers received several doses of vaccine and were divided into groups who received different amounts of urease together with LT. A number of the volunteers who received LT developed diarrhea, and although immune responses to *H. pylori* urease were detected, the adjuvant activity of LT was not clearly demonstrated. Human LT has also been formulated into a virosome preparation containing the hemagglutinin of influenza virus, and this vaccine has been administered intranasally to many people in Switzerland [57]. In preregistration volunteer studies, vaccine formulations containing hemagglutinin were prepared with or without LT and administered as two independent intranasal sprays. This immunization regime induced a humoral immune response to hemagglutinin that was equivalent to a single parenteral immunization and was associated with an anti-hemagglutinin IgA response in the nasal secretions of the volunteers. Incorporation of LT apparently enhanced the immune response to the virus antigen, demonstrating some adjuvant activity with LT in humans.

A study using the protease-sensitive mutant LTG192 as an adjuvant has recently been reported in human volunteers. In these studies, the protein was admixed with a formalin-inactivated whole cell *H. pylori* antigen with or without LTG192 [58]. The oral immunization was performed using both *H. pylori*-free and infected volunteers. Following vaccination, some of the volunteers developed diarrhea and other adverse events were reported. However, significant increases were detected in the production of anti-*H. pylori* IgA at appropriate mucosal sites (fecal and salivary) in the group receiving high doses of *H. pylori* cells, and lymphoproliferative responses associated with the generation of IFN- $\gamma$  were detected in some volunteers.

Progress towards further volunteer studies using mutant LT molecules has recently been inhibited by concerns that these holotoxin molecules may traffic to the brain through olfactory nerves particularly following intranasal immunization [59]. Wild-type toxin has been used in combination with commercial influenza vaccine [57], although safety follow-ups on the patients should have revealed some side effects. Other studies have found no olfactory involvement

following intranasal immunization [60]. It is reasonable to hypothesize that in this case, the use of a nontoxic mutant of these adjuvants would additionally minimize the risk of serious adverse events.

## V. CONCLUSION

Over the last 5 years, much progress has been made in the generation, development, and testing of bacterial enterotoxins as mucosal adjuvants. Using molecular techniques, a collection of mutants was generated which have allowed us to assign a role for binding, holotoxin structure, and enzymatic activity in the adjuvant activity of these proteins. Much work still remains especially regarding the specific immune mechanisms activated by such toxins, and further clinical trials are urgently needed in this area if LT- or CT-based mucosal adjuvants are ever to find use in human vaccines. Another exciting approach that could offer potential practical benefits in the future is the design of novel artificial mucosal adjuvants based on LT/CT components or mimetic equivalents [61].

## Recent Developments in Vaccine Delivery Systems

Derek T. O'Hagan

*Chiron Corporation, Emeryville, California, U.S.A.*

### I. INTRODUCTION

This chapter reviews recent developments in the use of vaccine adjuvants, which function primarily as “vaccine delivery systems.” Hence I will focus on emulsion, liposome, iscom, and microparticle-based adjuvants, whose principal mode of action is the delivery of antigens into the key cells and/or sites that are responsible for the induction of immune responses. Immunological adjuvants were originally described by Ramon [1] as “substances used in combination with a specific antigen that produced a more robust immune response than the antigen alone.” This broad definition encompasses a very wide range of materials [2], including a range of particulate delivery systems. Generally, immunological adjuvants have proven notoriously difficult to classify in any rational way, primarily because their mechanisms of action are often ill defined. Although this chapter will focus primarily on particulate adjuvants, in many situations these have been combined with additional adjuvants. Primarily, adjuvants are components of bacteria and viruses, or synthetic agents that mimic these, and are recognized as “danger signals” by receptors on innate immune cells, including the toll-like receptors (TLRs), which trigger the release of a cascade of proinflammatory cytokines [3]. Hence, many adjuvants have been referred to as representing pathogen-associated molecular patterns (PAMPs), although synthetic molecules can also be used as mimics. A full discussion of both adjuvants and delivery systems is beyond the scope of this chapter, but has been reviewed recently [4]. For an optimal adjuvant effect, it is becoming increasingly common to use delivery systems to target both antigen and adjuvants into the same immunocompetent cells. In these situations, it becomes even more difficult to determine the mechanism of action for the combined adjuvant formulation. In many studies that will be discussed in this chapter, it is clear that synergies between adjuvants and delivery systems are possible and optimal vaccine formulations using a variety of components.

Although many approaches have been extensively evaluated over the years, the only adjuvants currently approved

by the U.S. Food and Drug Administration are aluminum-based mineral salts (generically called alum). Alum has been used as an adjuvant for many years, but its mechanism of action still remains poorly defined. It was originally thought to provide a “depot” effect, resulting in persistence of antigen at the injection site following immunization. However, studies involving radiolabeled antigens have brought this assumption into question [5]. Recent work has indicated that alum upregulates costimulatory signals on human monocytes and promotes the release of IL-4 [6]. It has also been suggested that alum adsorption may make an important contribution to a reduction in toxicity for some vaccines because of the adsorption of contaminating endotoxin [7]. Nevertheless, although alum has a good safety record, comparative studies show that it is a weak adjuvant for antibody induction to protein subunit antigens, a poor adjuvant for cell-mediated immunity (CMI) in general, and ineffective for the induction of cytotoxic T lymphocytes (CTLs) [8]. Moreover, alum adjuvants can induce IgE antibody responses and have been associated with allergic reactions in some subjects [8,9]. Therefore, there is an urgent need for the development of new-generation adjuvants, which can induce potent CMI, including CTL responses, work with a broad range of antigens, to include recombinant proteins and DNA vaccines, and be appropriate for different routes of delivery, to include mucosal immunization.

A key issue in adjuvant development is toxicity, since safety concerns have restricted the development of adjuvants since alum was first introduced more than 50 years ago [10]. Many experimental adjuvants and delivery systems have advanced to clinical trials and some have demonstrated high potency, but most have proven too toxic for routine clinical use. For prophylactic immunization in healthy individuals, only adjuvants that induce minimal adverse effects will prove acceptable. In contrast, for adjuvants that are designed to be used in life-threatening situations, e.g., as a component of cancer vaccines, the acceptable level of adverse events would likely be increased. This might also be true for adjuvants to be used in vaccines as therapeutic agents in people already

infected with pathogens with life-threatening consequences, e.g., HIV and HCV. This review will focus primarily on antigen delivery systems to be used in prophylactic or therapeutic vaccines against infectious diseases. Developments in cancer vaccines have recently been reviewed elsewhere [11,12].

Following the discovery of some very potent adjuvant molecules in recent years, including synthetic oligonucleotides based on unmethylated bacterial DNA (CpG DNA), there has been some concern that these potent adjuvants might activate immunity to such an extent that autoimmune conditions might be triggered. This is a reasonable concern for adjuvant actives that mimic components of pathogenic microorganisms and provide potent proinflammatory signals. However, the timing and localization of the proinflammatory stimuli may prove to be important. In this context, limiting the systemic distribution of the adjuvants and focusing their effects specifically onto the key immune cells is likely to be beneficial. Hence, an important contribution of particulate delivery systems may be to limit the toxicity of adjuvants by limiting their systemic distribution following injection. Additional practical issues important for the development of adjuvants and delivery systems include biodegradability, stability, ease of manufacture, cost, and applicability to a wide range of vaccines. Ideally, for ease of administration and enhanced patient compliance, the adjuvant should allow the vaccine to be administered by a mucosal route, preferably orally.

## II. THE ROLE OF ADJUVANTS IN VACCINE DEVELOPMENT

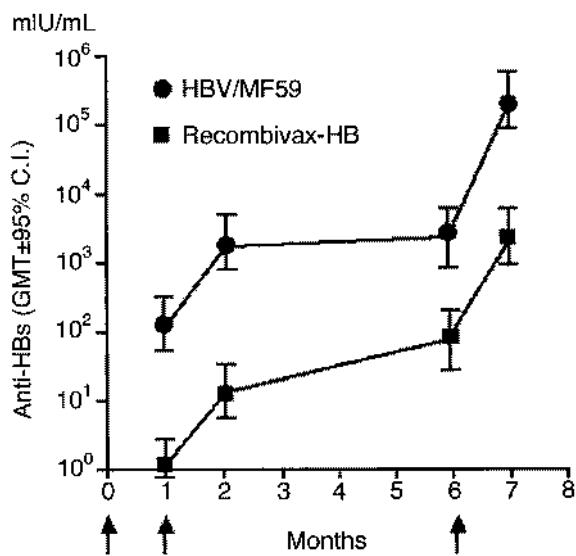

The precise mechanisms of action of most adjuvants still remain only partially understood, and this has impeded the rational development of new adjuvants. Immunization activates a complex cascade of innate and adaptive responses, and the primary effect of the adjuvant is often difficult to discern. However, if the geographical concept of immune reactivity is accepted, in which antigens that do not reach the local lymph nodes do not induce responses [13], it becomes easier to propose mechanistic interpretations for the important effects of some adjuvants, particularly those that function mainly as delivery systems. If antigens that do not reach lymph nodes do not induce responses, then any adjuvant that enhances delivery of the antigen to the node may be expected to induce an enhanced response. Antigen delivery to lymph nodes may be enhanced in a number of ways; the adjuvant may increase cellular infiltration into the injection site, so that more cells are present to take up antigen, it may directly promote the uptake of antigen into antigen-presenting cells (APCs) through activating phagocytosis, or it may directly deliver the antigen to the local lymph node by exiting from the injection site and moving into the lymphatics. The most important APCs involved in antigen capture are thought to be dendritic cells (DCs), which have the unique ability to present antigen to naive T cells in lymph nodes. However, macrophages are also known to be important APCs and their role may be underappreciated.

## III. PARTICULATE ANTIGEN DELIVERY SYSTEMS

The use of particulate antigen delivery systems as alternative approaches or in combination with adjuvant molecules has been evaluated extensively. Particulate adjuvants (e.g., emulsions, microparticles, immunostimulatory complexes [iscoms], liposomes, virosomes, and viruslike particles) have comparable dimensions to the pathogens that the immune system evolved to combat. Therefore, these particulates are normally taken up efficiently by phagocytic cells of the innate immune system and function mainly to deliver associated antigen into these key cells. Adjuvant molecules, often PAMPs, may also be included in particulate delivery systems to further enhance the level of response or to focus the response through a desired pathway, e.g., Th1 or Th2. In addition, formulating potent adjuvants into delivery systems may limit adverse events through restricting the systemic distribution of the adjuvant.

### A. Emulsions

A potent oil-in-water (o/w) emulsion adjuvant, the syntex adjuvant formulation (SAF) [14], was developed using a biodegradable oil (squalane) in the 1980s, as a replacement for Freund's adjuvants. Freund's complete adjuvant (FCA) is a potent but toxic water in mineral-oil-in-water (w/o) adjuvant, which includes Arlacet A as a detergent and contains killed mycobacteria [15]. Incomplete Freund's adjuvant, which does not contain mycobacteria, is still in use for cancer vaccines and as an immunotherapeutic vaccine in HIV-infected individuals [16]. However, mineral oil adjuvants are generally considered too toxic for routine use in prophylactic vaccines. SAF also contained a bacterial cell-wall-based synthetic adjuvant, threonyl muramyl dipeptide (t-MDP), and a nonionic surfactant, poloxamer L121, but proved too toxic for widespread use in humans [10]. Therefore, a squalene o/w emulsion was developed (MF59), without the presence of additional adjuvants, which proved to be potent, but with an acceptable safety profile [17]. Squalene, which is commercially derived from shark liver oil, is an intermediate in human steroid hormone biosynthesis and is a direct synthetic precursor to cholesterol. MF59 enhanced the immunogenicity of influenza vaccine in small animal models [18–20] and was shown to be a more potent adjuvant than alum for hepatitis B vaccine (HBV) in baboons [21]. Subsequently, the safety and immunogenicity of MF59-adjuvanted influenza vaccine (FLUAD™) was confirmed in elderly subjects in clinical trials [22,23], and these data allowed the approval of this product for licensure in Italy in 1997 and for several additional countries through mutual recognition in 2000. Recent clinical data have shown that the potency of MF59 as an adjuvant for influenza vaccine may be particularly advantageous in the face of a potential pandemic strain [24]. The potency of MF59 for HBV has also been confirmed in a human clinical trial [25], in which MF59 was shown to be 100-fold more potent than the commercial alum-adjuvanted vaccine (Figure 1). In addition, MF59 has also been shown to be an effective adjuvant for a protein/polysaccharide conjugate vaccine in infant

**Figure 1** MF59 in combination with a novel recombinant hepatitis B vaccine (HBV) induced significantly higher antibody responses in humans ( $n = 230$  subjects in total, receiving either vaccine) than the commercially available alum-adsorbed vaccine (Recombivax).

baboons [26]. Studies with labeled MF59 have shown that it is taken up by macrophages and DCs, both at the site of injection and in local lymph nodes [27]. Hence, it is thought that the principal mode of action of MF59 is to induce macrophage recruitment into the injection site and uptake and migration of the adjuvant and antigen to local lymph nodes. Apoptosis of MF59-carrying macrophages may then occur in lymph nodes, with transfer of apoptotic bodies to DCs [28]. Experience in the clinic (>18,000 subjects immunized in Chiron-sponsored clinical trials) with HIV, HSV, CMV, HBV, and influenza has shown that MF59 is safe and well tolerated in adults and children [29–32]. In addition, MF59 was shown to be safe and well tolerated in newborn infants in an HIV vaccine trial [33]. Moreover, MF59 can be used with recombinant proteins as an effective booster vaccine in individuals primed with a live virus vaccine [34] or with DNA [35]. In summary, MF59 is a safe and well-tolerated adjuvant in humans and is effective for the induction of potent antibody responses and CD4<sup>+</sup> T-cell responses. However, in most studies, MF59 has been ineffective for CTL induction. Nevertheless, a modified MF59 emulsion was recently described as a delivery system for DNA vaccines, which might be expected to induce CTL responses [36].

In many studies, emulsions have also been used as delivery systems for additional adjuvants, including mono-phosphoryl lipid A (MPL) derived from gram-negative bacteria and QS21, a purified fraction of Quil A from *Quillaja saponaria*. This approach allows adjuvant molecules to be targeted for enhanced uptake by APC. For example, an o/w emulsion containing MPL and QS21 induced protection in a mouse model of malaria that was

comparable or better than the levels of protection induced with the vaccine in FCA [37]. The o/w adjuvant formulation (called SBAS-2) subsequently showed protective efficacy against an experimental challenge in human volunteers exposed to infected mosquitoes, although protection was of short duration [38]. In a subsequent trial with recombinant HIV-1 env protein, SBAS-2 induced high titers and proliferative T-cell responses, but did not induce CTL or primary isolate neutralizing antibodies [39]. In addition, the formulation was associated with a significant number of adverse events and the reactogenicity profile appeared to preclude its use for most if not all prophylactic vaccines. The high reactogenicity appears to be caused by the presence of QS21, but may be reduced by modifications to the formulation and the addition of excipients [40]. In addition, there have been suggestions that the potency of Quil-based adjuvants may be adversely affected by degradation of this component [41]. Emulsion formulations of MPL and QS21 may have potential as adjuvants for cancer vaccines [42] and other therapeutic vaccines. An alternative emulsion-based approach involves the use of the Montanide series of adjuvants, which are based on the surfactant, mannide oleate [43,44]. The w/o mineral oil (Drakeol) adjuvant (ISA-51) has been evaluated as a therapeutic vaccine in HIV-infected individuals [45]. However, as discussed earlier, because of significant adverse effects, mineral oil adjuvants are unlikely to be considered as acceptable for prophylactic vaccines. An alternative approach, comprising a w/o non-mineral-oil emulsion (ISA-720), has also been evaluated in a malaria vaccine trial [43]. However, although potent, the adjuvant (ISA-720) induced severe local reactions in some volunteers and may prove too toxic for routine use in prophylactic vaccines [46,47].

## B. Liposomes

Liposomes are phospholipid vesicles that are used as drug delivery systems in several commercially available products. At least five liposomal products are on the market and at least another 10 are currently in clinical trials. Most of the formulations on the market use the naturally occurring phosphatidyl choline as neutral lipid, with fatty acyl chains of varying lengths and degrees of saturation to build membranes. Cholesterol is often included to modulate membrane rigidity and to reduce instability. A variety of liposomal formulations have been evaluated both as adjuvants and as delivery systems [48,49]. However, liposomes have often been used in complex adjuvant formulations, with many including MPL, which makes it difficult to determine the contribution of the liposome to the overall adjuvant effect. Recently, liposomes were described as effective delivery systems for T-independent antigens, when they were used in combination with CpG DNA [50]. In addition, Gursel et al. [51] reported that cationic liposomes were effective delivery systems for CpG adjuvants.

Liposomal vaccines based on viral membrane proteins (virosomes) without additional immunostimulators have been extensively evaluated in the clinic and are approved as products in Europe for hepatitis A and influenza [52]. Immunopotentiating reconstituted influenza virosomes

(IRIV) are unilamellar liposomes comprising mainly phosphatidyl choline, with influenza hemagglutinin intercalated into the membrane. The use of viral membrane proteins in the formation of virosomes offers the opportunity to exploit the targeting and fusogenic properties of the native viral membrane proteins, perhaps resulting in effective delivery of entrapped antigens into the cytosol for CTL induction [53]. An alternative approach to vaccine delivery that may have some advantages over traditional liposomes has been described using “archaeosomes,” which are vesicles prepared from the polar lipids of *Archaeobacteria* [54]. Archaeosomes have been shown to induce more potent responses than traditional liposomes [55,56]. Cationic lipid vesicles have also been described recently, which comprise cationic cholesterol derivatives with or without neutral phospholipids [57]. The best results were obtained with cationic vesicles to which antigen was bound to the surface, which greatly outperformed neutral liposomes that did not bind antigen [57]. In addition, oil-in-water liposomal formulations were recently described in which mineral oil was emulsified in the presence of liposomes, which donated phospholipids as stabilizers [58]. Clearly, this is a very complex formulation, which would need to show a dramatic improvement over alternatives before it can be accepted as a significant advance in the field. Modified liposomal structures termed “cochleates” are also being evaluated as systemic and mucosal adjuvants in small animal models [59].

### C. Immunostimulatory Complexes

The immunostimulatory fractions from *Q. saponaria* (Quil A) have been incorporated into lipid particles comprising cholesterol, phospholipids, and cell membrane antigens, which are called iscoms [60]. The principal advantage of the preparation of iscoms is to allow a reduction in the dose of the hemolytic Quil A adjuvant and to target the formulation directly to APCs. In addition, within the iscoms structure, the Quil A is bound to cholesterol and is not free to interact with cell membranes. Therefore, the hemolytic activity of the saponins is significantly reduced [60,61]. It is well established that iscoms induce cytokine production in a range of mouse strains, and a recent study has indicated that the induction of IL-12 is key to the adjuvant effect [62]. However, strong IFN- $\gamma$  responses have also been described [63]. In a study in macaques, influenza iscoms were shown to be more immunogenic than a classical subunit vaccine and induced enhanced protective efficacy [64]. A similar formulation has been evaluated in human clinical trials and successfully induced a CTL response [65]. In a comparative study in rhesus macaques, although iscoms induced a potent Th1 response against a recombinant HIV-1 env antigen, while MF59 induced a Th2 response, both vaccines offered a similar degree of protection against challenge [66]. Iscoms are generally accepted as the most potent adjuvant approach for the induction of CTL responses with recombinant proteins in preclinical models [67]. For example, in a recent study, we demonstrated the induction of potent long-lasting CTL responses in rhesus macaques immunized with recombinant core antigen from hepatitis C virus adsorbed to novel iscoms [68]. In addition, potent T-cell proliferative responses

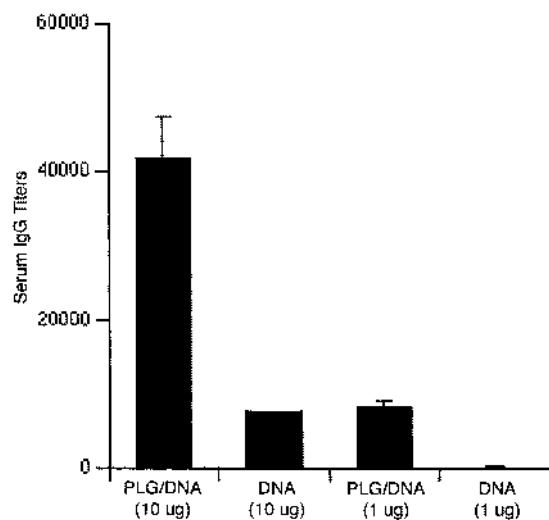

have been induced in primates with iscoms containing CMV, flu, HIV, and EBV antigens [60–69]. However, the efficacy for CTL induction and the safety profile of iscoms need to be further established in human subjects, although initial studies are encouraging [70]. In addition, a potential problem with iscoms is that inclusion of antigens into the adjuvant is often difficult, and may require extensive antigen modification [71]. Nevertheless, recent work has identified novel ways by which some antigens can be effectively associated with iscoms without significant formulation difficulties [68–72]. In addition, simplified approaches to the preparation of iscoms have also been described [73], as well as approaches to isolate Quil-based saponins, with less heterogeneity [74].

### D. Alternative Lipid Vehicles for Vaccine Delivery

An alternative approach involving lipid vesicles has also been described involving nonionic surfactant vesicle, or “niosomes,” which have induced potent responses in small animal models [75]. In addition, it has been suggested that an important component of the adjuvant effect of synthetic lipopeptide antigens is their ability to aggregate into particulate structures [76]. Although binding of lipopeptides to TLR2 is also important to their adjuvant effect [77]. Nevertheless, the potency of lipopeptides has been shown to be enhanced by their formulation into particulate delivery systems [78].

### E. Microparticles

Antigen uptake by APC is enhanced by association of antigens with polymeric microparticles, or by the use of polymers or proteins that self-assemble into particles. The biodegradable and biocompatible polyesters, the polylactide-co-glycolides (PLGs) are the primary candidates for the development of microparticles as adjuvants, because they have been used in humans for many years as suture material and as controlled-release drug delivery systems [79,80]. The adjuvant effect achieved through the encapsulation of antigens into PLG microparticles was first demonstrated more than 10 years ago [81–84]. Microparticles appear to function mainly as delivery systems, targeting associated antigens into APCs. In contrast to alum adjuvants, PLG microparticles are effective for the induction of CTL responses in small animal models [78,85–87]. Microparticles also have significant potential as delivery systems for DNA vaccines [4,88–90]. We recently described a novel approach in which cationic microparticles with adsorbed plasmids were used to dramatically enhance the potency of DNA vaccines [89–91] (Figure 2). Importantly, the cationic microparticles enhanced both antibody and T-cell responses in a range of animal models, including nonhuman primates; they efficiently adsorbed DNA and can be designed to deliver several plasmids simultaneously on the same formulation at a range of different loading levels [90,91]. The microparticles appear to be effective mainly as a consequence of efficient delivery of the adsorbed plasmids into DC [92]. Similar anionic microparticles can also be used for effective delivery of adsorbed proteins and have been shown to be effective for

**Figure 2** Serum IgG antibody titers in groups of mice ( $n = 10$ ) immunized intramuscularly with 1 or 10 µg DNA encoding HIV-1 p55 gag adsorbed to cationic microparticles or as naked DNA.

CTL induction in mice [93]. In addition, cationic microparticles can be used as delivery systems for adsorbed adjuvants, including CpG DNA [94]. Surprisingly, the potency of microparticles as an adjuvant can be significantly enhanced by their combination with MF59 emulsion [95]. A particularly attractive feature of microparticles is their ability to control the rate of release of entrapped antigens [96,97]. Controlled release of antigen may allow the development of *single-dose vaccines*, which would result in improved vaccine compliance, particularly in the developing world. However, although microparticles have significant potential for the development of single-dose vaccines, work is needed to ensure the stability of antigens entrapped in microparticles, and progress has been slow [98]. On several occasions, it has been shown that controlled-release microparticles work optimally for bacterial toxoids when they are combined with alum [97], and this approach may be evaluated in the clinic in the near future [99].

#### F. Alternative Particulate Adjuvants

Polymers that self-assemble into particulates (poloxamers) [100], or soluble polymers (polyphosphazenes) [101], may also be used as adjuvants, but the safety and tolerability of these approaches need to be further evaluated. A recent study suggested an adjuvant effect for CRL1005, a nonionic block copolymer (poloxamer) for a DNA vaccine in rhesus macaques [102]. However, in this same study, a combination adjuvant involving alum and MPL did not appear to provide any benefit for the DNA vaccine [102]. Recombinant proteins that naturally self-assemble into particles can also be used to enhance delivery of antigens to APC. The first recombinant protein vaccine that was developed, based on hepatitis B surface antigen (HBsAg), was expressed in yeast as a particulate protein [103]. Recombinant HBsAg is po-

tently immunogenic and can be used to prime CTL responses [104]. HBsAg and other viruslike particles (VLPs) can also be used as delivery systems for coexpressed antigens [105]. Recombinant Ty VLPs from *Saccharomyces cerevisiae* carrying a string of up to 15 CTL epitopes from *Plasmodium* species have been shown to prime protective CTL responses in mice following a single immunization [106]. In addition, Ty VLPs have also been shown to induce CTL activity in macaques against coexpressed SIV p27 [107]. Clinical trials of Ty VLPs have shown them to be safe and immunogenic in humans [108].

#### IV. ALTERNATIVE ROUTES OF IMMUNIZATION

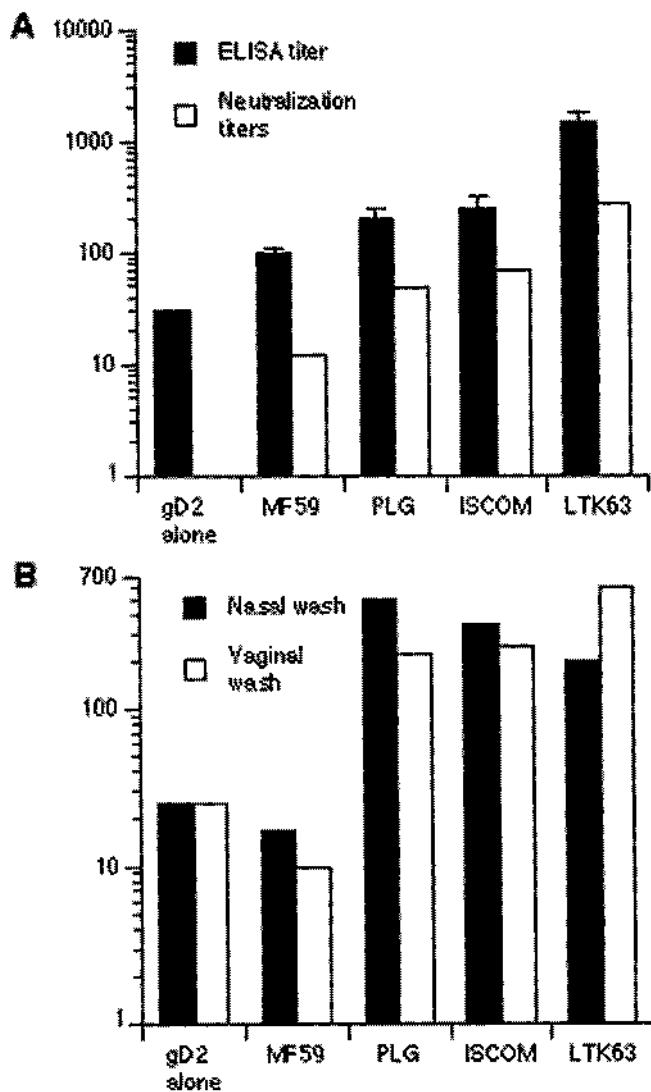

Although most vaccines have traditionally been administered by intramuscular or subcutaneous immunization, mucosal delivery of vaccines offers a number of important advantages, including easier administration, reduced adverse effects, and the potential for frequent boosting. In addition, local immunization induces mucosal immunity at the sites where many pathogens initially establish infection of hosts. Oral immunization would be particularly advantageous in isolated communities, where access to health care professionals is difficult. Moreover, mucosal immunization would avoid the potential problem of infection caused by the reuse of needles. Several orally administered vaccines are commercially available, which are based on live-attenuated organisms, including polio, *Vibrio cholerae*, and *Salmonella enterica* serovar Typhi. In addition, a wide range of approaches is currently being evaluated for mucosal delivery of vaccines [109], including many approaches involving nonliving adjuvants and delivery systems.

The most attractive route for mucosal immunization is oral, because of the ease and acceptability of administration through this route. However, because of the presence of low acidity in the stomach, an extensive range of digestive enzymes in the intestine and a protective coating of mucus that limits access to the mucosal epithelium, oral immunization has proven extremely difficult with nonliving antigens. However, novel delivery systems and adjuvants may be used to significantly enhance responses following oral immunization.

#### A. Mucosal Immunization with Antigen Delivery Systems

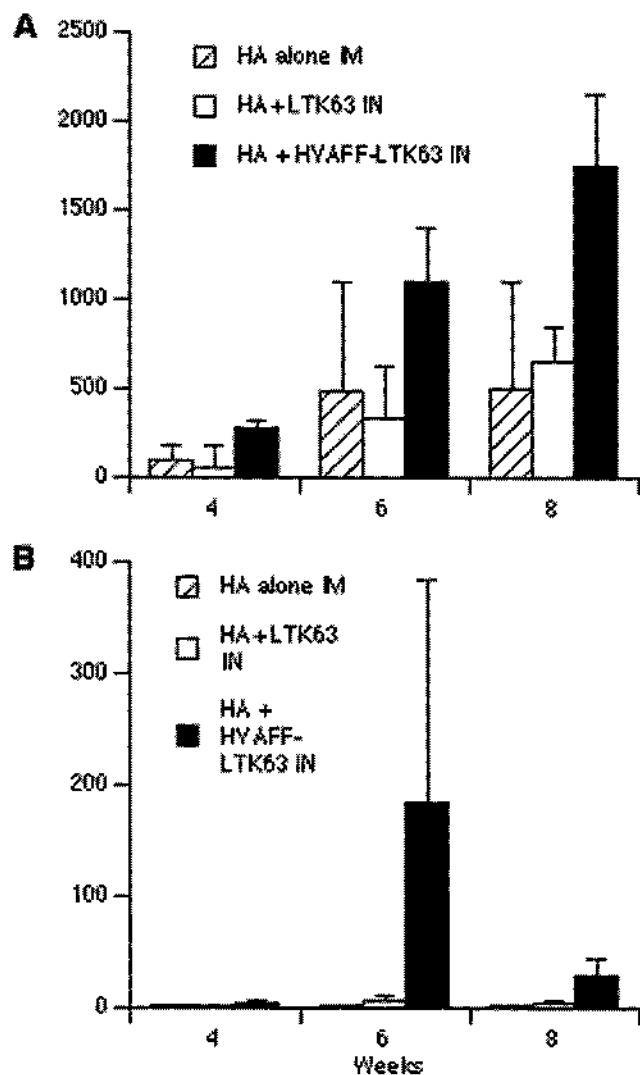

In mice, oral immunization with PLG microparticles of 1–10 µm has been shown to induce potent mucosal and systemic immunity to entrapped antigens [110–113]. In addition, mucosal immunization with microparticles has been shown to induce protection against challenge with *Bordetella pertussis* [114–117], *Chlamydia trachomatis* [118], *Yersinia pestis* [119], *Brucella ovis* [120], *Salmonella typhimurium* [121], and *Streptococcus pneumoniae* [122]. In primates, initial studies involving mucosal immunization with microparticles were encouraging, although oral immunization was not as effective as delivery to the respiratory tract. Mucosal immunization with inactivated SIV in microparticles induced protective immunity against intravaginal challenge [123].

Also in primates, mucosal immunization with microparticles induced protection against aerosol challenge with staphylococcal enterotoxin B [124]. Nevertheless, studies undertaken so far involving oral immunization with PLG microparticles in larger animal models and human clinical trials have been largely disappointing [125–127]. However, difficulty in translating observations from smaller to larger animals and humans is not unique to microparticle formulations. Generally speaking, although small animal models are necessary screening tools to be used for mucosal immunization studies, they are unlikely to prove predictive of potency in larger animal models and humans. This applies particularly to approaches for oral immunization, since the gastrointestinal tract and mucosal immune tissues of both small and large animal models are very different from humans. The potential of microparticles and other polymeric delivery systems for mucosal delivery of vaccines was recently reviewed in detail [128], as too was the use of a broader range of antigen delivery systems [129]. Although much of the literature has focused on PLG microparticles, several alternative approaches involving microencapsulation in different polymers have also been described [128]. While many have used similar sized microparticles (1–10  $\mu\text{m}$ ), some groups have described the use of larger microparticles that are designed to protect antigens against degradation in the stomach and to release it in the intestine [128]. Nevertheless, given the significant challenges associated with oral immunization using nonliving delivery systems, simple protection against stomach degradation is unlikely to prove successful without the inclusion of additional formulation components, including adjuvants. Moreover, although advantages are often claimed for alternative polymers to PLG, comparisons are rarely made and it is often difficult to understand what the likely advantages are, particularly when the microparticles are of similar dimensions. The ability of 1 to 10  $\mu\text{m}$  microparticles of any composition to perform effectively following mucosal administration is largely a consequence of their uptake into the specialized mucosal associated lymphoid tissue (MALT) [130]. However, the majority of literature in this area has concluded that the extent of uptake of microparticles into lymphoid tissue following oral delivery is very low [130], imposing a strict limitation on the likely success of microparticles for oral delivery. Nevertheless, although most of the studies undertaken so far have described microparticle uptake following oral delivery, uptake of microparticles following intranasal delivery was recently described in mice [119]. In addition, comparative studies have indicated that microparticles are one of the most potent adjuvants available for nasal delivery of recombinant protein vaccines in small animal models [131] (Figure 3A and B). In addition, microparticles also have potential for intranasal delivery of DNA vaccines [132] (Figure 4). While microparticles retain significant potential for mucosal delivery of vaccines, particularly for the intranasal route, their potency may be improved by use in combination with additional adjuvants. In a recent study in a large animal model, the potency of mutants of heat labile enterotoxin from *Escherichia coli* as mucosal adjuvants for an influenza vaccine was improved by formulation into a novel microsphere delivery system [133] (Figure 4A and B). The combination of optimal delivery

**Figure 3** Serum IgG antibody and neutralization titers (A) and mucosal IgA titers in nasal and vaginal wash samples (B) following intranasal immunization in mice with a recombinant glycoprotein (gD2) from herpes simplex virus type 2 in combination with MF59 emulsion, PLG microparticles, ISCOMs, or LTK63 adjuvants. Titers were determined 2 weeks after three monthly immunizations with 10  $\mu\text{g}$  HSV gD2 in combination with adjuvants.

system and adjuvant is likely to be a prerequisite for the development of effective oral vaccines, since the challenges faced should not be underestimated. Accumulated experimental evidence suggests that simple encapsulation of vaccines into microparticles is unlikely to result in the successful development of oral vaccines and improvements in the current technology are needed [134]. Nevertheless, microparticles continue to show significant promise as delivery systems for intranasal immunization [135]. However, most of these data have been generated in small animal models and the performance of microparticles for intranasal immuniza-

**Figure 4** Serum IgG (A) and nasal wash IgA (Ab) antibody responses following immunization in pigs ( $n = 4$ ) with influenza vaccine (HA) alone IM, IN with mucosal adjuvant LTK63, or IN with bioadhesive hyaluronic acid (HYAFF) microspheres in combination with LTK63. Pigs were immunized at 0 and 4 weeks with 25  $\mu$ g HA alone IM or 25  $\mu$ g HA in combination with 100  $\mu$ g LTK63 IN.

tion in larger animals and humans remains to be evaluated. Although the stability of antigens following microencapsulation into PLG microparticles can present significant problems, recent work has suggested that microparticles with adsorbed antigens may also be used for mucosal immunization [136,137]. These approaches are similar to the approach described earlier involving the preparation of PLG microparticles with adsorbent surfaces for antigen delivery [93]. In addition, particulate polymeric lamellae with adsorbed antigens may also be used for mucosal immunization [138]. Alternatively, significant success has been achieved recently by using soluble polymers or microparticles of chitosan for mucosal immunization [139,140]. In recent studies, micro-

particles have also shown some promise for mucosal delivery of DNA [141–143]. Nevertheless, optimal responses are likely to be achieved with microparticle formulations that have been modified to maintain the integrity of entrapped DNA [143,144].

A wide range of alternative delivery systems, including liposomes and iscoms, has also been evaluated for mucosal delivery of vaccines [129]. The development of polymerized liposomes, which show enhanced stability in the gut, offers potential for the development of oral vaccines [145], particularly if the delivery system can be targeted for optimal uptake into the M cells [146]. Nevertheless, this approach represents a very complex delivery system that might prove difficult and expensive to manufacture at large scale. However, work continues to identify the optimal targeting agents for use in the gastrointestinal tract [147]. Significant success has been achieved in the clinic using IRIV as an influenza vaccine for intranasal immunization and the approach appears to be safe and immunogenic [148–150]. Nevertheless, although the safety data were sufficient to allow this product to be introduced into the market in Switzerland in 2000, the inclusion of wild type, heat-labile enterotoxin from *E. coli* as an adjuvant in the vaccine will ensure that there will be close monitoring of this approach postlicensure. Unfortunately, the clinical data indicated that potent immune responses were not induced by IRIV in the absence of the enterotoxin adjuvant [148]. Iscoms can also be used for intranasal delivery of vaccines [151], including influenza [152].

Another alternative delivery system for mucosal immunization is represented by proteosomes, which are formed from the outer membrane proteins from *Neisseria meningitidis* [153]. Proteosomes were recently used for intranasal delivery of influenza vaccine in mice [154] and of *Shigella sonnei* LPS antigen in man [155].

## V. FUTURE DEVELOPMENTS IN VACCINE ADJUVANTS AND DELIVERY SYSTEMS

Several recent issues have served to highlight the urgent need for the development of new and improved vaccines. These have included the following: 1) the inability of traditional approaches to enable the successful development of vaccines against “difficult” organisms, including those that establish chronic infections, e.g., HIV and HCV; 2) the emergence of new diseases, e.g., Ebola, West Nile, and nvCJD; 3) the reemergence of “old” infections, e.g., TB; and 4) the continuing spread of antibiotic-resistant bacteria. A likely component of new and improved vaccines will be more potent adjuvants and delivery systems. The adjuvant formulations to be used in these vaccines may have to closely mimic an infection to elicit protective immunity. This may be achieved through the use of particulate antigen delivery systems that have similar dimensions to pathogens and are able to target antigens to macrophages and DCs. In addition, it may also be necessary to deliver one or more adjuvant active molecules, which will more fully activate the innate response and may result in the desired type of adaptive response. If this hypothesis is correct, it suggests that a delicate balance must

be maintained between the desired initiation of immune responses and avoidance of the problems potentially associated with an overly robust response, e.g., local tissue damage and systemic cytokine release. Many new-generation vaccines will require the induction of potent CMI, including CTL responses, to be effective. Accumulated research shows that induction of CTL is difficult with proteins and may require much stronger stimulation of the immune system than is normally required for a humoral response. Therefore, DNA remains an attractive approach for many pathogens, but needs to be delivered more effectively to improve its potency in humans. Microparticle-based delivery systems are showing considerable promise in this area.

Targeted delivery of adjuvants and antigens to specific cell types or tissues may reduce potential toxic effects and help to achieve a specific desired response. Targeting may be achieved at several different levels to include tissue specific delivery to local lymph nodes, cell-specific targeting to APC, or targeting to subcellular compartments, e.g., the proteasome to promote class I presentation or the nucleus for DNA vaccines. Most antigen delivery systems are effective, largely as a consequence of their "passive" uptake into macrophages and DCs following injection. However, "active" targeting may also be achieved through the use of ligands designed to specifically interact with preferred cell types. For example, the literature shows that lectins have been successfully used to target antigens [156], liposomes [157], and microparticles [158] to the M cells of MALT following mucosal delivery. An alternative targeting ligand is the mannose receptor, which has been used to target liposomes to APCs [159]. Further developments in the delivery of adjuvants may be achieved through the identification of the recognition mechanisms of specific receptors on APC, which might be extra or intracellular. If the receptors are intracellular, such as TLR 4 [160], then a means to promote uptake of the adjuvant by the relevant cells may be required for optimal efficacy. We have shown recently how synergy may be achieved through the combination of an adjuvant, an antigen, and a delivery system to induce potent immune responses [94]. Moreover, a similar synergy may also be achieved for mucosally administered vaccines [133].

Future developments in adjuvants are likely to include the development of more site-specific delivery systems for both mucosal and systemic administration. In addition, the identification of specific receptors on APCs is likely to allow targeting of adjuvants for the optimal induction of potent and specific immune responses. However, further developments in novel adjuvants will likely be driven by a better understanding of the mechanism of action of currently available adjuvants and this is an area of research that requires additional work.

## ACKNOWLEDGMENTS

I would like to acknowledge the contributions of my colleagues in the Vaccine Delivery Group at Chiron Corporation, including Manmohan Singh, Mildred Ugozzoli, Michael Vajdy, Jina Kazzaz, Elawati Soenawan, and Maylene Briones, who were responsible for generating the data

included in this chapter. I would also like to thank Nelle Cronen for help in the chapter preparation.

### I. BACKGROUND AND CHARACTERIZATION

#### A. Background

Successful subunit vaccines are comprised of two essential components. The first component is the antigen to which protective immune responses are to be generated. Such antigens may be proteins, polysaccharides, or lipopolysaccharides (LPS) purified from target organisms, or recombinant somatic proteins, genetically or chemically detoxified toxins, or synthetic peptides. Using defined products has the advantage of including only those moieties required for protective immune responses while excluding extraneous or toxic cellular or nuclear components commonly present in whole microorganisms or crude extracts. The second component is comprised of the adjuvant and/or vaccine delivery vehicle, which provides structure and/or immunostimulation. This component promotes antigen recognition, presentation, and processing in a manner that generates optimal immune responses of the types and at the sites required to provide protective immunity.

A great challenge of vaccine delivery and adjuvant research is to develop safe subunit mucosal vaccines that elicit protective mucosal immunity. Antigens adequately immunogenic when injected with adjuvant are frequently wholly ineffective when administered mucosally. Ideally, a mucosal vaccine would also provide systemic immunity when needed. Another much sought goal has been the development of vaccines that direct immune responses toward enhanced Type 1 T-cell immunity, which can be critical to eliciting protective responses for certain prophylactic or therapeutic vaccines. This chapter focuses on the development of Proteosome™-based delivery platforms and adjuvants to provide improved prophylactic and therapeutic vaccines against a variety of diseases. The ability of Proteosome technology to effectively and simultaneously confer both nasal immunogenicity as well as Type 1 immunity will

be highlighted. The advantages of Proteosome nasal vaccine delivery, demonstrated in both preclinical studies as well as in multiple human clinical trials, will be presented.

#### B. Design

The Proteosome nomenclature was selected to emphasize the distinctive physical and biological properties of preparations of outer membrane proteins (OMPs), particularly from meningococci [1–3] and other *Neisseria* [4,5]. Proteosome proteins are highly hydrophobic, reflecting their role as transmembrane proteins and porins [4,6,7]. When isolated by detergent extraction, their hydrophobic protein–protein interactions cause them to naturally self-assemble into multimolecular, membranous nanoparticles with morphological characteristics of vesicles, up to several hundred nanometers in diameter. Such Proteosome particles may be readily disassociated into vesicle membrane or multimolecular fragments to a variable extent, depending on the type and the strength of detergent chosen for their isolation, storage, or Proteosome vaccine formulation [1–8]. Indeed, the ability of Proteosome vaccine particles to be reconstituted upon substantial detergent removal is a key advantage of the simplicity of Proteosome vaccine design.

##### 1. Proteosome™ Noncovalent Complex Vaccines

The primary mode of creating Proteosome-based vaccines is to process a mixture of detergent-solubilized Proteosome particles and amphiphilic antigens in a manner that facilitates noncovalent complexing or association of the antigens with Proteosome particles while effecting marked diminution of the solubilizing detergent. This process can result in soluble Proteosome vaccine particles when antigen hydrophobic “anchor” moieties sufficiently satisfy Proteosome hydrophobic sites while antigen hydrophilic moieties remain exposed, creating a hydrophilic microenvironment around

the Proteosome vaccines [1–5,7,8]. Resultant Proteosome vaccines are thereby comprised of noncovalent complexes or associations in which reconstituted Proteosome multimolecular nanoparticles are studded with intercalating amphiphilic antigen. The current lead example of this Proteosome vaccine system is FluINsure™, a nasal Proteosome influenza vaccine currently in Phase 2 clinical trials under development [9] at ID Biomedical Corporation (IDB).

## 2. Proteosome™ IVX-908 Vaccine Adjuvant

A second approach to developing Proteosome-based vaccines is to formulate a mixture of vaccine antigen with a soluble preformed Proteosome adjuvant preparation comprised of Proteosome particles complexed with LPS. This system, tentatively called IVX-908 [10], differs from the first Proteosome system described in that vaccine antigens adjuvanted by IVX-908 (a) may be either amphiphilic or entirely hydrophilic and devoid of recognizable hydrophobic “anchor” moieties, and (b) are formulated by mixing antigens with the preformed LPS-solubilized Proteosome particles. IVX-908 is referred to as an adjuvant because the immunostimulatory properties of Proteosome particles (see below) are complemented by the well-described adjuvant properties of native LPS it contains and because it is effective when simply mixed with the antigen (although antigen interaction with IVX-908 particles has not been ruled out). Given the substantial amount of LPS in IVX-908, it is germane that a favorable safety profile of an IVX-908 prototype given nasally alone (as a Proteosome *Shigella* LPS vaccine) has already been demonstrated in both preclinical toxicity studies as well as in Phase 1 and Phase 2 clinical trials [11,12].

## C. Mechanisms of Action

### 1. Proteosome™ Vaccine Delivery Vehicle Characteristics—Particulate and Hydrophobic Structure

Proteosome particles are considered to serve as vaccine delivery vehicles for antigens associated with them by virtue of their nanoparticulate, multimolecular, vesicle-like nature. Proteosome vaccine particles and particle clusters are generally comparable to the size of certain viruses, ranging in size from 20 to 800 nm in diameter, depending on the type and the amount of antigen formulated. This biophysical characteristic, mandating that vaccine antigens associated with Proteosome particles are treated as particles rather than as soluble proteins, is deemed to benefit from immunogenicity because components of the immune system characteristically recognize and respond to particles differently and frequently more efficiently than they do soluble antigens. In addition, the hydrophobicity of both Proteosome porin proteins and the hydrophobic anchor of amphiphilic antigens associated with Proteosome particles may contribute to vaccine delivery capabilities by inhibiting antigen degradation, facilitating antigen uptake, and/or directing antigen processing to intracellular pathways that promote Type 1 T-cell responses. In this regard, the major OMPs in *Neisseria meningitidis* Proteosome particles, PorA (class 1) and PorB (class 2 or 3), are protein porins that naturally form trimers that constitute pores allowing anion exchange through the

bacterial membrane [5,6]. That these neisserial porins can, *in vitro*, translocate and insert into host cell membranes [6] suggests that Proteosome vaccine delivery function may be related to these unique porin properties. Although from the particulate or hydrophobic perspective, Proteosome particles may be viewed as having some commonality with certain microsphere [13], liposome [14], or other lipid-based vaccine delivery vehicles [15,16]; the intrinsic porin protein properties of Proteosome particles as well as the immunostimulatory capacity (described below) clearly distinguish them from the “inert” systems that rely only on their particulate nature to promote immune responsiveness.

### 2. Proteosome™ Adjuvant Characteristics—Immunostimulation

Proteosome adjuvant potential was first suggested by the ability of Proteosome OMPs to initiate B-cell activation as measured by B-cell proliferation and polyclonal antibody secretion in both human [17] and murine [18–20] cells. The murine mitogenicity experiments showed that OMP activation was not LPS-mediated [18,20–22]. This is significant because LPS is a well-known adjuvant and B-cell mitogen [23] and a minor component of Proteosome preparations (<2% in typical IDB Proteosome preparations). In these experiments, Proteosome proteins induced B-cell activation in C3H/HeJ mice that are resistant to LPS stimulation [18–22] due to a natural point mutation in the gene encoding the Toll-like receptor (TLR) 4 [24] necessary for LPS-mediated signal transduction [25]. Over the last several years, Wetzler et al. have provided considerable evidence to support the mechanism of Proteosome adjuvanticity. First, they demonstrated that *Neisseria* OMP recognize and upregulate B7.2 (CD86) costimulatory ligand on B-cell antigen-presenting cells, which results in augmented costimulation of T cells by interacting with its counterreceptor, CD28 [20]. They then showed, using TLR2 knockout mice, that this OMP-mediated activation is due to induction of NfkB nuclear translocation dependent upon B-cell expression of MyD88 and TLR2, but not TLR4 [26]. Porin OMP activation was therefore clearly differentiated from LPS activation, which depends on TLR4 and not TLR2 [25,27]. Most recently, they reported that Proteosome PorB (class 2 or 3) protein also induces maturation of professional APCs as shown by upregulation of B7.2, class I, and class II MHC molecules on C3H/HeJ dendritic cell (DC) surfaces with concomitant enhanced DC allostimulatory activity [28]. This increased expression of B7.2 costimulatory molecules on B cells and DC provides the “second signal” that increases their capacity to costimulate T cells by lowering the threshold number of T-cell receptors required to trigger T-cell responses at a given antigen dose [29]. The result is increased T-cell sensitivity to antigenic stimulation and enhanced immune responses.

These data support the theory of the involvement of TLRs with innate immunity and bacterial adjuvant functions [26,30] now including, in addition to Proteosome porins with TLR2, peptidoglycan and lipoprotein with TLR2 [30], LPS with TLR4, and CpG DNA motifs with TLR9 [31]. Promotion of expression of TLRs on B cell and DC APCs with subsequent upregulation of the efficiency of APC processing and presentation of antigens to T cells appears to be the key

to understanding the mechanism of Proteosome-mediated adjuvanticity and may also explain Proteosome vaccine promotion of Type 1 T-cell responses. Furthermore, the report [32] that alveolar macrophages present antigen inefficiently to CD4<sup>+</sup> T cells due to defective expression of B7 costimulatory cell surface molecules supports the concept that the nasal Proteosome vaccine advantage is to provide APC TLR activation to effect enhanced respiratory immunogenicity. And last, in addition to vaccine delivery and adjuvant activity, complexing antigen to Proteosome particles may provide broader or exclusive T-cell help for antigens that alone lack the ability to effectively stimulate helper T cells.

The role of TLRs in the adjuvanticity of Proteosome-based vaccines is also particularly relevant to the mechanism of action of the LPS-bearing Proteosome adjuvant, IVX-908, because both Type 2 and Type 4 TLR stimulation can be expected to contribute to adjuvanticity due to the presence of LPS, a known TLR4 stimulant, in IVX-908. Moreover, IVX-908 can be effective without formulating the antigen with Proteosome particles to facilitate complexing; hence, the “vaccine delivery” role is not applicable and the “adjuvant” role is paramount.

#### D. Safety for Human Use

Safety is the first prerequisite in choosing a system to improve vaccines and is a prime consideration in developing Proteosome platform technology. Meningococcal (Mgc) OMPs comparable to those present in Proteosome vaccines have been safely given parenterally to hundreds of millions of children in a *Haemophilus influenzae* Type b (Hib) conjugate vaccine licensed for infants and adults since 1990 [33]. In this Hib vaccine, Mgc OMPs are covalently linked via bigeneric spacers to Hib polyribosyl ribitol phosphate (PRP) polysaccharide to serve as carrier proteins for PRP so that the vaccine can provide bactericidal anti-PRP IgG antibodies [33]. Similar Mgc OMP preparations have also been hydrophobically complexed to Mgc capsular polysaccharide and given by injection to millions of children and adults in clinical trials designed to protect against meningococcal disease [7]. Most significantly, nasal Proteosome vaccines (including FluINsure and IVX-908) have demonstrated a good safety profile in ~500 persons in Phase 1 and Phase 2 clinical trials of influenza and *Shigella* vaccines. Indeed, in GLP-compliant toxicity studies performed prior to these trials, nasal Proteosome vaccines were successfully evaluated in over 1500 animals using dose levels up to 30-fold greater than projected human doses on a weight-adjusted basis.

#### E. Versatility for a Variety of Antigen Types for Immunoprophylactic and Immunotherapeutic Vaccines

Any antigen with a hydrophobic moiety available for interacting with Proteosome particles is suitable without modification for use in Proteosome vaccines. Such antigens include natural or recombinant transmembrane or envelope proteins with native hydrophobic amino acid anchor sequences and lipopolysaccharides, polysaccharides, or gangliosides with natural covalently bound lipid components. For LPS (and

hence, IVX-908), noncovalent complexing, verified by size exclusion HPLC [34] or standard chromatography [35], occurs via OMP interaction with LPS lipid A, whereas the *O*-polysaccharide, oriented outside the Proteosome particles, effectively solubilizes the hydrophobic OMPs such that the complex can be terminally sterilized by passage through a 0.22-μm membrane filter. Recombinant proteins can also be made suitable by inserting synthetic nucleotides coding for a hydrophobic anchor sequence into the recombinant genetical sequence toward either the carboxyl or amino terminus. Hydrophobic anchors can also be covalently coupled to antigens after purification. Synthetic peptides are particularly applicable for Proteosome vaccines because a hydrophobic anchor can be readily added toward either terminus of the peptide during synthesis. For any such antigens, either fatty acyl groups (e.g., lauroyl) or a series of 5–21 hydrophobic amino acids can serve as the hydrophobic anchor. A cysteine situated between the epitope and the anchor can be important to peptide immunogenicity perhaps due to cysteic dimerization of both the anchor and the peptide with resultant increases in stability of Proteosome interactions with antigen. The hydrophobic region of antigens responsible for Proteosome interaction may be subtle, as suggested by use of formalinized toxoids whose cross-linked free amino groups may serve this purpose.

Antigens should be oriented so that important epitopes are neither buried nor altered during formulation or complexing with vaccine adjuvants or delivery vehicles. This can be problematical for covalent complexing. Noncovalent complexing to Proteosome particles avoids this problem because antigens complex via hydrophobic moieties distal from important epitopes (which are usually highly hydrophilic [36]). This unidirectional binding of antigens to Proteosome particles allows antigen epitopes to remain unaltered and exposed for recognition by antigen processing cells. Optimal peptide or recombinant protein orientation can be determined by selecting the appropriate position for the hydrophobic anchor. For native transmembrane proteins, such as influenza hemagglutinin (HA), the antigen is posited to insert into the Proteosome particles much as it does in the native viral membrane, thereby promoting maintenance of its native antigenic three-dimensional structure.

The versatility of Proteosome-based vaccines has been further broadened by the IVX-908 adjuvant system because IVX-908 can be mixed with either amphiphilic or nonamphiphilic antigens, and the latter may be more readily available for certain vaccines. Versatility is further emphasized because, in addition to prophylactic vaccines against infectious diseases, IVX-908 is especially suited for nasal immunotherapeutic allergy vaccines, which benefit Type 1 immunity and the shift of immune response patterns away from the allergic responses associated with Type 2 immunity.

#### F. Simplicity of Scale-Up and Guanylic Acid Production

There has been much progress over the past several years in the scale-up and guanylic acid (GMP) manufacture of Proteosome particles and vaccines. To date, >30 Proteosome lots (>10 GMP and >20 development lots) purified from more than eight bacterial cell paste lots have been produced

with demonstrated consistency under a high level of quality systems oversight. The robustness and scalability of the Proteosome production process have allowed successful technology transfer/production at four sites including an FDA-inspected and FDA-licensed facility. Proteosome particles have maintained protein stability and integrity after more than 3 years at  $-20^{\circ}\text{C}$  in bulk storage and for 1 month at  $40^{\circ}\text{C}$  in accelerated stability studies. A Proteosome protein consistency profile with low level of residuals has been verified by LC-MS, SDS-PAGE/Western blots, RP-HPLC, N-terminal sequencing, and amino acid analysis. Proteosome vaccines and IVX-908 have inherently favorable stability profiles at clinical storage ( $4^{\circ}\text{C}$ ) demonstrated by retention of vaccine complex and protein integrity, particle size stability, and vaccine potency. IVX-908 and Proteosome vaccines can also retain potency after lyophilization and reconstitution (when the antigen tolerates lyophilization). Proteosome vaccines and IVX-908 are produced by a simple, scaleable 1-day process designed to promote optimal non-covalent complexing or association of Proteosome particles with antigen (or, for IVX-908, with LPS) while the solubilizing detergent is removed. This process allows production technology used in preclinical research to be consistent with that performed in scale-up GMP production suites for human clinical trials and for commercial production. Moreover, the simple and efficient design of the key manufacturing method (diafiltration/ultrafiltration) attests to the demonstrated ease of Proteosome vaccine formulation with a variety of antigens and allows for cost-effective production and inexpensive cost of goods favorable for commercial development.

## II. NASAL VACCINES FOR RESPIRATORY DISEASES

### A. Influenza

#### 1. Background

The Proteosome vaccine application that has made the greatest advance toward commercialization is FluINsure, the nasal Proteosome-based vaccine for influenza under development by ID Biomedical Corporation. Each year in North America and Western Europe, an estimated 57 million cases of influenza occur, leading to at least 210,000 hospitalizations and as many as 70,000 deaths [37]. Most deaths occur in the elderly [38], but there is a significant disease burden in infants [39] and preschool children, who also serve as major disseminators of the virus [20]. Although licensed injectable influenza vaccines reduce morbidity and mortality, vaccination compliance, especially in high-risk groups such as infants and the elderly, is often low [37]. In addition, despite being at least 70% effective in preventing influenza illness in healthy adults [41], the virus-specific serum antibodies elicited by current injectable influenza vaccines limit the spread of the virus, but are relatively ineffective at preventing infection or shortening viral shedding [37]. Moreover, current injectable vaccines are significantly less immunogenic (40–60%) in the elderly [42] and require two injected doses yearly in children [40]—two situations that further limit vaccine acceptance. Reduced

compliance and immunogenicity ensure that large sectors of the population remain at high risk of infection and complications caused by influenza.

#### 2. Rationale

FluINsure is efficiently manufactured using the diafiltration technology designed to remove solubilizing detergents and to facilitate Proteosome association with antigen. The antigens in trivalent FluINsure are three conventional “split-flu” influenza antigens comparable to those used yearly in all currently licensed inactivated injectable influenza vaccines. Like conventional intramuscular vaccines, FluINsure dosing is based on hemagglutinin (HA) content. FluINsure is a nasal spray vaccine with fewer safety issues because it is a nonliving, subunit vaccine that, unlike live influenza nasal vaccines, is noninfectious and cannot be transmitted from person to person or have unwanted interactions with wild-type viruses. FluINsure also has potential to provide decreased morbidity against influenza compared to intramuscular vaccines because, in addition to producing serum HAI antibodies, FluINsure elicits antiviral secretory IgA antibodies in nasal passages where influenza invades. Indeed, such nasal antibodies have been shown to be a strong correlate of reduced infection and illness [37,49,50]. Each of these factors (user-friendly needle-free vaccination, good safety profile, decreased safety concerns, and potential for more complete immunity) is expected to increase vaccination compliance in all age groups.

#### 3. Preclinical Immunogenicity Studies

Murine studies of nasal Proteosome influenza vaccines showed induction of virus-specific serum IgG, HAI, and virus-neutralizing antibodies in titers equivalent to those induced by HA vaccine antigens given in the same dose as classical inactivated intramuscular vaccines, or as a sublethal infection with homologous virus [43,44]. Induction of statistically significant virus-specific serum IgA responses, as well as nasal and pulmonary IgA responses including neutralizing antibodies in lung washes, was found in mice immunized nasally with Proteosome influenza vaccine, but not those of mice given the intramuscular vaccine or given the flu antigen without Proteosome particles. In addition, the nasal Proteosome vaccine generated virus-reactive T cells that produced the Type 1 cytokine interferon gamma (IFN- $\gamma$ ) without activating Type 2 cytokine (IL-5) responses. These data were in marked contrast to immunization either intramuscularly or nasally with influenza antigen alone, which resulted in strong IL-5 responses and less IFN- $\gamma$ , indicating a mixed Type 2/Type 1 response [44]. The pattern of strong Type 1 T-cell responses shown by the Proteosome influenza vaccine is consistent with the pattern typically associated with cytotoxic T-cell induction that prevents the spread of influenza virus. Furthermore, nasal Proteosome influenza vaccine induced solid protection against a lethal respiratory challenge of homologous mouse-adapted virus [44].

Subsequent murine studies were designed to verify the applicability of trivalent formulations of FluINsure for human use showing that (a) H1, H3, and B influenza proteins in FluINsure were immunogenic, and that (b) FluINsure can be given periodically to provide immunity to new or recur-

rent circulating strains. This is important because influenza vaccines are routinely given every year to match newly emerging circulating strains of influenza virus. In experiments designed to mimic the human experience, mice were reimmunized with a nasal Proteosome influenza vaccine 9 months after (1) receiving the identical Proteosome vaccine, or (2) exposure to antigens of an older strain of influenza given in the form of either (a) a nasal Proteosome influenza vaccine, (b) a standard intramuscular split-flu vaccine, or (c) live influenza virus. In each of these experimental situations, high levels of serum and mucosal antibodies that recognized the strain of influenza present in the Proteosome vaccine used for reimmunization were induced. These data indicate that yearly administration of nasal Proteosome influenza vaccine can be immunogenic for the most recent strain administered, whether the subject was previously exposed to influenza antigens as either a nasal Proteosome vaccine, a standard intramuscular vaccine, or influenza infection [45].

#### 4. Preclinical Toxicity Studies

Nasal Proteosome influenza vaccines were studied in 400 mice, a relevant animal model in which both influenza disease and influenza vaccine-induced protective immunity can be studied. All studies used a three-dose series, with the last dose given in the presence of a documented preexisting immune response. These studies evaluated dose levels up to 20-fold greater than projected human doses on a weight-adjusted basis. No vaccine-attributable weight loss or clinical findings, no changes in blood hematological or chemical parameters, and no vaccine-attributable pathology in any organ (including the nose, sinuses, upper respiratory tract, or adjacent central nervous system tissues such as the olfactory bulb) were found in any animal. The observed absence of pathology in neural tissue was especially important to nasal Proteosome vaccine development because advanced development of other powerful nasal adjuvants [notably those of the cholera toxin (CT) and *Escherichia coli* heat-labile toxin (LT) family] has been significantly impeded due to the finding of olfactory bulb toxicity in mice [46] and the inability to rule out an association with facial nerve palsy in humans (AP news report).

#### 5. Clinical Studies of FluINsure™ Nasal Proteosome™ Influenza Vaccines

As of this writing, seven Phase 1 or Phase 2 dose-escalating clinical trials of FluINsure using single-dose (15, 30, or 45 µg HA) and two-dose (7.5, 15, or 30 µg of HA per dose) regimens with placebo or vaccine comparator controls have enrolled 500 healthy adults in the United States and Canada. These trials to date include two Phase 1 trials of a monovalent (A/Beijing/H1N1) prototype [47], and a Phase 1 [48] and four Phase 2 trials of trivalent FluINsure. Safety data from this clinical experience indicate that FluINsure is well tolerated. Systemic reactions did not exceed those of the standard intramuscular influenza vaccine in one study, and could not be distinguished from those following placebo doses in another trial. No vaccine recipient has had fever. The only local reactions significantly associated with active nasal vaccine in both parallel and crossover study designs, mild and short-lived nasal stuffiness, and/or rhinorrhea occur in

30–60% of vaccinees (exceeding placebo recipients by 10–20%) and only rarely are reported to interfere with normal daily activities in any way. Immunogenicity data in humans have been similarly very encouraging. Significant increases in serum hemagglutination-inhibiting (HAI) antibodies are induced to all strains and at all dose regimens tested, and the observed dose response is shallow, suggesting that the clinically useful nasal dose of influenza antigen when given in FluINsure may be similar to, or only modestly higher than, the dose now used for intramuscular immunization. In addition, statistically significant rises in secreted IgA antibodies in nasal fluid are found in all treatment groups, and are especially high and persistent in recipients of two-dose regimens. This suggests that an important immune response is produced on the respiratory mucosa, where it can meet the invading virus before infection is established. Indeed, specific sIgA in the nose is documented to be a strong correlate of reduced infection rate, limited viral replication, and reduced illness in influenza challenge studies in adults [37,49,50]. Preliminary data in subjects from the first trivalent study indicate that potentially protective immune responses, consisting of one or more of a serum reciprocal HAI titer of  $\geq 40$ , a  $\geq 4$ -fold rise in HAI titer, and/or a significant rise in virus-specific nasal wash secretory IgA, are found, for H1, H3, and B strains, respectively, in 74%, 90%, and 95% of one-dose vaccinees and 83%, 94%, and 100%, respectively, of two-dose vaccinees. It is particularly encouraging that subjects nonimmune before immunization (serum reciprocal HAI titers  $< 40$ ) show comparable values. These serum HAI and nasal sIgA responses appear at least equal, and often superior, to those elicited by nasal immunization with live cold-adapted influenza virus vaccines in similar adult populations [51]. These data were so encouraging, that two of the placebo-controlled double-blind Phase 2 immunogenicity trials were followed by an experimental challenge of subjects with live influenza to demonstrate FluINsure-induced protection against influenza illness. While all the data from both challenge studies are not available as of the writing of this chapter, ID Biomedical has announced that the safety and immunogenicity results from the first challenge trial are consistent with the previous results cited above and furthermore, that the optimal regimen of FluINsure elicited 100% protection against laboratory confirmed influenza illness. With the success of these studies, a large field trial is scheduled for late 2003 to show efficacy during the winter 2003–2004 influenza season.

#### 6. Preclinical Influenza Pandemic Preparedness Studies

FluINsure is eminently suitable for pandemic influenza vaccine preparedness because its manufacture is just as readily accomplished with split-flu conventional antigens as it is with recombinant HA (rHA) produced in tissue culture [52]. Nasal immunization of mice with baculovirus-derived rHA formulated into Proteosome vaccines using dialysis technology resulted in higher levels of HAI antibodies and antiviral IgG in serum than mice immunized intramuscularly with the same doses of rHA alone. In addition, only the Proteosome rHA vaccine induced antiviral IgA in lung and nasal respiratory fluids. Furthermore,

as shown by analysis of IgG isotype ratios and cytokine ( $\gamma$ -IFN, IL-5, and IL-2) secretion from restimulated spleen cells, the nasal Proteosome rHA vaccine clearly elicited responses that were more strongly of the Type 1 phenotype than rHA alone. Live virus challenge studies showed that immunization with either the Proteosome rHA vaccine nasally or rHA alone intramuscular totally protected against death by lethal challenge; nevertheless, protection against morbidity, as measured by significant weight loss, was higher in mice immunized nasally with Proteosome rHA vaccine compared to mice given rHA alone by either the nasal or intramuscular route. This study expands the type of influenza antigen that can be used in FluINsure to include recombinant proteins and is a significant asset to pandemic preparedness because availability of conventional egg-derived influenza antigens from pandemic influenza strains may be problematical.

#### 7. Preclinical Influenza Studies with the Lipopolysaccharides-Bearing Proteosome Adjuvant, IVX-908

In mouse studies, nasal immunization with IVX-908, mixed with either conventional split-flu antigen preparations or baculovirus rHA, resulted in strong stimulation of serum HAI, serum IgG, and lung IgA titers [10]. These responses were of the Type 1 phenotype as measured by high IFN- $\gamma$  and absent IL-5 secretion, and were strongly protective against mortality and morbidity due to live virus challenge. Because IVX-908 can adjuvant immune responses either with amphiphilic or soluble antigens (see "Allergies" below), this technology is a promising candidate as a nasal vaccine adjuvant for a variety of viral or bacterial antigens.

#### 8. Preclinical Studies with Influenza Viral Peptides

A study of nasal Proteosome vaccines using influenza peptides showed that Proteosome vaccines containing influenza peptides representing T-cell and B-cell influenza-specific epitopes can protect a murine model of viral influenza infection [53]. Mice were immunized nasally with Proteosome peptide vaccines containing one to three influenza peptides: a conserved HA B-cell peptide for protective antibodies and two nucleoprotein peptides with either a T-helper cell or cytotoxic T-cell (CTL) epitope. The Proteosome vaccines containing the B-cell epitope elicited antivirus IgA in the lung and Proteosome vaccines containing T-cell epitopes induced proliferative responses and histological evidence of cellular immunity in mouse lungs and spleen. The latter correlated with protective immunity shown by reduction in lung viral titers in mice challenged 2 months after immunization with Proteosome vaccines containing both B-cell and T-cell epitopes [53]. These results support the concept that Proteosome technology is a versatile intranasal delivery platform for multivalent peptide vaccines that enhance humoral and cellular immunity against microbial pathogens.

### B. Biothreat Agents

#### 1. Plague

Plague is caused by *Yersinia pestis* bacteria responsible for over 150 recorded epidemics and pandemics and is recog-

nized as a major potential bioterrorism threat agent. Plague pneumonia is highly contagious because large numbers of bacteria can rapidly spread through coughing and initial symptoms are similar to the flu. For effective biodefense against plague, it is of paramount importance that a vaccine prevent the pneumonic form of infection and there is no such licensed vaccine. In collaborative studies between the U.S. Army Medical Research Institute for Infectious Diseases and IDB, nasal immunization of mice with a Proteosome-based Plague vaccine consisting of IVX-908 plus the recombinant fusion protein F1-V induced high levels of antiplague IgG antibodies in serum as well as IgA antibodies in respiratory lavage fluids. Most importantly, this vaccine with 1  $\mu$ g or 2.5  $\mu$ g IVX-908 elicited 100% protection against death in mice challenged either 35 or 55 days post-immunization by exposure to an aerosol containing 169 LD<sub>50</sub>s (inhaled dose) of lethal plague bacteria.

#### 2. Staphylococcal Enterotoxin B and Ricin

Staphylococcal enterotoxin B belongs to a family of *Staphylococcus aureus* superantigen [54] exotoxins that causes human food poisoning and nonmenstrual toxic shock syndrome (TSS) [55,56]. In nonhuman primates, SEB results in lethal shock after aerosol exposure and is therefore a potential biological weapon [57,58]. Nasal immunization of mice with formalinized SEB toxoid formulated with Proteosome particles elicited high levels of anti-SEB serum IgG as well as IgA in lung and intestinal secretions, and afforded significant protection against lethal intramuscular or respiratory SEB challenge in murine models of intoxication [59]. In contrast, intranasal or intramuscular immunization with toxoid in saline without Proteosome particles was not significantly protective against challenge by either route. Immunogenicity and efficacy were confirmed in the nonhuman primate aerosol challenge model of SEB intoxication [60]. Monkeys primed intramuscular (with alum) and boosted twice either intramuscular or intratracheally with the Proteosome SEB toxoid vaccine showed anamnestic anti-SEB serum IgG rises in all monkeys. Strong IgA responses in sera and in bronchial secretions were elicited both pre-SEB and post-SEB challenge only in monkeys boosted intratracheally [60]. The Proteosome SEB toxoid vaccine was efficacious by both routes, protecting 100% of monkeys against severe symptomatology and death from exposure to a 15 LD<sub>50</sub> dose of aerosolized SEB [60]. Nasal immunization of mice with Proteosome vaccines containing SEB or ricin peptides also elicited antitoxin IgA in lung and intestinal lavage fluids as well as serum IgG [61,62].

#### 3. Brucella

To develop a vaccine against respiratory exposure to *Brucella*, a potential biological threat agent, mice and guinea pigs were intranasally immunized with meningococcal OMPs hydrophobically complexed to *Brucella melitensis* LPS [63] using techniques comparable to those described for Proteosome *Shigella* LPS vaccines [35]. High and persistent levels of anti-*Brucella* LPS serum IgG and high IgG and IgA lung lavage fluid antibodies and antibody-secreting cells in lungs, cervical lymph nodes, and spleen were found

[63,64]. Mice were protected against respiratory challenge with virulent *B. melitensis* as shown by reduced bacterial dissemination to spleen and liver, although the course of the lung infection was unaltered [64].

### C. Allergies

Allergic individuals respond to allergen proteins by producing Type 2 T-cell cytokines (e.g., IL-4 and IL-5), which direct or reflect IgE production that leads to allergic symptoms. Allergy immunotherapy “desensitization” vaccine strategies reverse allergic disease in allergic individuals by switching antiallergen immune responses from the Type 2 to the Type 1 phenotype with production of Type 1 cytokines such as interferon gamma. For conventional immunotherapy to show benefits, however, weekly and monthly injections with allergen extracts are required for up to 3 years. Proteosome-based allergy immunotherapy is designed to achieve the same switch in phenotype via nasal administration and is designed to be beneficial more quickly. The major allergen of birch tree pollen, BetV1, induces Type 2 allergic responses (high IL-5, low IFN- $\gamma$ , and high IgE) when given nasally in a mouse model of allergic disease. In marked contrast, when recombinant protein BetV1 or an allergen extract containing BetV1 are given nasally with Proteosome particles or, especially, with IVX-908, to naïve or sensitized mice, the immune response switches to a Type 1 phenotype against the allergen with production of high IFN- $\gamma$  levels and low levels of IL-5 and serum IgE [10,65]. Furthermore, sensitized animals treated with allergen extract plus IVX-908 and subsequently exposed to the allergen kept their Type 1 phenotype, whereas mice untreated or given allergen alone maintained their Type 2 phenotype with higher levels of Type 2 cytokines and serum IgE.

## III. NASAL VACCINES FOR GASTROINTESTINAL AND SEXUALLY TRANSMITTED DISEASES

### A. Shigella

#### 1. Preclinical Immunogenicity and Protection Studies in Small Animals and Nonhuman Primates

*Shigella sonnei* and *Shigella flexneri* are major causes of dysentery and diarrhea in residents of developing countries and in travelers to such locations from developed countries [66,67]. The O-specific polysaccharides of LPS of shigellae are the protective antigens for shigellosis, and local intestinal type-specific antibodies are considered a prime protective mechanism against enteric *Shigella* infections [68]. Either nasal or intragastric immunization of mice with Proteosome *Shigella* LPS vaccines for *S. flexneri* 2a and *S. sonnei* induced homologous anti-*Shigella* LPS IgG and IgA in sera and in bronchial and intestinal mucosal lavage secretions, although nasal immunization required 10- to 100-fold lower doses and resulted in serum antibody levels that persisted and was strongly elevated for > 1 year [34,35,69]. Also, guinea pigs nasally immunized with a Proteosome *S. sonnei* vaccine acquired high levels of anti-LPS IgA and IgG antibody-secreting cells (ASCs) in cervical lymph nodes [34,70]. Same day administration of Proteosome *S. sonnei* and *S. flexneri*

2a vaccines was as immunogenic as either given alone, indicating that multivalent Proteosome *Shigella* vaccines strains are practical [34,71]. Nasal immunization in small (5  $\mu$ L) volumes to deliver vaccine only to the nasopharynx elicited comparable IgG and IgA antibody levels in sera and in intestinal mucosa [72], confirming that respiratory immunization can induce the common mucosal immune system to secrete antibodies at nonrespiratory sites [34,35,71–73].

Two models of *Shigella* infections demonstrated efficacy of Proteosome *Shigella* LPS vaccines. Either intranasal or intragastric immunization conferred significant homologous protection against keratoconjunctivitis (*Shigella* eye infection) in the Sereny Test [35], data that further supported the common mucosal immune system. Efficacy of nasal or intragastric Proteosome *Shigella* LPS vaccines was also demonstrated in protection studies against fatal suppurative pneumonia in a murine challenge model of *Shigella* infection [34,69,72]. The ability of Proteosome vaccines to safely present LPS in a nontoxic form is underscored by the lack of observed toxicity of Proteosome LPS vaccines, whereas the same amount of LPS given alone was toxic to mice [69].

Safety and immunogenicity were also shown in two nonhuman primate studies in which 30 rhesus monkeys were immunized with Proteosome vaccines for *S. sonnei* [34,74]. The Proteosome LPS vaccines were well tolerated without noticeable adverse reactions. In the first study, three doses of Proteosome *S. sonnei* LPS given as intranasal nose drops [74] elicited 4- to 2048-fold serum IgG rises in 14 of 15 monkeys. In the second study, all monkeys immunized intratracheally or by intranasal spray responded with high serum IgG titer rises 128- to 4096-fold and 8- to 10,240-fold, respectively, whereas orogastric immunization elicited 4- to 32-fold rises in only three of five monkeys. In addition, all monkeys immunized intratracheally showed at least fourfold IgA rises in sera and bronchial lavage fluids, and twofold to fourfold serum IgA rises were elicited in all intranasal immunized monkeys [34].

Toxicity studies were performed prior to clinical trials of Proteosome LPS vaccines for *S. sonnei* and *S. flexneri* 2a vaccines, utilizing a total of 760 rodents, each immunized three times. Doses up to 30 times the human exposure on a weight-adjusted basis were given nasally in small volumes to conscious animals (to avoid vaccine aspiration). These exposures were both clinically and histologically benign, with no tissue damage or pathology of the upper or lower respiratory tract or other adjacent tissues including the olfactory bulb. Only minor increased nasal-associated lymphoid tissue cellularity was noted and, consistent with a normal response to vaccine antigen exposure and processing, resolved in animals sacrificed after a recovery period.

#### 2. Clinical Studies of *Shigella* Vaccines

Three dose-escalating Phase 1 or Phase 2 safety and immunogenicity trials of Proteosome vaccines for *S. sonnei* or *S. flexneri* 2a have been performed, enrolling 135 subjects, of which 111 received Proteosome vaccines nasally [11,12,75]. Doses, given in a two-dose regimen 14 days apart, ranged from 100 to 1500  $\mu$ g of Proteosome protein and contained comparable amounts of *Shigella* LPS. In summary, clinical safety analysis showed that the vaccines were well tolerated

even at the highest doses. There were no fevers, no sustained illness, and no serious or unexpected adverse events attributable to the vaccine. Repeated ENT exam 2 and 7 days after each dose showed no inflammation, mucosal lesions, otitis, or sinusitis. Transient nasal congestion, clear rhinorrhea, or mild nasal irritation that occurred in approximately one-half to two-thirds of vaccinees was generally mild and short-lived (2–3 days) and greater than 95% of vaccine doses caused no complaint that interfered with daily activities; all complaints were less after the second dose. Immunogenicity analyses showed that *O*-polysaccharide-specific immune responses were consistently evoked in multiple compartments: 90–100% responded with ASCs (IgA was strongest); 60–90% responded with serum antibodies (fourfold GMT increases in IgG and IgA were typical at 1-mg doses); IgA and IgG responses (3.5- to 6-fold at 1-mg doses) were found in stool; and IgA responses were detected in urine [11,12,75].

An experimental challenge trial was performed in which 14 vaccinees and 13 placebo recipients, at intervals ranging from 27 to 62 days after their last dose of test article, ingested 500 CFU of freshly prepared *S. flexneri* 2a in sodium bicarbonate buffer [76]. Although protective efficacy (PE) against any disease (diarrhea, dysentery, or fever) was 36% ( $P=0.04$ ), volunteers challenged <48 days postimmunization showed 78% PE ( $P=0.003$ ) against fever and 56% PE ( $P=0.03$ ) against severe symptoms. Increased levels of *S. flexneri* 2a-specific serum IgA after immunization (but not prior to immunization) were associated with a lower frequency of diarrhea ( $P=0.02$ ) and a lower frequency of any disease ( $P=0.01$ ), whereas serum IgG and blood ASC levels were not found to be predictive. These data are the first demonstration of human protection against any enteric disease by a subunit nasal vaccine and delivery system [76]. The increased protection against severe disease <48 days after immunization suggests that improved efficacy might be achieved by monthly booster doses. This strategy may be practical for high-risk individuals such as short-term military or civilian travelers to endemic areas.

## B. Human Immunodeficiency Virus

Mucosal vaccines that induce immunity at intestinal and vaginal sites are designed to contribute to protection against HIV by reducing the likelihood of viral acquisition and dissemination at these entry portals [77]. Mucosal vaccination may also generate systemic immune responses to help reduce the systemic HIV burden. Mice were immunized nasally with the recombinant envelope protein rgp160, complexed to Proteosome particles [78], and delivered either in saline, with a nanoemulsion (Emulsomes™; Pharmos Corp., Iselin, NJ) containing a mucoadhesive biopolymer, or with cholera toxin B subunit (CTB). (Emulsomes are a novel lipoidal particulate vehicle with features intermediate between liposomes and oil-in-water emulsions [79].) Nasal immunization with the Proteosome rgp160 vaccine elicited improved anti-HIV IgG and IgA titers in serum and in vaginal, intestinal, and lung fluids and in fecal pellets and broadened the number of gp160 epitopes recognized compared to immunizing with rgp160 alone, and combining the Proteosome vaccine with either Emulsomes or CTB often

increased effectiveness [78]. The ability of nasal Proteosome vaccines to enhance anti-HIV IgG and IgA immune responses 2–3 logs in sera, in vaginal, intestinal, and lung secretions, and in fecal extracts [78] was confirmed [80] with a native HIV-1 oligomeric gp160 (oligo-gp160) [81] protein that has greater potential to elicit neutralizing antibodies. The demonstration of neutralizing antibodies in vaginal and lung secretions as well as in sera was unique to nasal Proteosome oligo-gp160 immunization in this study [80] and is particularly encouraging for human trials of this mucosal AIDS vaccine.

## IV. PARENTERAL VACCINES

### A. Proteins

#### 1. Parasitic and Viral Diseases: Schistosomiasis, Malaria, and Human Immunodeficiency Virus

For schistosomiasis, an intramuscular Proteosome vaccine containing an extracted 38- to 40-kDa *Schistosoma mansoni* antigen induced high levels of antibodies that mediated complement-dependant antischistosomal activity as well as in vivo protection, with >70% decrease in worm burden while immunization without Proteosome technology was not protective [82]. In another study, immunizing with a recombinant 62-kDa *S. mansoni* antigen formulated with Proteosomes elicited the most consistent and highest levels (83%) of protection [83]. In malaria studies in mice and rabbits, intramuscular immunization with any of three proteosome vaccines made with recombinant *Plasmodium falciparum* circumsporozoite proteins containing carboxyl terminus hydrophobic amino acids (that were either native to the molecule, or were recombinantly added) enhanced specific serum IgG responses up to 50-fold [84]. These data confirm the applicability of recombinant proteins with native or synthetic anchors for antiparasite intramuscular Proteosome vaccines. Similarly, Proteosome vaccines made with HIV rgp160 given intramuscularly in saline, with alum or with a submicron emulsion (SME), improved the magnitude and the breadth of antibody responses compared to rgp160 alone [87]. Strong CTL responses were also elicited by proteosome vaccines, especially when delivered in SME.

#### 2. Toxin Diseases: Enterohemorrhagic *E. coli* Shiga-Like Toxin-1 and Staphylococcal Enterotoxin B

Enterohemorrhagic *E. coli* that produce shiga-like toxins are important enteric pathogens that induce both hemorrhagic colitis and hemolytic uremic syndrome (HUS) [85]. Subcutaneous immunization with SLT-1B (the B subunit of SLT-1) formulated with Proteosomes plus alum induced anti-SLT-1B IgG that neutralized SLT-1 cytotoxicity in vitro and conferred significant protection against weight loss, gross and microscopical intestinal vascular lesions, and edema associated with RDEC-H19A challenge [86] in a rabbit model of human EHEC colitis. In addition, in models of SEB intoxication, intramuscular immunization with formalinized SEB toxoid plus proteosomes with or without alum enhanced antitoxin serum IgG levels compared to SEB toxoid

alone and significantly protected mice against lethal systemic or respiratory SEB intoxication [59] and monkeys challenged by aerosol with 15 LD<sub>50</sub> of SEB [60].

## B. Peptides

Complexing Proteosome particles to dozens of peptides derived from malaria, trypanosome, streptococci, SEB, and ricin antigens via lipid or hydrophobic anchors synthetically linked to the peptides resulted in highly improved intramuscular immunogenicity [1–3,62,88] and, using computer modeling, led to identification of a protective ricin peptide vaccine [89]. Another elegant use of a Proteosome peptide vaccine utilized the creation of a peptide mimicking a polysaccharide antigenic determinant. Computer analysis of the variable regions of an anti-idiotypic monoclonal antibody (MAb) mimicking meningococcal group C polysaccharide (MCP) elucidated the immunogenic site on the anti-id MAb responsible for inducing anti-MCP responses. Mice immunized with a Proteosome vaccine containing a peptide representing the MAb protective domain developed high-serum anti-MCP IgG and IgM that protected sensitized mice against virulent meningococci as measured by both survival (100%) and bacteremia clearing [90].

## C. Polysaccharides and Detoxified Lipopolysaccharides

The safety and immunogenicity of injectable Proteosome vaccines were emphasized by large clinical trials testing OMPs complexed to polysaccharides for vaccines against meningitis [7]. In other studies, immunization with a detoxified J5 LPS complexed to Proteosome OMPs [91] was used to produce rabbit IgG that passively protected neutropenic rats against lethal challenge with *Pseudomonas aeruginosa*. Because J5 antibodies elicited by this vaccine bound several types of gram-negative bacteria, the authors suggested that such vaccines have potential as a vaccine against gram-negative septicemia caused by a wide variety of bacteria.

## D. Cancer Cell Surface Gangliosides

A Proteosome vaccine containing GD3 ganglioside complexed via its hydrophobic ceramide component induced high anti-GD3 IgM antibody levels that mediated complement-dependant lysis of melanoma tumor cells, whereas numerous other formulations did not [92]. In other studies, a GM3 ganglioside complexed to Proteosome particles induced antimelanoma cell IgG responses that mediated complement-mediated cytotoxicity, suppressed tumor growth, and prolonged survival in mice challenged with live melanoma cells [93]. These data suggest that Proteosome technology is a promising candidate to augment antiganglioside responses for cancer immunotherapy vaccines.

## V. CONCLUSIONS AND FUTURE DIRECTIONS

This chapter has highlighted several advances in the understanding and application of Proteosome delivery vehicles

and adjuvants, particularly for nasal vaccines. The finding that B-cell activation by Proteosome porin proteins depends on TLR2 activation with concomitant upregulation of expression of B7.2, MHC-1, and MHC-2 costimulatory molecules on APCs, including both B cells and dendritic cells, allows classification of Proteosome stimulatory adjuvant activity with that of other known adjuvants that stimulate APCs. This, combined with the nanoparticulate structure of Proteosome vaccines, has provided conceptual grounds for understanding the basis of Proteosome enhancement of vaccine-induced immunity. Further work on the mechanism of action of Proteosome-based vaccines on the mucosal level would also be informative because the potential contribution of mucosal uptake and/or processing and presentation by Proteosome particles and adjuvants at mucosal sites is not currently completely clear. As shown by animal and/or human studies for vaccines against intestinal or sexually transmitted diseases such as shigellosis and AIDS, nasal Proteosome vaccines do stimulate the common mucosal immune system to provide mucosal antibodies at sites distal to the respiratory tract. The results of the nasal Proteosome *Shigella* vaccine in a human challenge study demonstrating significant protection against severe disease and fever is a significant advance for nasal subunit vaccines even though the level and duration of protection found needed improvement. Indeed, such improvement might be accomplished by more frequent nasal spray booster immunizations—a prospect not unreasonable for high-risk individuals exposed to infection by *Shigella* or HIV.

The most rapid advances in nasal vaccines will likely occur against respiratory targets. The progress of the nasal Proteosome influenza vaccine, FluINsure, from murine studies to Phase 1 and Phase 2 clinical trials, and to experimental challenge studies demonstrating protection in people over the last few years along with the upcoming field trial attests to the rapidity with which these vaccines can be developed for human use. The preclinical safety, immunogenicity, and toxicity package available for nasal Proteosome vaccines is now quite extensive. The success of FluINsure using split product viral protein preparations in human studies suggests that similar vaccines could be developed for other respiratory viral infections such as RSV, measles, and PIV, all of which display protective transmembrane proteins on their surface. Another important respiratory target for nasal Proteosome vaccines is against biothreat agents and preliminary data using IVX-908 vaccine showing protection of mice against a high lethal aerosol challenge with *Y. pestis* (plague) have significance for nasal vaccination against other biothreat agents such as anthrax, ricin, and SEB.

The ability of Proteosome vaccines and adjuvants, even when delivered nasally, to switch immune responses of antigens from Type 2 to Type 1 phenotype (with IFN-γ production) has several important implications. First, generation of Type 1 immunity indicates that cell-mediated mechanisms including CTL responses would be expected. This would be beneficial to influenza vaccines by providing cellular immunity that is considered to be important in reducing clinical morbidity from viral infection and eliminating the last traces of virus inside cells that may be

otherwise unavailable to antibodies. This would complement the demonstrated ability of mucosal IgA, also induced by nasal vaccines such as FluINsure, to neutralize viruses in cells. Second, it is now accepted that certain vaccines, notably against RSV, must provide Type 1 immunity in order to avoid the vaccine-associated pathology and adverse reactions found in the 1960s using formalin-inactivated viral vaccines with alum. Third, stimulation of Type 1 immunity opens the avenue of Proteosome therapeutic vaccines for allergy, currently under active investigation, where generating Type 1 responses is the fundamental basis for allergy immunotherapy as well as for cancer vaccines. The addition of IVX-908 as a Proteosome-based nasal adjuvant that is effective even when mixed with antigen devoid of hydrophobic anchors also expands the applicability of Proteosome technology.

The upgrade in the characterization, scale-up, and stability package for Proteosome vaccines has allowed rapid advancement of Proteosome-based products toward use in commercial vaccine products. Continued progress over the next several years in research, development, and advanced clinical trials leading to commercialization of Proteosome nasal vaccines and adjuvants is eagerly anticipated.

## ACKNOWLEDGMENT

We thank Dr. Philip R. Glade, M.D., whose advice, recommendation, encouragement, and inspiration at a critical time made this work possible.

### I. INTRODUCTION

Viruslike particles (VLPs) are nonreplicating, virus capsids made using recombinant DNA technology that mimic the structure of native virions [1,2]. They generally are formed when viral structural protein(s) are synthesized in eukaryotic or prokaryotic expression systems and the proteins self-assemble to form particles. VLPs are not infectious because they lack the viral genome. VLPs can be simple and formed by expression of one viral capsid protein (papillomavirus, parvovirus, calicivirus, hepatitis B core protein) or by coexpression of multiple proteins that form more complex capsid structures (orbivirus, Ebola virus, herpesvirus, and rotavirus). VLPs can be produced for both nonenveloped and enveloped RNA and DNA viruses. VLPs mimic the immunogenicity of native virions because they display authentic or near-authentic conformational epitopes. VLPs are being investigated in many viral systems as subunit vaccines and as vectors to carry other proteins, peptides, or nucleic acids for gene transfer, gene therapy, or DNA vaccines (Table 1). VLPs provide vaccine approaches in systems where native virions cannot be readily isolated or produced (e.g., papillomavirus, Ebola virus, or Norwalk virus) and traditional vaccine approaches are not possible [3–5]. VLPs are also useful reagents in these same systems to produce diagnostic reagents or to evaluate immune responses in vaccine trials [5–9].

VLPs are advantageous as vaccines because they can induce both arms of the immune system, they display a large repertoire of antigenic sites, and they display discontinuous epitopes that structurally mimic virus particles. In many cases, VLP vaccines are in preclinical testing in animal models, but some have progressed to Phase I or II clinical trials [4,6,10–13,33]. An important advantage of VLPs as vaccines is their apparent high safety compared to live or inactivated vaccine approaches. VLPs are safe both to produce and to

handle, and safe to administer as vaccines or carriers because when produced in baculovirus or yeast they lack mammalian cell proteins or mammalian-derived pathogens [14]. In addition, they are a safe alternative for vaccines for viruses for which a more traditional attenuated or inactivated vaccine approach is not feasible because of the serious consequences of a reversion to virulence or failure in inactivation (e.g., HIV or papillomavirus) [1,2]. Because VLPs are noninfectious and do not contain nucleic acid, there is no possibility of reversion to virulence, integration into the host genome, and spread to nonvaccinated individuals. These are important safety advantages, especially because of their potential safety in multiple populations including children and the increasing numbers of immunocompromised hosts throughout the world.

VLPs can be produced or expressed in many expression systems, including mammalian cells (HIV, Ebola, influenza, HTLV-I, rotavirus), baculovirus (orbivirus, rotavirus, Norwalk virus, papillomavirus, HIV), yeast (HBV, HPV, HIV), recombinant vaccinia (HIV), *Salmonella* (HPV L1), *Escherichia coli* (HPV, polyomavirus, HCV), alphavirus replicons (Norwalk virus), and plants (HBV, Norwalk virus, HPV, rotavirus) [1,13,15–24]. Baculovirus expression systems have been commonly used for expression of VLPs used in pre-clinical testing; these and other systems such as yeast and bacterial expression systems may be adapted for vaccine production. The system of choice depends on the particular VLP being produced. Assembly of some VLPs requires authentic posttranslational modifications of viral proteins possible only in eukaryotic cells, and some viral gene sequences are toxic in bacteria or yeast [16,25]. In these cases, modifications of the expression system or changes in codon usage may overcome initial potential disadvantages. Yields of VLPs have not been reported for all VLPs in the different expression systems, but reported yields range from ~3 to 65 mg/L [5,19,26–29]. Yields for VLPs composed of single

proteins generally exceed yields for multiple protein VLPs because of a limitation of total protein production in cells. Vectors that contain and express multiple gene sequences can increase yields for more complex VLPs [28,29].

## II. VLPs AS VACCINES

VLPs provide a vaccine immunogen with an ordered structure and intact conformational epitopes. VLP immunogenicity is dependent on ordered structure because disrupted VLPs or mutant proteins that are able to aggregate, but not self-assemble to form VLPs, are much less or nonimmunogenic [4,13,30,31]. VLPs are typically highly immunogenic and often do not need the coadministration of adjuvants to induce antibody responses but adjuvants may improve immunogenicity and protection [4,11,32–34]. VLPs are immunogenic or protective at doses ranging from 0.1 to 250 µg. Immunogenic or protective doses of VLPs are reported for parenteral or intranasal immunizations with doses from 0.3 to 50 µg [29,32–37] and for oral immunizations 10–200 µg [32,33,37–40].

VLPs are typically effective inducers of neutralizing antibodies. For most pathogens, vaccine-induced protection

against disease is dependent on the presence of neutralizing antibodies at the time of subsequent exposure to the pathogen. However, an advantage of VLPs is that they can also induce T-cell responses, as measured by bulk culture proliferation assays and cytotoxic T-lymphocyte assays, and VLPs can be presented by both class I and II MHC pathways. VLPs induce both cytotoxic and helper T cells, frequently without the addition of adjuvant, and can confer protection from virus challenge. However, more potent induction of cytotoxic T-cell responses may occur when adjuvants or other moieties that activate antigen-presenting cells are included in the vaccine [31,41–48]. While VLPs are strong inducers of immune responses, they may induce different or more limited immune effector responses compared to responses to native virus infection [49,50]. Different VLPs may be processed by antigen presenting cells differently or induce different immune mediators, even if the VLPs are similar in size and structure (papillomavirus versus polyomavirus) [31,51]. The route of VLP administration and adjuvant can also affect the immune response. Papillomavirus VLPs administered parenterally induce vaginal IgG but not IgA, whereas orally administered VLPs induce vaginal IgA [37]. Taken together, these data suggest that although presentation of structure is an important parameter of VLP-induced

**Table 2** Summary of Characteristics of Rotavirus and Norwalk virus VLPs as Vaccines

Experimental system	Immunogenic		Induce		Adjuvant		Protective administered			Human trials	Proteins included in VLPs
	Systemic	Mucosal	Neutralizing antibodies	T cells	Required	Act as	Mucosal	Parenteral	Carrier		
Rotavirus	Yes	Yes	Yes	NT	No	NT	Yes	Yes	NT	No	VP2, VP4, VP6, VP7
Calicivirus (NV)	Yes	Yes	?	Yes	No	No	?	?	Yes	Yes	ORF2, ORF3

NT, not tested.

?, currently not able to test.

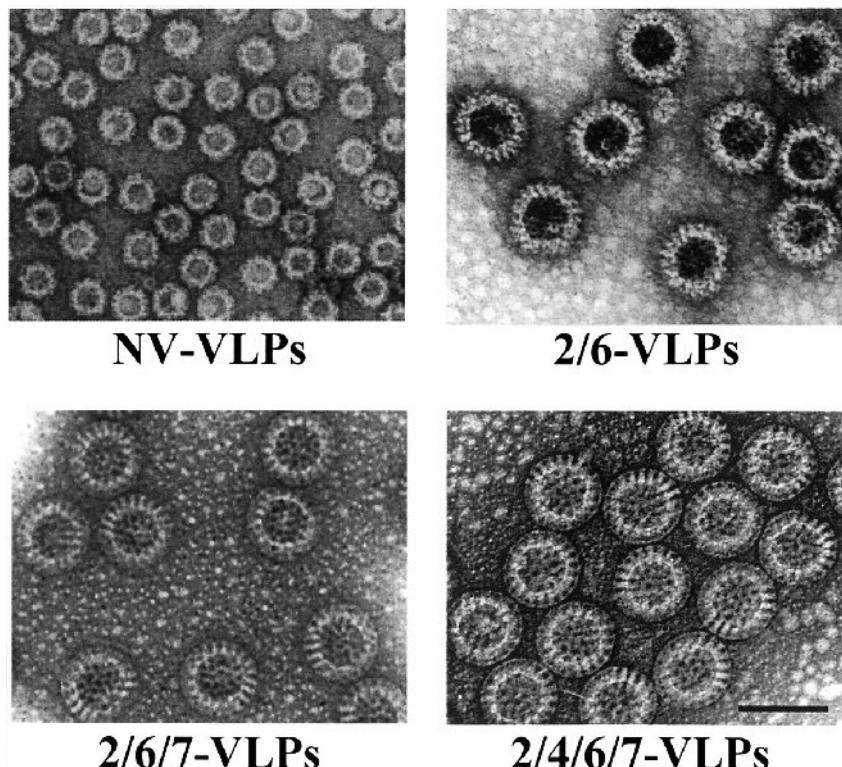

immune responses, other factors also affect the immune response induced by VLPs.

The remainder of this chapter will focus on use of viruslike particles as vaccines for mucosal diseases, specifically enteric infections caused by Norwalk virus and rotavirus. These systems are being emphasized because these VLPs have undergone extensive preclinical testing and Norwalk virus VLPs are in Phase I clinical trials (Table 2).

### III. NORWALK VIRUS AND ROTAVIRUS VLPs

Candidate VLP vaccines are being pursued for two enteric viral pathogens, rotavirus and Norwalk virus (Figure 1).

Both viruses cause acute, local gastrointestinal infections of humans and both are also important pathogens in many animal species. Rotavirus is the leading cause of severe dehydrating and diarrhea-associated deaths (400–600,000) in young children worldwide. Norwalk and related human caliciviruses are the leading viral cause of epidemic food- and water-borne diarrheal and vomiting illness in all age groups. The human caliciviruses are considered “emerging pathogens” because of the rapidly expanding disease burden attributed to infections with these viruses as new tests for diagnosis have become available. The caliciviruses are also considered Class B biodefense pathogens because of their apparent low infectious dose and potential to cause large outbreaks of waterborne, and possibly airborne, disease.

**Figure 1** Norwalk virus and rotavirus VLPs produced in Sf9 cells and used for vaccine studies in humans and animals.

Challenges for development of effective vaccines for both rotavirus and Norwalk virus include the need to induce mucosal immune responses to protect from diarrheal disease and the need to target the vaccine to young children, particularly for rotavirus. We review below the progress toward development of Norwalk virus and rotavirus VLP vaccines for use in humans and animals.

### A. Norwalk Virus and Norwalk-Like Viruses

Norwalk virus is the prototype virus of the *Norovirus* (NoVs) genus of the genetically diverse, single-stranded RNA viruses belonging to the family *Caliciviridae* [52–54]. In the United States, NoVs cause an estimated 23 million episodes of illness, 50,000 hospitalizations, and 300 deaths each year [55]. NLVs can be transmitted by fecally contaminated food and water and by direct person-to-person contact or through droplets from infected persons [56,57]. Outbreaks are a particular concern in elderly residents of nursing homes [58], military personnel [59], and travelers [60]. The use of new diagnostic assays to detect these genetically diverse pathogens has rapidly determined that these viruses cause significantly more infections than previously recognized and they infect all age groups [61]. The clinical manifestations of NLV infections include sudden onset of vomiting and/or diarrhea after a 24- to 48-hr incubation period that typically lasts 12–24 hr [56,62]. The increasing disease burden and significance of infections in selected settings, combined with the discovery that the expressed capsid protein of Norwalk virus folds spontaneously into VLPs that lack nucleic acid [63] and have desirable properties for use as a subunit vaccine, have stimulated vaccine development [64,67]. Norwalk virus VLPs have been made using baculovirus vectors [63] and a Venezuelan equine encephalitis replicon system [20].

Studies with NV VLPs also serve as an excellent model to dissect and understand effective strategies for mucosal immunization with nonreplicating antigens because of the following useful properties. First, the VLPs are stable at low pH so they can be administered orally. Second, they can be lyophilized and stored at 4 °C in water or phosphate-buffered saline (PBS) for at least 3 years without degradation. Third, the VLPs are easily made by using the baculovirus expression system; yields of more than 22 mg per  $9 \times 10^8$  cells are obtained in sufficient purity for vaccine evaluation and successful crystallization [65]. Fourth, the unique structure of the single protein that folds to make a VLP, and mutational studies, suggest these particles can be modified to be an antigen-delivery system [65,66]. Finally, rNV VLPs are immunogenic when tested in inbred and outbred mice, and in volunteers following oral administration, even in the absence of a mucosal adjuvant [5,6].

Norwalk virus is a noncultivable human pathogen, and there are no small animal models available to study pathogenesis or protection from disease. Therefore, the immunogenicity of VLPs has been tested in mice and confirmed in volunteers. Efficacy studies will require reestablishing a human challenge model [6,68]. Preclinical studies in mice administered rNV VLPs have shown that these nonreplicat-

ing vaccines are immunogenic when administered by systemic and mucosal (intranasal and oral) routes [5,40,69]. Immunizations have been given in the presence or absence of a mucosal adjuvant, either cholera toxin or mutant *E. coli* heat-labile toxin LT(R192G), and rNV specific IgG and fecal IgA were evaluated by ELISA. Intranasal delivery of rNV VLPs is more effective than the oral route at inducing serum IgG and intestinal IgA responses to low doses of rNV particles. Vaginal responses of female mice given VLPs by the intranasal and oral routes are also induced. All mice that receive two immunizations with low intranasal doses (10 or 25 µg) of rNV VLPs and the majority of mice that received two high doses orally (200 µg) in the absence of adjuvant produce rNV-specific serum IgG responses, fecal responses, and vaginal responses. These experiments show that low doses of nonreplicating rNV VLPs are immunogenic when administered by the intranasal route, high doses are immunogenic by the oral route in the absence of adjuvant, and these VLPs represent a candidate mucosal vaccine for Norwalk virus infections in humans.

Based on the preclinical responses in mice, Phase I studies have evaluated oral administration of two doses (100 µg and 250 µg) of rNV VLPs without adjuvant to healthy, adult volunteers [6]. The VLPs were safe and immunogenic. Serum IgG responses to the VLPs were dose-dependent, and all vaccinees given 250 µg responded with serum IgG titers. Most of the volunteers responded after the first dose and showed no increase in serum IgG titer after the second dose. However, the maximal titers of serum antibody induced by VLP immunization were lower than titers seen following infection with Norwalk virus. A follow-up Phase I study evaluating escalating doses (250, 500, and 2000 µg) of VLPs administered to volunteers that measured systemic and mucosal (stool, saliva, vaginal, and semen) humoral and cellular immune responses confirmed the vaccines are safe [10]. All vaccinees developed significant rises in IgA antibody secreting cells after vaccination. Ninety percent of vaccinees who received 250 µg developed rises in serum IgG anti-VLP antibody, and neither the rates of seroconversion nor titers increased at the higher doses. About 30–40% of volunteers developed salivary, fecal, or genital fluid IgA antibody and lymphoproliferative responses and interferon-γ production were observed transiently in vaccinees who received the 250 and 500 µg, but not 2000 µg of VLPs [10]. Other studies have shown that mice and volunteers fed potatoes that express NV capsid protein also respond and produce antibodies [70,71]; these studies show proof of concept for edible vaccines for viruses whose capsid proteins can form VLPs (see Chapter 28).

Because rNV VLPs are immunogenic in the absence of adjuvant, experiments have evaluated if rNV VLPs can function as a mucosal adjuvant by evaluating the immune responses to two soluble proteins, keyhole limpet hemocyanin (KLH) and chicken egg albumin (OVA). Under the conditions tested, rNV VLPs did not enhance the serum IgG or fecal IgA response to these soluble proteins when coadministered by the intranasal or oral route [40]. However, because the two test antigens used in these studies have the capability to induce tolerance, further studies should reevaluate adjuvant activity using other antigens.

Overall, studies with rNV VLPs have shown that adult antibody-positive volunteers respond to rNV VLPs in a manner similar to naïve mice. Studies to increase the immunogenicity of VLPs in volunteers using a mucosal adjuvant and to test the efficacy of VLPs against Norwalk virus challenge are planned. If successful, further studies to determine if heterotypic protection against other types of NLVs can be induced with immunization with a single VLP. Mice immunized with a single type of NLV VLP can produce cross-reactive antibodies to other types of NLVs so the potential exists for inducing cross-protection [72].

## B. Rotavirus

Rotaviruses cause nearly 50% of diarrheal disease in infants and young children worldwide; 30% of all children develop a rotavirus infection before 9 months of age and 80% within the first 3 years of life [73]. The peak age of disease of children in developing countries is younger than in developed countries and is frequently between 3 and 6 months of age [74–76]. Rotavirus infections cause disease ranging from asymptomatic infections to severe, dehydrating, fatal diarrhea. Rotaviral-related diarrheal deaths are rare in developed countries but in developing countries cause an estimated annual 352,000–592,000 deaths [77,78]. In the United States, rotavirus is a major health concern, causing 55,000 hospitalizations, 500,000 physician visits, and 20–40 deaths, which is estimated to cost more than one billion dollars annually [73,79]. Most children in the world are infected with rotavirus multiple times but, typically, it is the first rotavirus infection that is most severe. For these reasons, the development of a rotavirus vaccine to prevent severe dehydrating diarrhea in young children is a major global health priority.

There are many serotypes of rotavirus that infect children, and multiple serotypes of rotavirus circulate concurrently. Rotaviruses have a dual serotype classification system of P and G types, based on two neutralization antigens, VP4 and VP7, respectively [80]. Rotavirus disease worldwide has been most frequently associated with G1–G4 types [81,82] and targeted in vaccine development. However, unusual serotypes may be rising in prevalence or may be more important than G1–G4 serotypes in specific locales [74–76,83]. There is conflicting information from animal models, natural outbreaks in children, and vaccine studies as to whether protection from rotavirus disease is entirely homotypic or whether heterotypic protection is achievable [84]. Immune correlates of protection for rotavirus have not been clearly defined in children or animals, but intestinal antibodies are thought to be of primary importance in protection [84,85]. Protection from rotavirus infection or disease correlates in some, but not all, studies with neutralizing antibodies or IgA. In the absence of IgA, other factors, possibly local IgG can protect from rotavirus infection [86,87].

### 1. Rotavirus Animal Models for Vaccine Testing

There are multiple animal models for rotavirus. The advantages and disadvantages of each animal model system have been reviewed and reported elsewhere and will only be briefly

summarized here [85,88–90]. Young calves and gnotobiotic piglets are susceptible to rotavirus infection and develop diarrhea up to at least 6 weeks of age. There are three rotavirus small animal models, adult rabbits, mice, and rats [91–94]. Diarrheal disease is severely age-restricted in rabbits, mice, and rats to animals <14 days of age. Therefore, protection from diarrhea is studied in neonatal animals and protection from infection is studied in adult rabbits, mice, and rats [95]. Following primary rotavirus infection, rabbits and mice, but not rats, develop sterilizing immunity and cannot be reinfected with rotavirus [91–93]. Different vaccine formulations and immunization regimens have been tested in mice, rabbits, and piglets; the results from these studies do not always concur, and it is not yet clear which model will accurately predict responses in children.

Traditional vaccine approaches for rotavirus are being actively pursued and have been reviewed elsewhere [85,96]. Live rotavirus vaccines have been licensed for use in children or are in field trials. Live attenuated human and animal rotavirus reassortant rotavirus vaccines can protect children from severe rotavirus disease. The safety of live attenuated rotavirus vaccines has been questioned in light of the adverse event (intussusception) associated with Rota-Shield® vaccine and its subsequent removal from the market [97]. Inactivated rotaviruses, DNA vaccines, and recombinant protein vaccines have also been tested in animal models and exhibit variable efficacy dependent on the immunogen and animal model in which it was tested [85,90,98–101]. Safety concerns about live attenuated vaccines and the availability of the technology to make subunit vaccines have led to the pursuit of subunit vaccination strategies. VLPs have been studied most extensively of any rotavirus subunit approach.

### 2. Rotavirus VLP Vaccines to Induce Active Immunity

Rotavirus VLPs are made by coinfecting insect cells with baculovirus recombinants that express rotavirus structural proteins; these proteins self-assemble into VLPs that are morphologically and antigenically similar to rotavirus [27,28,32,36,102]. Rotaviruses are composed of three concentric capsid layers but intermediate noninfectious subviral particles are also formed. Expressing VP2 alone produces single-layered VLPs [103]. Coexpression of the rotavirus proteins VP2 and VP6 that form the innermost and middle capsid layers of rotavirus particles, respectively, produces double-layered 2/6-VLPs. Coexpression of VP4 with VP2 and VP6 form double-layered VLPs with VP4 spikes (2/4/6-VLPs) [27]. Coexpression of VP2, VP6, and VP7 produces triple-layered 2/6/7-VLPs. Coexpression of VP2, VP4, VP6, and VP7 results in 2/4/6/7-VLPs that are complete triple-layered VLPs with the VP4 spike protein. Double-layered 6/7-VLPs comprised of the middle and outer capsid proteins can form but are not as homogeneous or stable as 2/6/7-VLPs [35]. Chimeric rotavirus VLPs are readily formed with individual rotavirus proteins from different rotavirus strains or with one protein from two different rotavirus strains on one particle [27]. One advantage of VLP vaccines is the potential ability to easily interchange genes encoding pro-

teins from different P and G serotypes that may allow development of geographic-specific vaccine formulations. Complete and subviral VLPs induce active immunity in adult rabbits, adult mice, and gnotobiotic piglets, and induce passive protection in neonatal mice and calves.

The availability of different formulations of VLPs allowed the pursuit of which proteins provide protection from rotavirus and whether neutralizing antibodies are necessary to induce protection in the various models. Vaccination studies have focused on 2/6-, 2/6/7-, and 2/4/6/7-VLPs, which have been administered parenterally (intramuscularly) or mucosally (orally or intranasally). The following section briefly reviews current data and discusses what has been learned with each formulation of VLPs given by the different routes and in different animal models for both active and passive vaccination strategies. Each vaccine formulation is discussed separately and the results with different formulations and routes of administration are compared.

**2/6-VLPs.** Double-layered 2/6-VLPs do not contain the rotavirus neutralization antigens (VP4, VP7) and fail to induce neutralizing antibodies in mice or rabbits [32,36]. Therefore, if rotavirus-specific neutralizing antibodies were an absolute requirement for protection, 2/6-VLPs would not provide any protection. However, if efficacious, 2/6-VLPs would be a relatively simple two-component vaccine to make that can be produced in high yields [28] and might induce more cross-protective antibodies to VP6 than VLP formulations with VP4 and VP7. Such 2/6-VLPs have been administered to rabbits, mice, and pigs intranasally, orally, or intramuscularly and protection against infection (rabbits, mice) or diarrheal disease (pigs) assessed. The results with 2/6-VLPs vary depending on the animal model in which they were tested and the route of administration.

2/6-VLPs are immunogenic in mice [28,32,104,105], rabbits [36], and piglets [106–108] by all routes tested, with the exception of intranasal administration in rabbits [28]. The immunogenicity and protection of 2/6-VLPs are enhanced for all routes of administration tested by inclusion of adjuvants. Protective efficacy of 2/6-VLPs varies by animal model. In mice, 2/6-VLP immunization provides at least partial protection from infection by all routes and intranasal immunization provides high levels of protection. In rabbits, 2/6-VLPs administered intramuscularly or intranasally are not protective or are generally less efficacious than other VLP formulations (see below). In piglets, 2/6-VLPs are not protective alone either intranasally or orally even with multiple doses, but they provide moderate protective efficacy against diarrhea and virus shedding as part of prime-boost immunization protocol with live attenuated rotavirus. Immunization of mice and rabbits with 2/6-VLPs results in widely variable protection in individual animals within groups. For example, the mean levels of protection induced by 2/6-VLPs administered intramuscularly in rabbits are low (5–41%) but individual rabbits are highly protected (up to 94%). Overall, immunization with 2/6-VLPs appears to be a promising vaccine candidate for use in a prime-boost strategy with other vaccine formulations or for strategies to induce passive immunity (see below). However, the utility

of 2/6 VLPs alone as an immunogen for active immunity remains unresolved.

**2/6/7-VLPs.** Triple-layered 2/6/7-VLPs that contain VP7, one of the rotavirus neutralization antigens, have been tested to determine if the presence of VP7 increases the protective efficacy of VLPs. If protection is dependent on neutralizing antibody independently induced by VP4 and VP7, then the inclusion of VP7 would be protective. Compared to 2/6-VLPs, 2/6/7-VLPs would be the next least complex VLP formulation to produce commercially. 2/6/7-VLPs have been tested in mice by all three routes and in rabbits by intramuscular administration.

In mice, intranasal administration of 2/6/7-VLPs induces 100% protection from a low-challenge dose in mice and is superior to orally administered 2/6/7-VLPs [32]. 2/6/7-VLPs provide low (5%) to partial (53%) protection when administered orally at 25- or 100- $\mu$ g doses, respectively [32]. Parenteral administration of 2/6/7-VLPs induces high levels of both homotypic and heterotypic protection when administered with QS-21, but not aluminum phosphate [109]. Double-layered 6/7-VLPs are similarly immunogenic to triple-layered 2/6/7-VLPs when administered intramuscularly to mice but 6/7-VLPs are less stable than 2/6/7-VLPs [35]. In rabbits, two 50- $\mu$ g doses of 2/6/7-VLPs administered intramuscularly provide low (28%) to moderate (58%) mean protection but individual rabbits were highly protected [36]. 2/6/7-VLPs can induce higher levels of protection. However, the protective efficacy of 2/6/7-VLPs is not significantly different than 2/6-VLPs administered either intranasally or orally in mice, or intramuscularly in rabbits, indicating that in mice and rabbits with the regimens tested, inclusion of VP7 in VLPs does not increase protective efficacy against infection. Whether inclusion of VP7 in VLPs is important in protection against disease (diarrhea) remains to be determined.

**2/4/6/7-VLPs.** Native rotavirus virions are composed of triple capsid layers with the spike protein. Triple-layered 2/4/6/7-VLPs that contain both the neutralization antigens VP7 and VP4 have been tested to determine if VLPs, similar to complete rotavirus virions would increase the protective efficacy of VLPs. 2/4/6/7-VLPs contain both neutralization antigens (VP4 and VP7) and are capable of binding to cells via VP4, the viral attachment protein [27]. 2/4/6/7-VLPs have been tested in mice by all three routes and in rabbits by intramuscular administration.

Parenteral administration of 2/4/6/7-VLPs or inactivated SA11 rotavirus to rabbits with QS-21 induces higher levels (84–100%) of protection than either 2/6- or 2/6/7-VLPs (5–58% protection) [36]. In addition, serotype G1 and G3 2/4/6/7-VLPs induce both heterotypic and homotypic protection from rotavirus infection. Protection of rabbits by VLPs correlates moderately with the inclusion of VP4, indicating that VP4 enhances, but is not absolutely required to induce protection. Mice parenterally administered G1 2/4/6/7-VLPs develop both homotypic and heterotypic (G3) immunity but the protective efficacy in mice has not been evaluated [102]. Mice immunized orally or intranasally with 2/4/6/7-VLPs develop moderate levels of protection against a high challenge dose (Warfield, Estes, and Conner, unpub-

lished data). 2/4/6/7-VLPs can be highly protective against infection in both mice and rabbits, supporting the need to test whether the VLPs will stimulate high levels of protection against rotavirus diarrhea.

### 3. Rotavirus VLP Vaccines to Induce Passive Immunity

VLPs have been investigated to induce passive immunity for veterinary use. Induction of passive immunity by vaccination of dams is an important strategy to protect young farm animals during the first few weeks of life when they are most vulnerable to mortality from rotavirus disease. This model has also been used in mice to test what antibodies are essential to protect pups against rotavirus-induced diarrhea in the neonatal period. A similar strategy may also prove efficacious to protect young infants in developing countries where rotavirus infection and disease occur early in life.

VLP vaccination of dams serves to boost preexisting rotavirus-specific antibody titers in the dams shortly before parturition to increase the titers of rotavirus-specific antibody in the colostrum and milk ingested by the young animal. This vaccination strategy has proven effective with live or inactivated rotavirus vaccines in cows [110,111]. Intramuscular immunization, followed by booster intramammary injections of 2/4/6/7-VLPs or 2/6-VLPs with adjuvant to pregnant cows, significantly increases rotavirus-specific antibody titers in milk and colostrum compared to control cows [112]. Calves fed this colostrum and challenged with rotavirus are protected from diarrhea and virus shedding [113]. 2/4/6/7-VLPs are somewhat superior to 2/6-VLP vaccines.

Passive immunization studies performed in the mouse model have shown that intranasal immunization of mice with 2/6- or 2/6/7-VLPs (VP7 G6), with or without adjuvant, induces serum and lactogenic antibodies in the mouse dams [114]. Protection from rotavirus diarrhea was observed in a high percentage of pups whose mothers were immunized with 2/6/7-VLPs (73%) but not 2/6-VLPs (29%). Unexpectedly, heterotypic protection from challenge by a rotavirus serotype different from the VLP serotype was not observed. The protection against diarrhea induced by 2/6-VLP immunization of cows, but not mice, is likely because naïve seronegative mice were vaccinated with 2/6-VLPs, whereas cows vaccinated with 2/6-VLPs had preexisting antibodies to rotavirus acquired from natural infections. Thus, although both 2/4/6/7- and 2/6-VLPs could readily induce antibodies in either situation, only 2/6/7-VLPs would induce neutralizing antibodies in the naïve animal. These results suggest that neutralizing antibodies are required to provide protection from diarrhea.

A maternal vaccination approach for humans either alone or in combination with an active vaccination program in children may be useful and highly effective in developing countries where primary rotavirus infections occur earlier and breast-feeding is practiced widely. Maternal vaccination of pregnant women might provide longer-lasting protection from severe diarrhea and reduce mortality in young children. Vaccination of pregnant women would require safe non-

replicating vaccines. VLPs seem to be an ideal candidate for such an approach. VLPs boost preexisting antibody responses in pigs and induce protective levels of lactogenic immunity in cows and mice [90,112–114], so it is expected they will boost responses in antibody-positive women as well.

### 4. Rotavirus VLP Summary

All the preclinical data with rotavirus VLPs support the testing of rotavirus VLPs in humans. Rotavirus VLPs alone are immunogenic and at least partially protective by all routes tested. Coadministration of adjuvants increases immunogenicity, lowers the protective dose of VLPs and may enhance the longevity of the protective immune response. Mucosal administration of rotavirus VLPs to humans provides many advantages, including ease of delivery, elimination of the need for needles, and cost especially in the developing world where vaccines are most urgently needed but where health-care funding is limited. Intranasal delivery of VLPs is a very effective route of administration to induce rotavirus-specific antibody in the intestine in two of the three animal models in which it has been tested. Comparisons of doses between oral and intranasal routes of immunization indicate that intranasal delivery of VLPs induces higher levels of protection and requires up to 10-fold lower doses of VLPs than needed to achieve low to moderate protection when VLPs are administered orally. Intranasal administration of VLPs may be superior to oral administration because of limited degradation in respiratory compared to intestinal tract, increased retention of and interaction of VLPs with M cells or lymphocytes, and differences in antigen uptake or processing. However, it is not clear whether intranasal administration of vaccines and adjuvants will be approved soon for use in humans because of possible introduction of any potential pathogen or toxin into the brain via the olfactory bulb [115–117]. Further work is needed to determine if this highly promising vaccination route will be safe for use in humans. Studies are under way to understand the differences in immunogenicity and protective efficacy induced by the two mucosal routes and to determine if modifications to the vaccine protocol or VLPs themselves can reduce the variability in protection and enhance the immunogenicity and protective efficacy of orally administered VLPs. Additional studies of parenteral administration of VLPs to induce mucosal protection are also warranted. Studies in human subjects, which are long overdue, may help to delineate some of these factors and define which animal model(s) are most predictive of responses in children or pregnant women, the target populations for rotavirus VLP vaccines.

## IV. CONCLUSIONS

VLPs are a promising candidate for parenterally and mucosally administered subunit vaccines to prevent diarrheal diseases. Rotavirus VLPs have been extensively tested in animal models and await testing in humans. Norwalk VLPs are immunogenic in both animals and humans but protective efficacy needs to be tested in humans when a human chal-

lengen model can be reestablished. VLP vaccines for sexually transmitted infections caused by papillomavirus are also being actively pursued and are currently in preclinical through Phase II clinical trials (see Chapter 85) [33]. When studies with VLPs or other subunit vaccines were first envisioned, one of the theoretical problems raised was the expectation that ingested nonreplicating immunogens would result in tolerance to the immunogen, not protective immune responses. In fact, oral administration of VLPs or other immunogens may ultimately prove useful to specifically downregulate autoimmune responses [118]. However, data with VLPs applied orally or ingested in plant material as edible vaccines (see Chapter 28) indicate that particulate VLP vaccines administered orally are immunogenic and they can induce protection. Oral administration is a promising vaccination route, if we can overcome some limitations, including relatively high doses required and for rotavirus the need for nontoxic mucosal adjuvants. It has been proposed that live virus vaccines work more effectively than subunit vaccines because live virus stimulates more components of the immune system than subunit vaccines [49,50,119,120]. Further work is needed to understand the differences in immunity and protection induced by VLPs and live virus infections and to determine if VLP-induced protection can be enhanced to levels obtained by live virus vaccines. These challenges should be met by inclusion of efficacious and safe adjuvants, or directed engineering or targeting of VLPs without induction of potential safety concerns associated with the same live virus vaccines.

## ACKNOWLEDGMENTS

The authors are grateful to our students, postdoctoral fellows, and colleagues who have worked with us to demonstrate the effectiveness of VLPs as immunogens and to understand their mechanisms of inducing immunity.

Supported by Applied Technology program grants 04949-033 and 004949-055 from the Texas Higher Education Coordinating Board, National Institutes of Health training grants T32-DK07664, General Clinical Research Center grants M01 RR00188, N01 A165229, DK56338, and R01 A124998, and Office of Medical Research Service Department of Veterans Affairs.

## Immunostimulating Reconstituted Influenza Virosomes

Reinhard Glueck

Berna Biotech Ltd., Bern, Switzerland

### I. INTRODUCTION

New vaccine formulations have been under study over the last years, which are directed not only against infectious agents, but also against antigen structures related to certain types of cancer, allergies, and autoimmune disorders [1–4]. Subunit vaccine research investigated the use of small antigens or portions of them known to be protective, for example, synthetic peptides, recombinant antigens, bacterial toxoids, polysaccharides, lipopolysaccharides, and protein structures. However, the successful development of the majority of these vaccines, due to their generally low immunogenicity, has been dependent on adjuvants; even antigens that are sufficiently immunogenic when injected with an adjuvant are often less effective when administered by mucosal route.

Sometimes, classic alum-salts, which have been for years the only adjuvant licensed for human use, are not optimal immune enhancers. In fact, their activity, based on a local inflammatory response, may produce undesirable side effects. In addition, when used as an adjuvant for small proteins [5], alum-salts have proven to be less effective (Table 1).

Pathogens with complete intact proteins are effective immunogens. Their surface glycoproteins contain B cell epitopes in certain regions which recognize the B cell lymphocytes, which then manufacture and secrete antibodies inhibiting pathogenic infection [6]. As a survival mechanism, some pathogens have mutated to sabotage the immune system by adapting their surface glycoproteins to contain regions termed dominant B cell epitopes, as in the case of the human immunodeficiency virus (HIV) and malaria. Moreover, the antibodies reacting against these regions do not interfere with the infectivity of the pathogen and, in some cases, even serve to enhance pathogenic infectivity. These dominant B cell epitopes can suppress the immune response to weakly immunogenic neutralizing B cell epitopes while stimulating the host immune response to themselves, hence sabotaging the immune system and guaranteeing continued survival.

The search for better adjuvants and more efficient carrier systems received impetus from the successful studies on liposomes carried out during the past 26 years since Allison and Gregoriadis [7] first demonstrated that liposomes enhanced the antibody response to the diphtheria toxoid. Liposomes, vesicles comprised of phospholipids, have been used as tool to investigate areas bridging from biophysics to cell biology and medicine [8–12]. In particular, they have been shown to be effective adjuvants for a large number of protein antigens [7,13,14]. When used in subunit vaccines against viral disease, they were demonstrated to efficiently present the surface glycoproteins of many enveloped viruses by anchoring the viral glycoprotein into the liposomal bilayer via a transmembrane segment and assuming a conformation analogous to their native structure in the viral envelope, culminating in stimulation of a protective immune response.

Synthetic peptides are only weakly or nonimmunogenic when used alone as a vaccine [15]. This necessitated the use of a large highly immunogenic protein as a carrier system, covalently coupling the peptide. However, because there was no relationship to the pathogen which the vaccine was designed against, these carrier systems, although helpful in producing an initial antibody response, did not evoke pathogen-specific T cell help. This meant that when one was vaccinated with a peptide–carrier complex subsequently challenged with the pathogen, a primary rather than a secondary response resulted. Booster immunizations unfortunately led to a stronger antibody response to the carrier and a lesser one to the peptide.

To test the hypothesis that anchorage of a peptide in the liposomal bilayer might mimic the normal presentation of antigen on an infectious agent thereby potentiating the immune response to the peptide, peptides were covalently linked to a phospholipid, providing a hydrophobic anchorage into the phospholipid bilayer. When viral envelope proteins or peptides representing defined Th cell epitopes are combined into the same phospholipid matrix as a B cell epitope, it stimulates the T helper cells, and a highly efficient immunogen is produced. Sequences, which are not recognized by T helper cells, do not elicit antibody responses even

**Table 1** IRIV Combination Vaccine vs. Single Alum Vaccines

Immunogen	Adjuvant	Day 0		Day 28	
		GMT <sup>a</sup> (IU/mL)	p	GMT <sup>a</sup>	p

when formulated into peptide–phospholipid complexes [16–18].

A crucial aspect of the mechanism in which peptide epitopes are presented to CD8+, MHC Class I-restricted cytotoxic T lymphocytes, is the capacity to introduce antigen into the cytoplasm but not the endosomes of antigen-presenting cells. To mimic this mechanism, the integration of lipid-linked membrane proteins into the lipid bilayer of large, mainly unilamellar liposomes was attempted by Gould-Fogerite and Mannino in 1985 [19]. The glycoproteins of influenza viruses maintain their activities of receptor binding and receptor-induced endocytosis when reconstituted into protein lipid vesicles, which have been named virosomes [20]. An effective delivery vehicle for antigens, drugs, proteins, and DNA water-soluble materials can also be encapsulated within the virosomes.

## II. IMMUNOPOTENTIATING RECONSTITUTED INFLUENZA VIROSOMES

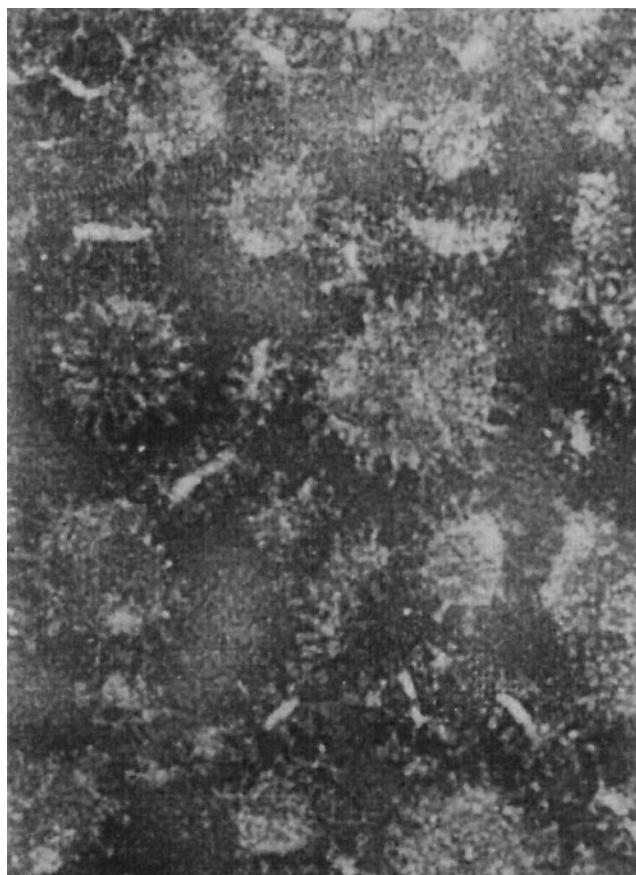

Virosomes also proved to be effective as an immunogen in mice, rabbits, and monkeys and were able to stimulate strong CD8+ cytotoxic T cell responses (CTL) to lipid bilayer-integrated glycoproteins or lipid-linked peptides, as well as to encapsulated peptides, proteins, and formalin-fixed whole viruses [21–27]. Immunostimulating reconstituted influenza virosomes are unilamellar, spherical vesicles with an approximate mean diameter of 120 to 170 nm. They have short spiked surface projections of 10–15 nm (Figure 1). They are initially prepared by detergent removal of influenza surface glycoproteins and a mixture of natural and synthetic phospholipids containing 70% egg yolk phosphatidylcholine (EYPC), 20% phosphatidylethanolamine (PE), and 10% envelope phospholipids originating from H1N1 influenza virus (A/Singapore/6/86) [28] (Figure 2). Egg yolk phosphatidylcholine is well tolerated in man and has been an important constituent in commercial solutions for i.v. applications in undernourished persons. Egg yolk phosphatidylcholine has been used in nearly all liposomal preparations which were produced for the enhancement of immune responses. Phosphatidylethanolamine was chosen for two

reasons. First, in the case of the hepatitis A virus, attachment to the host cell occurs via binding into PE regions of the cell membrane. Furthermore, it has been shown that liposomes containing PE are able to directly stimulate B cells to produce antibodies without any T cell determinant being present [38]. There were several reasons for including influenza virus envelope glycoproteins. The hemagglutinin (HA) plays a key role in the mode of action of the immunostimulating reconstituted influenza virosomes (IRIVs). Hemagglutinin is the major antigen of influenza virus, containing epitopes on both HA-1 and HA-2 polypeptides, and is responsible for the fusion of the virus with the endosomal membrane [39,40]. The HA-1 globular head groups contain the sialic acid site for HA, and it is therefore expected that the IRIVs bind to such receptors of antigen-presenting cells, e.g., macrophages and lymphocytes initiating a successful immune response. The entry of influenza viruses into cells occurs through HA receptor-mediated endocytosis [41]. It is likely that this mechanism also functions with the IRIV particles. The HA-2 subunit of HA mediates the fusion of viral and endosomal membranes, which is required in order to initiate infection of cells. At the low pH of the host cell endosome ( $\sim$ pH 5), a conformational change occurs in the HA that is a prerequisite for fusion to occur. Fusion activity tests have shown that there was no difference of activity between influenza virus and IRIV. It is suspected that this mediates the rapid release of the transported antigen into the membranes of the target cells [42].

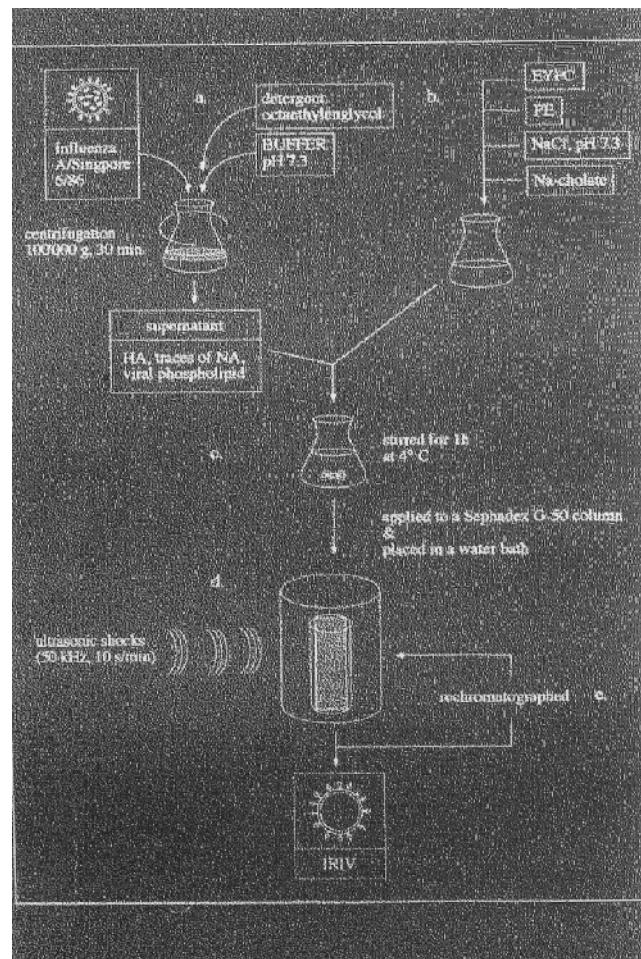

Studies providing evidence for further immunopotentiating effects of influenza virus hemagglutinin were described describing the stimulation of peritoneal B lymphocytes by HA, a so-called B cell “superstimulatory” antigen [43,44]. This study implied that the superstimulatory glycoprotein adapted itself to activate not only conventional B2 cells, but a B cell subset as well, representing a major defense against invading microorganisms. The predilection of B1 cells to build up an immediate immune response against microbial antigen is paralleled by its increased susceptibility to cross-react with “third-party” antigen. This phenomenon has been further investigated by showing that this new example of B cell stimulation by multivalent type-2 antigen (e.g., HA) seems to be mediated by a phosphatidylinositol and  $\text{Ca}^{2+}$ -independent signaling pathway [43,44]. It was also reported

that B cell superstimulatory influenza virus (H2-subtype) induced B cell proliferation by a protein kinase C (PKC)-activating,  $\text{Ca}^{2+}$ -independent mechanism.

The enzyme neuraminidase (NA) is a tetramer composed of four equal, spherical subunits hydrophobically embedded in the membrane by a central stalk and is the second glycoprotein exposed on the IRIV surface. Neuraminidase catalyzes the cleavage of *N*-acetylneurameric acid (sialic acid) from bound sugar residues [45]. This process leads to decreased viscosity in mucus and allows the influenza virus to have easier access to epithelial cells (which could be useful in the development of a nasal virosomal vaccine). In the cell membrane, the same process leads to the destruction of the HA receptor. Consequently, newly formed virus particles do not adhere to the host cell membrane after budding, and aggregation of the viruses is prevented. Therefore NA allows the influenza virus to retain its mobility. With IRIVs, these characteristics are useful, so that after coupling with HA, IRIVs not taken up by phagocytosis could be cleaved off again and would therefore not be lost. As a side benefit, it would come to bear that the reduction in

**Figure 1** Transmission electron micrograph of IRIV ( $\times 100,000$ ). The electron micrograph of the IRIVs shows spherical unilamellar vesicles with a mean diameter of  $\sim 150$  nm. The vesicles show spike projections of  $\sim 15$  nm, which originate from influenza glycoproteins (E.M. by T. Wyler, Bern).

**Figure 2** Production scheme for IRIVs egg yolk phosphatidylcholine (EYPC), phosphatidylethanolamine (PE), hemagglutinin (HA), and neuraminidase (NA).

viscosity of the mucus would be found to be useful when developing an intranasal vaccine.

### III. PROPOSED MECHANISM OF ACTION—VIROSOMES IN GENERAL

One feature of a virosomal vaccine is that along with the vaccine antigen, the virosomes contain hemagglutinin (and the subchains HA-1 and HA-2) which enables the antigen to be conveyed into immunocompetent cells. All humans, at some time or another, have been exposed to influenza, thus priming their immune systems to HA, which is the major antigen of the influenza virus [34,62,63]. It is thought that the HA enables the virosomes to bind to macrophages and other immunocompetent cells, which have been primed to influenza virus [42], and then enters the cells by endocytosis, mediated by HA-1 receptors [41]. After exposure to the low pH ( $\sim 5$ ) of cell endosomes, the HA-2 undergoes conformational changes and induces fusion of the virosome and endosome membranes [64].

The endoplasmic reticulum manufactures major histocompatibility class II (MHC II) molecules which are then transported through the Golgi apparatus and the trans-Golgi reticulum [65]. The MHC class II molecules join with endosomes containing antigens which were proteolyzed to antigenic peptides [66]. The invariant chain is then removed from the MHC class II molecules by cathepsins B and D, enabling binding to the processed antigenic peptides. The MHC class II molecule/antigenic peptide complex is then transported to the cell surface, initiating a specific humoral and/or cellular immune response [42,65,67].

As stated above, it is thought that the influenza glycoprotein neuraminidase, which is included when isolating the HA when formulating the virosomes, works as an enzyme to catalyze the cleavage of sialic acid (*N*-acetylneurameric acid) from membrane-bound sugar residues [45], and it is theorized that it might destroy the virosomal HA when bound to cell membranes. This might contribute to the increase of the availability of the vaccine, as the neuraminidase may release the virosomes which are fruitlessly bound to cells [42].

Cephalin has also been shown to stimulate B cells without the presence of T cell determinants [38]. Cephalin also appears to facilitate binding of hepatitis A virions to virosomes [42].

#### IV. OVERVIEW OF THE EVOLUTION OF VIROSOMAL VACCINES

The natural biocharacteristics of IRIVs as adjuvants were demonstrated in several different prototypical systems. Virosomes were first utilized in the commercial development of a hepatitis A vaccine which contained formalin-inactivated and highly purified hepatitis A viruses (HAV) of strain RG-SB, cultured on human diploid cells, electrostatically coupled to the IRIV vesicle [28]. The surface spikes of hemagglutinin and neuraminidase of three influenza strains were attached to the virosomal membrane, with successful clinical results. The antigen is believed to be attached to the liposomal vesicles by interacting with phospholipids probably corresponding to its natural receptor on hepatocytes.

Then, a combined hepatitis A and hepatitis B vaccine based on virosomes was produced. The highly purified, inactivated hepatitis A virions and the hepatitis B surface antigens (HBsAg) genetically engineered in yeast were covalently coupled to the surface of the virosome [51].

Combination vaccines were then developed in a combined diphtheria–tetanus–hepatitis A vaccine. The diphtheria toxoid, the alpha-tetanus toxoid, the beta-tetanus toxoid, and the inactivated hepatitis A virion were covalently bound via cross-linker molecules to the IRIV surface. A “supercombined” vaccine based on virosomes was also developed, containing covalently bound HAV, HBs, diphtheria, alpha-and-beta tetanus, as well as HA and NA from three different influenza strains [33,35]. Today, several different virosomal vaccines are registered in European, Asian, and American countries.

#### V. A CLOSER LOOK AT A SUCCESSFUL VIROSOMAL HEPATITIS A VACCINE (STRAIN RG-SB)

As mentioned earlier, the first vaccine was developed from the hepatitis A strain RG-SB, cultured on MRC-5 human diploid cells and inactivated by formalin, and the vaccine antigen was adsorbed onto virosomes. In clinical trials, a dosage of 0.5-mL suspension of 500 radioimmunoassay units of inactivated hepatitis A antigen was injected into the deltoid muscle. Relative to the World Health Organization reference sera information, a protective level of antibodies is generally considered to be  $\geq 20$  IU/L, as determined by enzyme-linked immunosorbent assay (ELISA) [68].

The first hepatitis A vaccine was extensively tested and went through several chemical analyses, in vitro tests, pre-clinical trials, and, ultimately, large clinical trials consisting of several thousands of volunteers [28,32,46,47]. Initial studies compared three different formulations. In two of the formulations, the inactivated hepatitis A virus was adsorbed onto virosomes or aluminum hydroxide. The third formulation contained only soluble hepatitis A with no adjuvant [31,32]. Local reactions occurred at a significantly reduced rate in the virosomal vaccine [30–32], and the IRIV vaccine induced a more rapid immune response, with statistically higher rate of seroconversion at day 14 accompanied by a higher geometric mean titer (GMT) (Table 2).

In the larger phase 3 clinical studies, in adults and children, seroconversion [ $\geq 20$  ELISA units per liter of anti-hepatitis A virus (anti-HAV) antibodies] was induced in almost all volunteers within 4 weeks (usually 2 weeks) of vaccination with the virosomal hepatitis A vaccine (500 ra-

**Table 2** Kinetics of the Immune Response Following Immunization with Different Hepatitis A Vaccines

Vaccine formulation <sup>a</sup>	Geometric mean titer (% $\geq 20$ IU/mL)				
	Day 0	Day 14	Day 28	Day 180	Day 352 <sup>b</sup>
Fluid	<20	16 (30)	388 (100)	211 (80)	39 (50)
AL (OH) <sub>3</sub>	<20	21 (44)	871 (100)	535 (95)	57 (60)
IRIV	<20	140 (100)	831 (100)	1499 (100)	655 (100)

<sup>a</sup> One dose of each vaccine formulation contained 1000 radioimmunoassay units of HAV antigen and was administered to 40 healthy adults.

<sup>b</sup> Data from 14, 10, and 22 subjects immunized with fluid, AL (OH)<sub>3</sub>, or IRIV vaccines, respectively.

Source: Ref. 59.

dioimmunoassay units), as demonstrated in noncomparative studies [28–30].

By 4 weeks postimmunization, seroconversion rates were still around 98–100%. Antibody titers were still rising during the 4th and 26th week after vaccination and were lasting mainly over one year with GMT of the IRIV vaccine recipients >10-fold higher than for the other two vaccine groups [28,47,48].

Booster injections of the virosomal vaccine 12 months after the initial dose increased antihepatitis A virus (anti-HAV) antibody titers by 11–40-fold. Following the administration of the booster injection, 100% of the volunteers seroconverted [48].

Studies were carried out for 3 years (with a booster vaccination after 1 year) and showed high anti-HAV antibody titers; protection against hepatitis A infection has been estimated to last for over ten years.

A schedule of a single-dose immunization was tested and found effective, reaching protective antibody titers in ≥95% of vaccinated subjects [30–32,49,50] and protecting from hepatitis A outbreaks and endemic disease [49,50].

Data collected from immunogenicity studies and results from multiple field trials have proven that virosomal hepatitis A vaccination (strain RG-SB) is effective in protecting against hepatitis A infection.

## VI. IRIV-BASED INFLUENZA VACCINE

With the exciting results achieved with the virosomal hepatitis A vaccine, attention was turned toward a vaccine against influenza.

The safety and immunogenicity of a trivalent virosomal influenza vaccine was compared with the effects of a commercial whole-virus vaccine and with a subunit vaccine in the elderly [59,70,83]. Elderly as well as immunocompromised patients are at increased risk of complications associated with influenza because of an increasingly poorly functioning immune system [3,70–74]. At that time, the available vaccines were efficacious only in particular settings and suffered from several limitations. Infants and young children require two doses of vaccine spaced 1–2 months apart, and the available vaccines at that time did not result in high, long-lasting protective immune responses. Long-lasting protective immune responses were also lacking in the elderly, but only a single dose of vaccine could be administered per year. This variable immunogenicity was one of the most important reasons for low vaccine uptake among these two groups. Although the existing vaccines were well tolerated, occasionally moderate to severe reactions precluded giving further doses [75,76]. Given the wide variation in immune responses to influenza vaccines, new vaccines which combine an improved immunogenicity with a low rate of side effects were clearly needed.

The search for vaccines with improved immunogenicity [77,78] stimulated the development of formulations with whole virus and subunit vaccines containing new adjuvants and antigen-free delivery systems [81–84]. The new strategies pointed to preparations able to target both local and systemic antibody responses since mucosal immunity consti-

tutes the first line of defense for the host against influenza pathogens and is a major component of the immunological cell-mediated response in the upper and lower respiratory tract passages.

We then became interested in studying the virosomal vaccine concept for other routes of vaccination, in particular, for the intranasal vaccination.

## VII. VIROSOME-FORMULATED INFLUENZA VACCINE FOR PARENTERAL ADMINISTRATION

Virosomes were confirmed to possess significant adjuvantial properties and increased immunoprotective activity when administered as a trivalent influenza vaccine formulation. The results from an early comparative clinical investigation [69] against commercial whole virion and subunit vaccines demonstrated a higher seroconversion rate (a fourfold or greater rise in anti-HA titer) and a significantly greater protection rate (individuals with antibody titers  $\geq 1:40$ ) in subjects vaccinated with the virosome formulation when compared with the existing commercial formula [69].

Further studies confirmed similar results of immunogenicity and safety with the virosome-formulated influenza vaccine [85,87,106]. The virosomes bind to antigen-presenting cells by the influenza virus surface glycoproteins HA and are internalized by receptor-mediated endocytosis, then the virosomes fuse with the membranes of the endosomal cell. This process provides optimal processing and presentation of the antigens to immunocompetent cells.

However, presently used injectable influenza vaccines stimulate serum HA-specific immunoglobulin G (IgG) of HA inhibition antibody in the majority of healthy individuals, but they give a significant rise in HA-specific nasal IgA antibodies in only a minority of subjects.

## VIII. POTENTIAL FOR AN INTRANASALLY ADMINISTERED INFLUENZA VACCINE

The reduced ability of parenteral vaccines to elicit an immunological response at the mucosa, the site of influenza virus entry and propagation, as confirmed by animal experiments [86], is an important determinant of the suboptimal protective capacity of current vaccines. It may also be particularly relevant when considering that mucosal immunity represents the first line of defense for the host and is a major component of the immunological cell-mediated response in the upper and lower respiratory tract. The need to improve vaccine efficacy has led to the development of an intranasal virosome-based influenza vaccine. An efficient vaccine applied to the site of virus entry, i.e., intranasal, may be expected to stimulate humoral and cellular immune responses at both mucosal and systemic levels [87,88]. A further advantage of an intranasal influenza vaccine is the needle-free administration that may improve vaccine coverage due to greater patient acceptance particularly in risk groups. Thus the high tolerability of virosome-based influenza vaccines, namely, Inflexal V, combined with intranasal

administration should provide a safe and effective vaccine that is easy to use.

## IX. OTHER VIROSOMAL-BASED VACCINES

### A. Combined Vaccines

Surface antigens of many viruses when covalently coupled to IRIVs were shown to be immunogenic. Clinical trials with combined IRIV vaccines are still in phase I and II clinical trials; however, some preliminary results have already been published [33–35].

Combined hepatitis A–hepatitis B (HBs) vaccine on a virosomal basis has also been formulated by mixing inactivated HAV virions with hepatitis B surface antigen genetically grown on yeast, and it showed a better effect than that of the commercial monovalent alum products available [35].

Other combinations such as diphtheria–tetanus (DT)–hepatitis A vaccine, where diphtheria toxoid,  $\alpha$ -tetanus toxoid,  $\beta$ -tetanus toxoid, and inactivated virions are covalently bound to the surface of virosomal particles by using cross-linker molecules, are being evaluated because alternatives are needed to current alum-adsorbed DT vaccines, which require two or three doses to be effective and are often accompanied by pain at the injection site.

The IRIV-based formulations appeared to be superior to the alum-based vaccines not only in terms of immunogenicity, but also protectively as reported in mice experiments, where an IRIV-based toxoid vaccine (diphtheria and tetanus) was compared to a standard alum-adsorbed toxoid vaccine in mice. In vitro tests and challenge experiments showed that influenza-primed mice had a threefold higher neutralizing and protective antibody titers after receiving the new vaccine, compared to the group receiving the classical alum formulation [60].

Another “supercombined” vaccine was constructed by binding HAV, HBs, diphtheria toxoid,  $\alpha$ - and  $\beta$ -tetanus toxoids, and, respectively, Ha and NA of three different influenza strains type A and B with very interesting results in a series of clinical trials on human volunteers [51].

After exclusion of epitope-specific suppression by single components, particularly diphtheria and tetanus antigens

showed “antigenic competition” on the HAV and possibly on the HBs antigens.

By reducing the diphtheria and tetanus toxoid subunits, the immune response to these antigens could be increased and antigenic suppression on other antigens was completely removed [34].

First results on the immunogenicity and tolerability of the combined vaccine, compared with that of the corresponding single vaccines, are shown in Table 3.

### B. Nucleic Acid and Peptide-Based Vaccines

The generation of an effective cell-mediated immune response (CMI) is an important factor in the overcoming of certain viral infections. Therefore the ability to generate CMI in addition to antibodies production is a wished feature of a vaccine against virus infection. In the last years, several experiments of DNA vaccination by using plasmid vectors have been showing promising results [52–54] in the induction of humoral and CMI responses.

Because of the need of high quantities of DNA and many vaccination doses, several new delivery systems to target cells have been tested to optimize immunogenicity, including viral and lipid-based methods [55,56].

Virosomes are also being studied as a carrier system for nucleic acid vaccines, particularly to potentiate the poor uptake in target cells of antisense oligonucleotides (ODNs), considered as promising therapeutic agents against viral diseases, in cancer therapy, or as immunomodulators.

Recent data showed evidence that ODNs encapsulated into fusogenic, reconstituted cationic influenza virosomes (better interactions between positively charged lipids on virosomes and negatively charged oligonucleotides) are rapidly and efficiently internalized into cancer cells due to mediation of the fusion activity of the hemagglutinin of the influenza virus [57]. In these experiments, the addition of cationic virosomes containing antisense L-myc ODNs in the picomolar range to small-cell-lung-cancer cultures overexpressing the L-myc oncogene induced inhibitory effect on thymidine uptake by those cells.

During this process, the content of oligonucleotides is released into the cytoplasm where they stay protected from

Source: Ref. 34.

enzymatic degradation; this protection could be efficacious also in the blood, an important feature for a future *in vivo* application of this type of vaccine.

Investigations carried out on influenza virosomes used as a tumor-associated antigen-gene delivery system also showed very promising results [58].

For these experiments, engineered plasmid (GC90) expressing the parathyroid hormone-related peptide (PTH-rP) associated with prostate and lung tumor cells was inserted on influenza virosomes (GC90V). The ability of such virosomes including PTH-rP plasmids to elicit a multiepitopic CTL-mediated immune response *in vitro* and in a mouse model has been described, providing a rationale for investigating this system in clinical trials of active specific anticancer immunotherapy.

Further studies will include clinical trials with GC90V to elucidate the possible *in vivo* ability to migrate in tumor tissue where they could have an antitumor effect.

The efficacy of mumps DNA vaccine delivered by virosomes administered intranasally in mice was recently described [61]. In this study, a plasmid vector expressing viral hemagglutinin or the fusion protein associated with virosomes was tested for humoral, mucosal, and cell-mediated response. Results showed production of specific s-IgA in respiratory tract and circulating IgG antibody in the blood. PCR techniques revealed the presence of the plasmid 1 month after immunization. DNA-influenza virosome composition was shown to be safe and nontoxic in mice at doses also producing a good immune response. Doses as small as 5 µg DNA were sufficient to induce an immune barrier to prevent infection at the mucosal entry site [61].

Virosomes were used as a delivery system for the development of a synthetic peptide-based malaria vaccine SPf66 [36]. Mice were immunized twice intramuscularly with peptide-loaded virosomes, and the amount of elicited anti-SPf66 IgG was determined by ELISA. Titers were higher and immunization doses were lower for the SPf66-IRIV vaccine than with alum-adsorbed, when mice were preimmunized with a commercial whole virus vaccine because of the priming effect. Monoclonal antibodies produced by four B cell hybridoma clones derived from a mouse vaccinated with IRIV formulation cross-reacted with *Plasmodium falciparum* blood stage parasites in immunofluorescence tests, and all were specific for the merozoite protein-1-derived 83.1 portion of SPf66. In this study, biomolecular interaction analyses and sequencing data provided evidence that a synthetic peptide vaccine delivered virosomally has great potential as a combined vaccine targeted against several antigens as well as against multiple pathogens.

An HIV vaccine, based on genetically modified glycoprotein and nonstructural peptides, and a vaccine against hepatitis C and respiratory syncytial virus (RSV) by using the virosomal carrier system are all under study [37].

## X. CONCLUSION

Immunostimulating reconstituted influenza virosomal vaccines comprised of viral glycoproteins, bacterial toxoid, inactivated virus, recombinant proteins, synthetic peptides,

and DNA plasmids or polynucleotides were formulated and tested. The safety profile of IRIV vaccines has been excellent, and the immunopotentiating effect was superior to comparable alum-based vaccines.

Compared to alum-adsorbed vaccines, they elicit far fewer local reactions. Both local and systemic reactions are predominantly mild and transient. Additionally, immunization with IRIVs does not induce a serum antiphospholipid antibody response even after repeated doses of vaccine have been administered. IRIV-based vaccines are currently manufactured on a large scale and are available under the brand names Epaal® for hepatitis A and Inflexal V® for influenza. New formulations of antigens incorporated into IRIVs are undergoing testing and clinical evaluation.

### I. INTRODUCTION

A major focus of biotechnology is the improvement of human health around the globe. It is anticipated that the genomic revolution will greatly expand our knowledge of the molecular basis of many diseases and pathological states. Combining this knowledge with powerful screening techniques will be used in the development of safe and efficacious drugs for the prevention, diagnosis, and treatment of disease, including new vaccines and vaccine technologies. Unfortunately, the availability of these new treatments for use by all those who need them greatly depends on economic considerations such as the cost of their development, production, and delivery. Therefore, a major challenge of biotechnology is to reduce clinical innovations to economically viable practice, and the production and oral delivery of plant-derived vaccines is a step in that direction.

### II. WHY PRODUCTION AND DELIVERY OF VACCINES IN PLANTS MAKE SENSE

Despite the public health success of current vaccines in controlling various infectious diseases, there are limitations in the technology as we are faced with many emerging infectious diseases, some of which are the result of pathogens that have the ability to mutate rapidly to circumvent vaccination, as well as the unprecedented reality of bioterrorism. Production and delivery can be an issue in vaccine development, and manufacturing may be hampered by high costs for vaccines against many of the pathogens for which vaccines are needed. Furthermore, for certain live vaccines, attenuation may impact immunogenic properties, making such vaccines ineffective or unsafe.

Mucosal immune responses, characterized by production of secretory antibodies such as secretory immunoglobulin A (sIgA) and the transport of these antibodies across the epithelium, represent a first line of defense against pathogens that colonize and infect mucosal surfaces. As a result, stimulation of the mucosal immune system may be a particularly advantageous route of vaccination. Furthermore, mucosal vaccines that can be delivered by oral or nasal route have the advantage of not requiring the use of needles, and are perhaps safer and may result in improved patient compliance. Consequently, vaccine development focuses on finding alternatives to traditional vaccines in terms of both immunogen source and route of administration.

Subunit vaccines, especially those that target the mucosal immune system, can potentially fill this gap in vaccine development. To create these vaccines, a gene encoding an antigenic determinant from an infectious agent is cloned, put under the control of an appropriate expression system, and transferred into a host organism. The transgenic host will then produce a “subunit” of the pathogen, a protein that cannot cause disease but can elicit a protective immune response against the pathogen. In most studies of the last 15 years, subunit vaccines have been purified from transgenic “production hosts” (e.g., cultured yeast cells) and have been delivered via injection to immunize against a specific disease. To date, the only recombinant subunit vaccines licensed for use in humans are a yeast-derived hepatitis B vaccine and an *Escherichia coli* recombinant Lyme disease vaccine, which are delivered by intramuscular injection.

While still in experimental stages of development, plant-produced, orally delivered subunit vaccines provide a strategy to efficiently improve modes of production, distribution, and administration. Such plant-based vaccines merge innovations in medical science and plant biology. Since the emer-

gence of the original idea about 13 years ago [1], it has been embraced by a growing number of laboratories in the academia and industry. Work in this field was reported in the previous edition of this volume [2], and due to the subject's interdisciplinary nature, importance, and appeal, it continues to be periodically reviewed [3–10]. In this chapter, we present an update on advances in the technology and, in particular, on recent Phase I clinical trials run in the United States. We also address areas of research that require further attention if plant-based vaccines are to become a viable reality and contributor to world health.

### III. EXPRESSION OF ANTIGENIC PROTEINS IN PLANTS

Plants can cost-effectively produce large amounts of functional proteins, free of animal pathogens, and production can be increased to agricultural scale. As a result, transgenic plants have emerged as a promising alternative to available fermentation-based production systems for valuable pharmaceuticals. The ability of a plant to produce, correctly process, and assemble complex foreign proteins from a variety of organisms is well documented and is based on extensive research during the past two decades in the realms of plant molecular biology, plant transformation, and regeneration. This work has not been confined to the developed world, as many scientists and public health authorities in developing countries have embraced the new technology for the possible future benefit of their people. Regardless of the many reported successes, expressing a particular recombinant protein to significant levels in plants remains an empirical exercise, which often requires custom tailoring and optimization. Unfortunately, except for a few rules of thumb, insights gained while studying one protein are not always readily transferable when approaching a different expression project. However, when focused on the endproduct, such as a plant-expressed antigen as a vaccine candidate, the expenditure of time, effort, and resources directed at gene optimization can significantly contribute to success. A few studies (e.g., Richter et al. [11]) have attempted to address the issues surrounding the low levels of expression of recombinant proteins that may sometimes occur in transgenic plants. Questions regarding the "how, where, and when" to express a transgene to allow maximal accumulation of its product while retaining its functional properties have been addressed by many workers in the field of agricultural biotechnology. It is especially important in the case of plant-based vaccines, where the goal is sufficient dosage and minimal processing of antigenic proteins in edible plant tissue, to ensure that sufficient quantities survive passage through the stomach to elicit a clinically relevant immune response.

### IV. PLANT-DERIVED VACCINES IN CLINICAL TRIALS

The genesis of the concept of plant-based vaccines occurred in 1986 [12] and was first documented in a patent application entitled "Oral Immunization by Transgenic Plants" known in the field as the "Curtiss–Cardineau Patent" after its inventors [1]. Although this publication is the first description

of the plant expression of an antigen of an important mucosal pathogen (*Streptococcus mutans*) and the subsequent feeding of transgenic plant tissue to elicit a secretory immune response, the results of the work were never reported in the scientific literature. Shortly afterward, in 1992, a paper describing the expression of hepatitis B surface antigen (HBsAg) in tobacco plants was published by Mason et al. [13], who proposed that this recombinant protein produced in plants could serve as a vaccine candidate. Following the publication of their pioneering paper, Arntzen and Mason continued to develop the concept of plant-based vaccines and reported on their work in a succession of papers. The initial report focused on the expression and structural consideration of the plant-produced HBsAg, which assembled into 22-nm virus-like particles (VLPs) similarly to the yeast-derived commercial vaccine antigen. Partially purified and concentrated tobacco-derived HBsAg was used in parenteral immunization experiments in mice, demonstrating its ability to invoke the expected B and T lymphocytic responses [14]. In order to further prove that plant-derived HBsAg could stimulate mucosal immune responses via an oral route, the group refocused their attention to expression in potato tubers [11]. Surprisingly, the plant-derived material proved superior to the yeast-derived antigen in both priming and boosting immune responses in mice [11,15]. Success in these preclinical trials led to Phase I clinical trials with HBsAg potatoes (Thanavala, Mason, and Arntzen, submitted for publication). To complement the efforts with HBV vaccine, Arntzen and Mason explored plant expression of other vaccine candidates following essentially the same experimental approach. Progress on two of these antigens, the labile toxin B subunit (LT-B) of enterotoxigenic *E. coli* (ETEC) and the capsid protein of Norwalk virus (NVCP), actually occurred more rapidly than did their work on HBsAg [16–20]. These antigens of two important enteric pathogens may represent examples of the ideal oral subunit vaccine candidate. Both are oligomers: LT-B is a pentamer, which has a high affinity to GM<sub>1</sub> gangliosides present on mucosal cells [16], whereas NVCP can form VLPs [19]. Furthermore, both have evolved to survive the extreme conditions of the stomach and infect (in the case of NV) or colonize (in the case of *E. coli*) the gut epithelium.

Another apparent advantage associated with plant expression of these proteins was accumulation to higher levels in potato tuber than that seen with HBsAg. Significantly, both assembled correctly into functional oligomers that could elicit oral immune responses in animals [17,19] and humans [18,20]. The Phase I clinical trial with potato tubers expressing LT-B not only provided the proof of concept that orally delivered, plant-based vaccines could result in an immune response in humans, but also shared the distinction of being one of the first experiments with a pharmaceutical product derived from a transgenic plant that were conducted in humans. Results of a clinical experiment with plant-derived monoclonal antibodies against *S. mutans* were published in the same issue of *Nature Medicine* [21].

The clinical trials were intended to test both the safety and immunogenicity of plant-produced LT-B, NVCP, and HBsAg (Phase I/II) [18,20] (Thanavala et al., unpublished manuscript). In all three trials, individuals who consumed raw potato tubers containing 0.3–1.0 mg of the antigens

developed antibody responses. It is important to note that three very different pathogens are represented by the three antigens and represent viral (NV and HBV), bacterial (*E. coli*), enteric (NV and *E. coli*), as well as nonenteric (HBV) organisms. The titers of mucosal and systemic antibodies in some of the test subjects suggest that they would be protected from infection [18,20] and provide the basis for anticipated wider-scale clinical trials with these antigens.

## V. PLANT-DERIVED VACCINES CAN PROVIDE PROTECTION AGAINST A PATHOGEN CHALLENGE

The initial successes of early clinical trials encouraged other groups to explore the ability of plants to produce, fold, and assemble other vaccine candidates for the prevention of human and animal diseases. Various laboratories reported on efforts to produce transgenic plant-based vaccines for oral delivery to protect against human viruses such as rabies [22], respiratory syncytial virus (RSV) [23], measles [24], rotavirus [25–27], hepatitis B [28], and human cytomegalovirus [29,30]. Advances toward plant-based vaccines targeting cholera [27,31–33] and ETEC [27,34] were also reported.

Plant-derived oral vaccines for veterinary use are aimed at foot and mouth disease virus (FMDV) [35–38], swine-transmissible gastroenteritis virus (TGEV) [10,39–41], rabbit hemorrhagic disease virus [42], and *Mannheimia haemolytica*, the bacterial agent that causes shipping fever [43].

Although high titers of secretory and circulating antibodies following oral vaccination with plant-derived vaccines is an important immune correlate, proof of efficacy requires that vaccination results in immune system memory to provide long-lasting protection against a pathogen challenge. In a few cases [17], surrogate protection assays have been performed. By contrast, veterinary vaccines provide an opportunity to assess the degree of immune protection more directly. The series of papers published by Carrillo et al. [35,36] and Wigdorovitz et al. [37] serves as an excellent example of this methodological approach in a veterinary context. Their first report described the use of a model plant system (*Arabidopsis thaliana*) for the expression of the VP1 protein of FMDV [35]. Plant extracts containing VP1 provided full protection in mice after parenteral delivery and constituted the first demonstration of protection by a recombinant vaccine candidate produced in transgenic plants. Further studies using a larger number of mice immunized with extracts from transgenic potatoes [36] corroborated the initial work. They next expressed VP1 in alfalfa and delivered the transgenic plant material orally to mice. Despite low antigen expression, they achieved 70% protection against a virulent challenge after repeated oral boosting [37].

## VI. FORMING MULTIVALENT AND MULTICOMPONENT VACCINES

The design of vaccines to stimulate several facets of the immune system, such as induction of strong humoral and mucosal responses as well as effective cellular immune responses, is highly desirable. Similarly, combination vaccines

targeting multiple pathogens in one formulation are preferred. Therefore, developing both multivalent and multi-component plant-based vaccines provides both efficacious and cost-effective immunization strategies. Plants harboring transgenes encoding the antigens of several pathogens—either by direct transformation or sexual crosses of individually transformed lines, or the blending of separately transformed plant tissues—can easily fulfill this need.

An alternative approach to achieve the same goal was taken by Yu and Langridge [27]. In their paper, they describe a recombinant multicomponent vaccine based on cholera toxin (CT). They fused peptides containing important protective epitopes derived from two other enteric pathogens—ETEC, which causes bacterial traveler's diarrhea, and rotavirus, which causes acute viral gastroenteritis—to the CT-A2 and CT-B subunits of CT, respectively. The two recombinant CT subunit fusions were expressed from a single bi-directional promoter, ensuring a coordinated expression pattern for the two gene fusions and potentially facilitating the assembly of the chimeric holotoxin. In this approach, CT provides a scaffold for presentation of the protective epitopes, acts as a mucosal targeting molecule without toxic effect due to use of the nontoxic CT-A2 and B subunits, and is itself a vaccine candidate. The recombinant protein represents a trivalent vaccine that can elicit significant mucosal and humoral responses against *Vibrio cholerae*, ETEC, and rotavirus. Mice, orally immunized with potatoes expressing these recombinant antigens, developed immune memory B cells as well as helper T cell type 1 (Th1) responses, which are indicators of successful immunization. Further, pups of immunized dams were protected from challenge with rotavirus, with a significantly lower morbidity rate as compared to controls. These results provide robust evidence for a vaccine strategy employing chimeric microbiological proteins expressed in plants.

## VII. PLANT-VIRAL VECTORS AS ALTERNATIVE EXPRESSION SYSTEMS

Low-level antigen expression in transgenic plants (0.01–2% of total soluble protein) remains a critical issue. Up to three doses of 100 g of raw potato tubers expressing LT-B were needed in the clinical trials described above to elicit a significant immune response [18,20]. It is likely that antigens with less immunogenic potential would require substantially larger doses to be effective. Even with more palatable alternatives to potatoes, such as tomatoes, low levels of antigen expression could severely limit the utility of any vaccine product.

Recently, plant viral expression vectors have been constructed to allow efficient expression of recombinant proteins in plants [44–46]. These vectors are transgenic viruses incorporating a foreign gene that expresses a recombinant product as the virus spreads throughout the plant. Although plant virus-based vectors have been useful in directing the expression of medically important transgenes, such as single-chain antibodies [47] and a hepatitis C virus hypervariable region 1/CT-B fusion [48], there may be certain insert size limitations. Alternatively, some plant virus vectors make use of coat-protein peptide fusions [49–51]. Viral vectors based

on tobamoviruses, such as tobacco mosaic virus, have received the most attention [48,51–53]. Other plant virus vectors that have been described are based on potyviruses (e.g., plum poxvirus) [54], comoviruses (e.g., cowpea mosaic virus) [53,55,56], and bromoviruses (e.g., alfalfa mosaic virus) [57].

The selection of antigens expressed by viral vectors is also impressive, including bacterial pathogens such as *V. cholerae* [27,48], *Staphylococcus aureus* [58], and *Pseudomonas aeruginosa* [53,59,60]. An even larger selection of viral antigens has been expressed via plant viral vectors such as hepatitis C virus [48], RSV [57], rotavirus [61], human immunodeficiency virus [49,62,63], rabies [49,51], mink enteritis virus [56], canine parvovirus [56,64,65], FMDV [38], and rabbit hemorrhagic disease virus [54].

In most cases, viral vectors result in increased accumulation of the expressed recombinant antigens. Accumulation levels of the FMDV VP1 protein were low when the gene was expressed in stably transformed plants on the order of 0.005–0.01% total soluble protein [35,36,38], but were substantially higher when the antigen was expressed using a tobamovirus vector, approaching up to 150 µg/g fresh weight, or approximately 15% total protein [38]. Interestingly, it is not uncommon to see similarly high levels of expression of stably integrated recombinant gene products in transgenic seeds without the use of viral vectors [10]. The success of viral expression vectors relies primarily on the fact that plant viruses are very efficient pathogens, employing very small genomes to infect their hosts. However, disadvantages include genetic instability due to recombination among viruses to remove inserted sequences, a requirement for individual plant inoculation and environmental concerns regarding the release of agronomically important plant pathogens. All of these issues will need to be addressed with further research if viral vectors are to become a successful alternative to current plant transformation systems.

## VIII. PLASTID TRANSFORMATION

Over the past several years, data have been published on the transformation and expression of transgenes in plant chloroplasts, thereby taking advantage of the semiautonomous genetic machinery of these organelles [8,66–68]. Potential advantages of this system are high ploidy state, high transcription and translation rates, and the lack of gene silencing, all of which can contribute to high levels of foreign protein accumulation. Although site-directed integration through homologous recombination appears to be a requirement, it might also provide more control of genetic engineering and increased uniformity of transgene expression [8,67,69,70]. Additionally, one can make use of polycistronic operons, much like a bacterial system, to permit coordinated expression of multiple genes [70,71]. Lastly, and of great importance particularly for biopharmaceutical crops, environmental transgene containment is ensured through the strictly maternal inheritance of plastids in most species [72].

Direct transformation of chloroplasts results in high levels of protein accumulation, up to several percent of total soluble protein, which is considerably more than those

reported for other systems. In one case involving an operon from *Bacillus thuringiensis*, more than 40% was reported [70]. Pharmaceutically important proteins expressed in plastids include human somatotropin [67], a biodegradable synthetic polymer [73], and also CT-B as a vaccine candidate [33].

Plastid transformation has recently been extended to the experimental model plant *A. thaliana* [74] and two important solanaceous crop species, potato [75] and tomato [68]. In relation to the latter two crops, transgene expression and recombinant protein accumulation were observed to occur in plastids that are specific for these two plants: potato tuber amyloplasts and tomato fruit chromoplasts. This is of particular importance because it provides expression in the edible tissues of these plants.

Unique advantages and disadvantages of plastid expression depend on the prokaryotic nature of the organelle, but so do its shortcomings. For example, N-glycosylation strictly depends on the endomembrane system, which might preclude utility for viral antigens. However, in the case of prokaryotic antigens, or proteins and antigens that do not need to be glycosylated, plastids may offer some distinct advantages.

## IX. OTHER TARGETS OF PLANT-EXPRESSED ANTIGENS

Transgenic plants have been proposed for the production of autoantigens. One concept is the expression of human autoantigens to treat autoimmune diseases by tolerizing the immune system rather than stimulating it. An autoantigen implicated in diabetes, glutamic acid dehydrogenase (GAD), was produced in plants and fed to nude obese diabetic (NOD) mice, which have a particular susceptibility to the development of diabetes. This resulted in a reduction in pancreatic islet inflammation, an indication that immunotolerance had occurred [76]. Arakawa et al. [77] used a similar approach by feeding plant tissues expressing either proinsulin or a CT-B/proinsulin fusion to NOD mice, and they also observed a reduction in pancreatitis. This result suggested that they had immunotolerized the mice against this type of cytotoxic T cell-mediated autoimmune disease. In this case, reduction of pancreatic inflammation coincided with increase in anti-insulin antibodies, mostly of the IgG1 isotype, leading to the conclusion that the cytotoxic T-cell response is suppressed. They were able to enhance this effect with the addition of a second antigen fusion, CT-B/GAD. It is interesting to note that the reduction in pancreatitis was considerably greater with the fusions than with the autoantigens alone, supporting targeting or adjuvant activity due to the CT-B component. We should also mention the differences in feeding protocols used in these two experiments. Ma et al. [76] fed very large amounts of recombinant GAD (1–1.5 mg/mouse/day) daily for 4 weeks, a more frequently used toleration protocol. Arakawa et al. [77], on the other hand, fed potato containing 20 µg of the CT-B-proinsulin fusion protein in five doses over a 4-week period, which is almost identical to the feeding regimen they had reported to be effective in eliciting protective immune responses against foreign antigens [27]. As Arakawa et al. suggested in their

paper and as mentioned above, perhaps the fusion to CT-B may facilitate the presentation of the antigen to the gut-associated lymphoid tissue to enhance the response. The control of mammalian wild species experiencing overpopulation in a humane and effective manner through the use of edible immunocontraceptive vaccines provides another option for the technology [78,79]. The approach is used to express in plants a protein or a carrier protein harboring an antigenic epitope of an essential component of the mammalian reproductive system with the intention of inducing a humoral response, upon feeding by the animal, that results in sterility. The animal would remain sterile coincident with immune memory, or until the next boosting vaccination. Antigenic targets reportedly under investigation include the gonadotropin-releasing hormone and ZP3 from the zona pellucida of the mammalian ovulated egg [79,80]. Although effectiveness is still under study, this application is bound to meet considerable objections, the principal one of which is the danger these broadly cross-reacting vaccines potentially present to other mammalian species that will have access to them. This is a legitimate environmental concern that must be addressed.

## X. ISSUES AND CHALLENGES

The remarkable growth of the field of plant-produced, orally delivered vaccines, from its germination well over a decade ago in a couple of laboratories to a research area involving many laboratories around the world, has occurred despite initial skepticism by many in the scientific, and particularly the immunology, community. The idea was initially advocated principally by plant biologists, yet has advanced to date through three successful Phase I human clinical trials. Successful development of the technology comes in spite of deficiencies in our understanding of mucosal immunity. In fact, many of the original criticisms are still valid and we have been able to identify other areas that will require investigation in order to bring this technology out of the laboratory to become a functional reality. These issues should be seen as challenges rather than impenetrable roadblocks.

In no particular order, we see issues associated with addressing concerns about oral tolerance; the identification and use of oral adjuvants; the potential impact of glycosylation of antigen proteins in plants, dosing concentration and timing, selection of the optimal plant production system, and control of antigen expression within the plant to enhance expression level; and location and the determination of processing protocols for optimal delivery to both facilitate patient compliance and enhance the immune response.

The concept of an edible vaccine presents itself to some immunologists as a contradiction in terms. They argue that the most common response to food antigens is an induced state of specific unresponsiveness, which is called oral tolerance [83–85]. From a tolerance perspective, we must be cognitive of the fact that tolerance plays an important role in the response of the host to environmental antigens and to resident microflora. At the very least, it certainly would be counterproductive should a vaccine candidate induce long-term tolerance rather than a protective immune response.

The issue is further complicated by reports in the literature of the use of comparable experimental approaches with similar constructs and feeding regimens to induce either immune responses or tolerance [27,77]. The issue of oral tolerance is quite controversial within the immunology community, reflecting the complexity of the phenomenon. Clearly, avoidance of tolerance to antigenic determinants of pathogens delivered via plant-based vaccines is critical. Dosing regimens must be employed to prevent such an outcome. Additionally, optimal concentration of antigen provided in both primary inoculum and subsequent boosting, as well as the timing of the boosting, will need to be determined empirically. Due to the high levels of antigen anticipated to be necessary for oral delivery and appropriate stimulation of the mucosa-associated lymphoid tissue, it is likely that some sort of adjuvant will be required for optimal response. Identification of appropriate adjuvants is another focus of research in this area. The inclusion of nontoxic mutant forms of CT or LT as part of a formulation may be one approach [86], whereas the identification of additional potential oral adjuvants should also be pursued. For example, plant products such as lectins and saponins are being explored for their oral adjuvanticity [62,81,82].

We know that plants glycosylate proteins and this can be used to our advantage. However, we also know that carbohydrate side chains, while added at the same sites in plants and animals, have slightly different structures. What we do not know is if that is, or will be, important in the immune response. In some instances, it has been reported that the expression levels of the antigens are so low and that an unrealistic quantity of plant material would have to be consumed to achieve meaningful immune responses. As a result, concerns regarding the unpredictable and highly variable levels of expression are relevant. These are recurrent problematic themes that can be solved by improving the expression systems. Careful identification and selection of the host plant married to optimization of expression vectors and/or novel expression systems may provide a solution to low expression level. Furthermore, compartmentalization of expression in discrete tissues may provide additional benefits with regard to controlled expression, level of protein antigen produced, and stability, and may also impact processing concerns. In fact, minimal processing and creation of edible vaccine “batches” may contribute to a solution of the variability problem. Currently available food processing technologies may be employed to generate formulations that are not only more concentrated but have delivery advantages as well (Kirk, in preparation). It is important to note that even with the limitations of variable and/or modest antigen levels, edible vaccines were able to establish clinically relevant immune responses in adult human volunteers. Further research can only lead to improvements in the system.

## Vaccinia Virus and Other Poxviruses as Live Vectors

Bernard Moss

National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland, U.S.A.

### I. VACCINIA VIRUS AS A HUMAN VACCINE FOR SMALLPOX

On May 14, 1796, Edward Jenner inoculated 8-year-old James Phipps with cowpox virus obtained from an infection on the hand of Sarah Nelmes, a milkmaid. Subsequent events established that this simple procedure provided complete protection against smallpox and formed the basis for its ultimate eradication: The last case of endemic smallpox was in 1977 [1]. The prophylactic effect of vaccination was due to the close genetic and antigenic relationships between variola virus, the causative agent of smallpox, and its more benign relatives cowpox virus and vaccinia virus. The latter virus may have been isolated from an infected horse and, presumably because of its milder reactivity, was substituted for cowpox virus [2]. Vaccinia virus was economical to produce, active in low amounts, heat stable, resistant to freeze drying, simple to administer, relatively safe, and provided long-lasting immunity. Of equal importance for smallpox eradication, however, were the ease of diagnosis of the disease, variola's lack of antigenic variation, and the absence of latently infected human or animal reservoirs. Although the vaccine was immediately successful, eradication of smallpox proved difficult for logistical reasons. In 1967, the World Health Organization implemented a new intensified global ring vaccination strategy that ultimately contained and eliminated variola virus from nature. Nevertheless, registered stocks of variola virus are preserved in both the United States and Russia. With the eradication of smallpox, the general need for vaccination was eliminated and the practice largely stopped. As a result, most people are now susceptible to variola virus, as well as other orthopoxviruses such as monkeypox virus. As a precaution against the possible reintroduction by terrorists of variola virus from an unregistered stock, a new tissue-culture-derived vaccinia virus vaccine will soon be available. In addition, attenuated strains of vaccinia virus are being evaluated as safer alternatives to the conventional vaccine.

Soon after the eradication of smallpox and the cessation of general vaccination, the ability to produce recombinant

vaccinia viruses that express genes of other microorganisms was developed [3,4]. Such genetically engineered viruses have been used extensively as research tools to establish the targets of humoral and cell-mediated immunity and are being evaluated as live recombinant vaccines. Similar approaches have been used to generate immunogenic avipoxvirus recombinants [5,6] and could be applied to other poxviruses.

### II. CONSTRUCTION OF POXVIRUS EXPRESSION VECTORS

#### A. Insertion of Foreign DNA into the Poxvirus Genome

The development of expression vectors depended on an understanding of the molecular biology of poxviruses, a subject that is reviewed in detail elsewhere [7]. The distinctive characteristics of vaccinia virus (and other poxviruses) include the following: a large, complex, enveloped virion containing enzymes for mRNA synthesis; a genome composed of a linear, double-stranded DNA molecule of about 200,000 base pairs; and the ability to replicate within the cytoplasm of infected cells. Detailed protocols for preparing and characterizing recombinant vaccinia viruses are available [8–11] and only general concepts are dealt with here.

The large size of the vaccinia virus genome posed an initial hurdle to the incorporation of foreign genetic material. In addition, the viral DNA is not infectious because enzymes contained within the virion are essential for gene expression. However, it was known that recombination occurs between homologous DNA sequences of poxviruses [12]. Furthermore, recombination was shown to occur between virus-derived genomic DNA and either subgenomic DNA fragments [13,14] or recombinant plasmids [15] that had been transfected into the cell. The latter finding provided a way of inserting foreign DNA into the vaccinia virus genome: A plasmid containing a foreign gene flanked with vaccinia DNA is transfected into an infected cell, allowing homologous recombination to occur during DNA replication.

Of course, for the recombinant vaccinia virus to remain infectious, the foreign DNA must not interrupt any vital viral function. This was not an obstacle, however, because there are many nonessential vaccinia virus genes and it is possible to insert DNA between genes. In this manner, foreign DNA segments as large as 25,000 base pairs were recombined into the vaccinia virus genome [16]. Several methods are available to select recombinant viruses or distinguish the plaques from the parental virus. Similar methods have been used to generate recombinant avian poxviruses.

Two additional methods have been used to form recombinant vaccinia viruses. Both depend on the *in vitro* cleavage of the vaccinia virus genome at a unique restriction endonuclease site. In one procedure, a DNA fragment containing the foreign DNA is ligated to the cleaved genome, which is then transfected into cells infected with a helper virus—either a temperature-sensitive vaccinia virus or an avian poxvirus [17,18]. The procedure is especially useful for very large DNA inserts or to avoid intermediate cloning in bacteria. Alternatively, three-way recombination can be achieved by transfecting the cleaved genome and a foreign DNA segment with flanking vaccinia virus sequences into cells infected with a helper virus [19,20].

### B. Expression of Foreign Genes

Poxviruses encode their own transcription system, which includes a multisubunit RNA polymerase, stage-specific transcription factors, poly(A) polymerase, and capping and methylating enzymes [7]. Because the DNA sequences that are recognized by the viral transcription system are unique, the use of poxvirus promoters for foreign gene expression is obligatory. Vaccinia virus gene expression is temporally regulated: Early-stage genes are transcribed before DNA replication and intermediate and late-stage genes are transcribed after DNA replication. Some genes are expressed throughout infection because they have two promoters. A foreign gene inserted into the vaccinia virus genome will be regulated in a predictable manner, depending on the vaccinia virus promoter placed adjacent to it. In general, high expression is obtained by using late promoters derived from vaccinia virus genes encoding major structural proteins, but early or early/late promoters are best for expression in antigen-presenting cells and inducing cytotoxic T-cell responses [21,22]. Therefore, synthetic early/late promoters have been designed [23,24]. Because vaccinia virus can accommodate large amounts of additional DNA, multiple genes can be expressed using vaccinia virus vectors.

Care needs to be taken in choosing the form of the foreign gene to be expressed. Most importantly, only continuous open reading frames may be used, as splicing does not occur in the cytoplasm. This problem is avoided by using cDNA copies of mRNAs. In addition, any cryptic poxvirus early transcription termination signals, TTTTNT in which N is any nucleotide, should be eliminated [25].

### C. General Methods of Isolating Recombinant Poxviruses

Vaccinia virus is cytopathic and produces large plaques on monolayers of appropriate cell lines; most virus isolation

procedures depend on the discrimination of plaques formed by parental and recombinant viruses. Recombinant viruses can be recognized by the presence of foreign DNA sequences or expression of the gene products. Thus, plaques can be screened by hybridization to specific DNA [26] or by binding to antibody [8]. However, because recombinants usually comprise less than 0.1% of the progeny, additional selection or screening methods have been devised.

To facilitate the process of recombinant virus formation, plasmid transfer vectors have been constructed in which a vaccinia virus promoter followed by unique restriction endonuclease sites has been inserted into the vaccinia virus DNA needed for homologous recombination. The first of these general transfer vectors used the vaccinia virus thymidine kinase (TK) gene as the site for promoter insertion to provide a method for the selection of recombinant viruses [27]. The selection depends on the disruption of the TK gene upon recombination of the foreign DNA into the vaccinia virus genome. The basis for the selection is the lethal effect of the incorporation of certain nucleoside analogs into viral DNA and the need for a functional TK for this to occur. Other selection approaches depend on the cotransfer of a dominant selectable marker along with the foreign gene. Genes encoding the neomycin-resistance [28], guanine phosphoribosyltransferase [29,30], hygromycin-resistance [31], puromycin-resistance [32], and herpes simplex virus TK [33] genes have been used for this purpose.

Several screening methods, some of which may be used in conjunction with selection procedures, have been developed. These include the cotransfer of the  $\beta$ -galactosidase [34],  $\beta$ -glucuronidase [35], or enhanced green fluorescent protein [36] genes, which allow the color staining or fluorescence of recombinant plaques. Still other screening methods depend on the plaque phenotype of the recombinant virus [37] or host range [38].

### D. Hybrid Expression Vectors

A high-expression system with great utility for protein synthesis in cultured cells, rather than for live virus immunization, has been developed. This innovation took advantage of the bacteriophage T7 (or related SP6) RNA polymerase, which is a single-subunit enzyme with high catalytic activity and strict promoter specificity. By attaching a vaccinia virus promoter to the T7 or SP6 RNA polymerase gene, recombinant vaccinia viruses that express bacteriophage RNA polymerase have been constructed [39,40]. Cells are infected with the latter and then either transfected with a plasmid that has a foreign gene regulated by the bacteriophage promoter or coinfect with a second vaccinia virus that has the bacteriophage promoter regulated foreign gene [39,41]. Inducible systems have been developed in which both the T7 RNA polymerase gene and the T7 promoter regulated foreign gene are in the same virus [42]. Expression can be enhanced by inserting the untranslated leader sequence of encephalomyocarditis virus before the initiation codon [43].

### E. Fidelity of Expression

Excellent results have been obtained using vaccinia virus vectors to express foreign genes from viral, prokaryotic, or

eukaryotic sources. Factors that contribute to the high success rate include the cytoplasmic site of expression and concomitant use of vaccinia transcription factors. The cytoplasmic site avoids potential problems related to cryptic splice sites, processing, and nuclear-cytoplasmic transport. For example, the structural proteins of HIV-1 were expressed without the need for regulatory factors *rev* and *tat* [44,45].

The proteins made by recombinant vaccinia viruses are usually processed and transported in a manner similar to that occurring in uninfected cells. For example, N- and O-glycosylation [46], proteolytic cleavage [44,47], polarized membrane insertion [48], and nuclear transport [49] all occur. Biologically active enzymes, such as reverse transcriptase [45] and bacteriophage T7 RNA polymerase [45] and ion channel proteins [50] are made. Perhaps most striking is the expression of multiple genes by recombinant vaccinia virus leading to the assembly of infectious RNA virus particles [51–53].

### III. RECOMBINANT VACCINIA VIRUS VACCINES

#### A. Experimental Vaccines

Vaccinia virus can infect most mammalian as well as avian species, making it a useful vector for studying the immune response to proteins of both human and veterinary pathogens. Recombinant vaccinia viruses are standard laboratory tools for defining protective antigens and fine-mapping immunogenic epitopes from infectious agents. Prophylactic, live recombinant vaccinia viruses have protected animals from challenge with numerous viruses, bacteria, and parasites [54]. In addition, poxvirus vectors expressing tumor antigens have been investigated for the immunoprophylaxis and immunotherapy of tumors in animal models [55–58].

#### B. Immunogenicity

A particular advantage of vaccinia virus as a recombinant vaccine vector is its ability to mimic the immune responses elicited by viral antigens during the course of a natural infection. Consequently, cell-mediated as well as humoral immunity is evoked [59]. Antibody responses induced by recombinant vaccinia virus can be as high as those induced by natural infection [60]. Mice vaccinated with a recombinant expressing herpes simplex virus (HSV) glycoprotein D were still protected from a lethal challenge with HSV one year after vaccination [61], and macaques vaccinated with a simian type D retrovirus (SRV-2) envelope glycoprotein recombinant were still protected against SRV-2 two years after vaccination [62].

Route and dose of vaccinia virus are important in eliciting efficient immune responses. Dermal inoculation is considered to be the most immunogenic route in man, apparently reflecting a preferred site of replication of orthopoxviruses as well as the presence of a large number of antigen-presenting cells. Percutaneous vaccination with vaccinia virus produced significantly higher antibody titers and a longer duration of immunity than subcutaneous vaccination [63,64]. Intramuscular vaccination of mice with a rabies virus nucleoprotein recombinant was substantially less im-

munogenic than intradermal inoculation [65]. In primate species, there was a linear relationship between the size of skin lesions formed by vaccinia/RSV recombinants and titers of RSV neutralizing antibody [66]. Intradermal vaccination of mice and hamsters with a vaccinia/influenza HA recombinant elicited mainly IgG, which prevented lower respiratory infection; intranasal inoculation induced secretory IgA production and prevented both upper and lower respiratory tract infections [67]. Limited testing of oral smallpox vaccine in humans indicated that vaccinia is immunogenic when administered by this route. Successful oral vaccinations of domestic and wild animals with vaccinia/rabies glycoprotein recombinants [68,69] may be mediated by replication in tonsillar or buccal tissue [70]. Furthermore, intrajejunal vaccination of mice with vaccinia-influenza recombinants leads to generalized mucosal immunity against influenza [71]. Oral or intranasal routes of inoculation could potentially be exploited with other vaccinia-based veterinary or human vaccines.

Although disease protection correlates with vaccine-induced antibody titers in some cases, other vaccinia recombinants appear to protect by priming for immunoglobulin and/or inducing effector lymphocyte responses. In some cases, it is difficult to discriminate between these two possibilities. A vaccinia/hepatitis B surface antigen (HBsAg) recombinant failed to stimulate protective titers of anti-HBsAg antibody in chimpanzees, but did protect against disease. Apparently, vaccinated animals were primed for accelerated antibody production and possibly cell-mediated immunity [72]. Similarly, a recombinant expressing the bovine leukemia virus envelope glycoprotein failed to elicit neutralizing antibodies, but partially protected vaccinated animals presumably through induction of cell-mediated immunity [73]. When a recombinant virus expresses only internal structural or regulatory proteins, which cannot induce neutralizing antibody, protection is attributed to cytotoxic T-cell responses. For example, mice vaccinated with vaccinia/influenza nucleoprotein recombinants developed lower respiratory tract infections after challenge with influenza A virus, but had reduced symptoms, and some were protected from death [74]. The protection from influenza in mice vaccinated with vaccinia/influenza NP appeared to be CTL mediated, because vaccination was effective only in murine strains capable of generating a strong anti-NP CTL response. Similarly, recombinants expressing the rabies virus nucleoprotein did not prevent illness, but prevented fatal rabies in dogs [75]. A vaccinia recombinant expressing the murine cytomegalovirus immediate early protein pp89, an internal protein that regulates gene expression, afforded partial protection against a lethal challenge [76]. Depletion of vaccinated mice with anti-CD8 antiserum abrogated protection, and adoptive transfer of CD8<sup>+</sup> lymphocytes from vaccinia/pp89-primed animals into unvaccinated animals limited murine cytomegalovirus replication [76,77]. In addition, CD4<sup>+</sup> effector T cells may mediate the protective immunity induced by certain vaccinia/measles recombinants [78]. Recombinant vaccinia viruses that express simian immunodeficiency virus gag-pol proteins have provided protection in a monkey challenge model [79,80].

Effector T cells may also play a central role in the antitumor response elicited by vaccinia recombinants. Al-

though antibodies to tumor antigens are often present postvaccination, CTLs were likely mediators of tumor regression in a murine mastocytoma model [81].

Several techniques have been developed to improve the immunogenicity of live recombinant vaccinia vaccines. Because the magnitude of the response may be dependent on the amount of foreign protein expressed, a high level of protein production is desirable. This can be achieved by using strong natural or synthetic vaccinia promoters [23,24, 82,83]. Elimination of cryptic vaccinia transcription termination sequences from an HIV envelope gene boosted the level of HIV env production in infected cells [25]. Moreover, the corresponding recombinant virus was more immunogenic than the vector containing the termination sequence, as determined by anti-gp160 antibody titers in vaccinated mice, and by enhanced lysis of infected human CTL target cells.

Immunogenicity may also be enhanced by altering protein presentation on the surface of infected cells. Fusion of a secreted malarial blood stage antigen to the murine immunoglobulin G transmembrane anchor sequence resulted in surface expression of the protein and a greatly enhanced antibody response [84]. A related strategy has been used in which repeating epitopes of the malarial circumsporozoite protein (CSP) were fused to the ectodomains of the RSV glycoprotein G, thereby enhancing anti-CSP antibody titers in vaccinated animals [85]. Elimination of proteolytic cleavage sites from the HIV env gene prevented release of gp120 from the env precursor gp160, and the resulting recombinant produced a stronger anti-gp120 antibody response in vaccinated animals, presumably by increasing the amount of surface-associated gp120 [86].

The incorporation of additional helper T-cell epitopes in expressed antigens may also increase immunogenicity through enhanced recruitment and proliferation of B cells. A short peptide derived from the sequence of the neutralizing epitope of the viral capsid protein VP1 of foot-and-mouth disease virus produced a weak antibody response in cattle and pigs. However, fusion of the VP1 epitope to hepatitis B core protein (HBcAg) led to a dramatic increase in antibody titers in animals vaccinated with the purified protein expressed by recombinant vaccinia virus and greatly enhanced virus neutralization [87]. Inclusion of murine helper T-cell epitopes led to increased titers of antimalarial antibodies in mice vaccinated with a CSP fusion construct [88].

Protein targeting may also enhance immunogenicity. Fusion of antigen genes to endoplasmic reticulum or lysosomal targeting sequences may direct expressed proteins into intracellular compartments where processing for antigenic recognition is facilitated, boosting the immune response to viral and tumor-associated antigens. In one case, endoplasmic reticulum targeting was reported to increase CD8<sup>+</sup> T-cell recognition of tumor cells [81]. Fusion of HIV gp160 sequences to the lysosomal targeting sequence LAMP-1 boosted the CD4<sup>+</sup>, class II-restricted effector T-cell response to the expressed peptide, through enhanced transport of peptide into processing compartments [89]. In addition, boosted antibody titers, lymphoproliferative, and CD4<sup>+</sup> CTL responses followed immunization with a vaccinia LAMP-1/human papillomavirus E7 construct, as compared to the standard construct [90].

Recombinant poxviruses that coexpress certain cytokines or other mediators exhibit increased immune responses. Expression of interleukin-2 enhanced the serum IgG response to influenza nucleoprotein [91] and expression of interleukin-5 or -6 increased the secretory IgA response to influenza HA following intranasal vaccination [92]. Interleukin-2 coexpression with β-galactosidase enhanced activity against β-galactosidase-expressing tumors in mice [93]. Similarly, expression of granulocyte/macrophage colony-stimulating factor produced by recombinant avian poxviruses enriched the regional lymph nodes with antigen-presenting cells and acted as an immunoadjuvant [94]. Expression of the CD28 ligand B7 by recombinant vaccinia viruses enhanced antitumor activity in mice by mediating a Th1-type T-cell response [95]. Synergistic effects were reported for a triad of costimulatory molecules, namely, B7-1, ICAM-1, and LFA-3 [96].

Heterologous priming and recombinant poxvirus boosting greatly enhanced T-cell responses. This was first noted using a recombinant influenza virus as the prime followed by a recombinant vaccinia virus [97]. This approach works particularly well using a DNA prime followed by a vaccinia virus or avipoxvirus boost [98–100]. The generally accepted explanation is that immune competition between the many poxvirus proteins and the recombinant protein limits the extent of the immune response to the latter. However, if the animal has already made a primary immune response to the recombinant protein, then the recombinant vaccinia virus can specifically boost this.

The presence of maternal antibodies is a major obstacle to vaccination of infants with some attenuated viruses such as measles and also diminishes the immune response to recombinant vaccines. Passive administration of antiserum to influenza A [101] or respiratory syncytial virus (RSV) [102,103] abrogated both the desired antibody response and disease protection mediated by vaccinia-based influenza or RSV vaccines. Replication of the recombinant viruses and stimulation of antibodies to vaccinia proteins was unaffected, indicating that antibodies to the influenza or RSV proteins produced specific immune interference. Normal immune responses were restored after waiting for clearance of passively administered antibodies to measles virus in mice repeatedly vaccinated with vaccinia/measles recombinants [104]. The inhibitory effect depends on the level of passive antibody, however, and a recombinant vaccinia virus provided significant protection of monkeys against measles infection [105]. Changing the site of inoculation may partially overcome passive blockade of antigen, because intranasal administration of vaccinia/RSV vectors was significantly more immunogenic than dermal administration in cotton rats given anti-RSV antiserum parenterally [106].

Existing immunity to the vector is a potential problem with any live recombinant virus, and holds true for vaccinia virus [61,107]. Because of the cessation of smallpox vaccination in the early 1970s, individuals under 30 are generally vaccinia naive. Systemic immunity to vaccinia virus can be circumvented to some extent by administering the recombinant vaccine by a mucosal route [108]. Repeated vaccination or priming with a DNA vaccine may also be useful. Because

of their large genetic differences, immunity to vaccinia does not appreciably affect vaccination with avipox vectors.

### C. Safety

During the extensive use of vaccinia virus as a smallpox vaccine, adverse reactions in addition to the routine swelling and soreness at the site of administration and low-grade fever were frequently observed. The most serious of these were progressive or disseminated infection in immunocompromised individuals, eczema vaccinatum, and postvaccinal encephalitis or encephalopathy in infants. The incidence of the latter was reported to vary with different vaccine strains, ranging from 1 in 2,000, for the Copenhagen strain, to 1 in 200,000 or more for the New York City Board of Health (Wyeth) and Lister strains [1,109]. There is a fear that adverse reactions would be even more prevalent now because of the high incidence of HIV, use of immunosuppressive drugs in transplant patients, and increased atopic dermatitis.

Before the eradication of smallpox, highly attenuated strains of vaccinia virus were made by serial passage in tissue culture [1]. The strain most extensively tested in humans, called modified vaccinia virus Ankara (MVA), was passed 570 times in cultured chick embryo cells and induces only a slight reddening at the site of inoculation [110,111]. MVA has multiple gene deletions [112,113] resulting in an inability to replicate efficiently in human and most other mammalian cells [114–117]. Further studies indicated that replication is blocked at a step in virus assembly and that early and late viral or recombinant protein synthesis occurs normally [118]. Remarkably, recombinant MVA strains seem to induce as good an immune response in mouse and monkey models as replicating strains [119,120]. Avian poxviruses, which are naturally host restricted in mammalian cells, also provide a safe vector system [121].

With knowledge of the vaccinia virus genome sequence and functions of many genes [7], it has become possible to attenuate vaccinia virus by making specific deletions [122,123]. NYVAC, a genetically engineered vaccinia virus with many of the same deletions as MVA, appears safe and immunogenic although it has not been as extensively tested in humans [124,125].

Coexpression of genes encoding certain immunomodulators attenuates live recombinant vaccinia viruses. Human interleukin-2 expression prevented generalized lethal vaccinia infection in immunodeficient athymic nude mice [91,126]. This appeared to be mediated by elevation of natural killer cells and interferon- $\gamma$  activity in mice vaccinated with the recombinants [127–129]. Interleukin-2 expression also attenuated recombinant vaccinia viruses in normal, immunocompetent rodents [91,130] and primate species [131,132] without significantly reducing vector immunogenicity. Similar results have been achieved with recombinant vaccinia viruses expressing interferon- $\gamma$  [133] and tumor necrosis factor- $\alpha$  [134].

Increased safety of vaccinia virus might be achieved by altering the route of inoculation, although this could diminish immunogenicity [63,64]. Subcutaneous, intramuscular, and oral routes may reduce the risk of person-to-person

spread of virus but still leave the risk of progressive infection in the immunocompromised host.

Given recent successes in the development of antiviral drugs, it should be possible to identify effective chemotherapeutic interventions for vaccinia virus [135]. This could provide a “safety net” for the rare but serious adverse effects of vaccination. Certain DNA replication inhibitors such as Cidofovir and derivatives appear particularly promising [136–139].

### D. Veterinary Applications

Both vaccinia virus and avian poxviruses are being used as veterinary vaccines. Successful oral vaccination of animals with a vaccinia virus rabies glycoprotein vaccine [140,141] led to its extensive field testing as a wildlife vaccine. Live recombinant vaccinia-vaccine-impregnated bait, scattered in areas where rabies is endemic, produced a protective immune response in most animals. Raccoons [69] and foxes [68] were targeted in the United States and Europe, respectively. The vaccinia virus rabies glycoprotein vaccine contributed to the elimination of rabies in a red fox population in Belgium [142]. A raccoon poxvirus recombinant expressing rabies virus glycoprotein has also been shown to be effective as an oral vaccine [143]. A bait strategy has been proposed to control the fertility of wild or feral animal populations by using live recombinant vaccines expressing antifertility immunogens such as  $\beta$ -chorionic gonadotropin [144].

Recombinant vaccinia viruses that express vesicular stomatitis virus [145] or rinderpest [146] glycoprotein genes were shown to protect cattle against the respective pathogens. The rinderpest vaccine provides long-lasting protection and because of its economical production and ease of administration would be attractive for remote areas of the developing world [147]. A recombinant capripoxvirus expressing the hemagglutinin protein gene has also been proposed as a rinderpest vaccine [148]. Live recombinant vaccinia viruses have been shown to protect chickens against avian influenza [149] and Newcastle disease [150]. Many other recombinant vaccinia viruses have been shown to be effective against pathogens in small animal models.

Avian poxvirus recombinants are immunogenic in chickens and have been shown to protect against avian influenza virus [151–153], Newcastle disease virus [154], infectious bursal disease virus [155–157], and infectious bronchitis virus [158]. Fowlpox virus vaccines against Newcastle disease virus and avian influenza virus have been licensed. Avian poxviruses are also immunogenic in non-avian species [6], and the demonstration that recombinant canarypox vectors protect canine distemper virus [159], feline leukemia virus [160], and rabies virus [161] have led to veterinary vaccines.

### E. Clinical Applications

Many recombinant poxviruses that express genes of human pathogens have been tested for immunogenicity in small animal models and no attempt will be made to summarize them all here. Instead, this review will be limited to selected candidate vaccines that have been used clinically or in

nonhuman primates. Also largely omitted from this review are the attempts to develop therapeutic cancer vaccines using poxvirus vectors [162]. The demonstration that a recombinant vaccinia virus could protect chimpanzees against hepatitis B virus gave credibility to poxvirus vectors [72,163], although the existence of licensed vaccines against this disease hindered its further development. Recombinant vaccinia viruses expressing Epstein–Barr virus glycoprotein provided protection in marmosets [164,165] and in a small clinical trial [166]. Phase I and II clinical trials have been performed with a recombinant vaccinia virus Hantaan vaccine [167]. After two doses by the subcutaneous route, Hantaan virus neutralizing antibodies were detected in 72% of vaccinia virus naïve but in only 26% of vaccinia virus immune volunteers. An MVA expressing a truncated dengue type 2 E protein protected monkeys against a challenge [168].

Phase I trials of canarypox vectors expressing human cytomegalovirus glycoprotein B or phosphoprotein 65 were reported. The glycoprotein vaccine induced only a weak antibody response even after multiple inoculations but primed for a subsequent boost with an attenuated human cytomegalovirus [169]; the phosphoprotein vaccine induced a cytotoxic T-cell response in all subjects [170]. In another study, priming with a canarypox glycoprotein B vaccine and boosting with the subunit protein was not more immunogenic than priming and boosting with the subunit protein [171]. A canarypox rabies glycoprotein vaccine elicited dose-dependent antibody responses that were in the protective range, although lower than that of the standard human diploid rabies vaccine [172].

A recombinant NYVAC expressing seven genes from all stages of the *Plasmodium falciparum* life cycle was tested in a Phase I/II efficacy trial [173]. Antibody responses were low, but cell-mediated immunity was detected in most volunteers. After challenge with five infected mosquitoes, only 1 of 35 was uninfected, but there was a small but significant delay to parasite development in the experimental group compared to the control. A prime-boost immunization regimen using DNA followed by recombinant MVA induced strong cellular immune responses against the *P. falciparum* TRAP antigen in chimpanzees [174]. A multistage, multiantigen DNA prime and canarypox boost malaria vaccine provided partial protection against *Plasmodium knowlesi* in rhesus macaques [175].

Live attenuated measles vaccines are ineffective in the presence of maternal antibody, indicating a need for a vaccine that can be used during the first 6 months of life. Passive antibody studies in primates gave some hope that recombinant MVA expressing the measles F and HA genes may provide some protection under these conditions [105,176].

The most extensive preclinical and clinical investigations of recombinant poxviruses have involved those expressing HIV or related SIV genes. Recombinant vaccinia viruses were used to demonstrate CTL in HIV-infected humans [177,178]. The first clinical studies, performed with a recombinant vaccinia virus that expresses the HIV envelope gene gp160, provided evidence for safety but were not highly immunogenic [179,180]. A history of prior smallpox vaccination did not prevent an antibody response to gp160,

although vaccinia naive subjects in general developed a more vigorous antibody response. Priming followed by boosting with recombinant purified protein, however, produced a strong anamnestic response, with the production of type-specific neutralizing antibody [181,182]. Similar results were obtained using a recombinant canarypox expressing gp160 alone or with a gp160 boost [183]. Other canarypox virus vectors expressed HIV gag, protease, pol, and nef as well as envelope and induced CTL memory in 61% of volunteers at some time during the clinical trial [184]. Preclinical studies of MVA-based SIV and simian human immunodeficiency virus (SHIV) vaccines have shown great promise. MVA alone or preceded by a DNA boost induced high gag and env CTL levels in macaques [100,185,186]. When given prophylactically, such vaccines significantly lower the viral loads and protect macaques against CD4 depletion and clinical illness caused by SIV or SHIV challenge [100,120,187,188]. In one DNA prime and MVA boost study, expression of env plus gag and pol provided more uniform protection than expression of gag and pol alone [189]. Phase 1 studies with recombinant MVA HIV vaccines have just started.

Because vaccinia virus vectors have the capacity to incorporate at least 25,000 bp of extra DNA [16], the concept of polyvalent vaccines is extremely attractive. Recombinant vaccinia viruses that simultaneously express three or more foreign proteins have been constructed [190,191]. Besides enhancing risk/benefit ratios, polyvalency would circumvent the reduction in immunogenicity of live vectors accompanying revaccination. The logistics of developing such a polyvalent vaccine, however, may prove daunting.

## Live Adenovirus Recombinants as Vaccine Vectors

L. Jean Patterson, Bo Peng, Xinli Nan, and Marjorie Robert-Guroff

National Cancer Institute, National Institutes of Health, Bethesda, Maryland, U.S.A.

### I. INTRODUCTION

Live virus vaccines characteristically induce cellular and humoral immunity and produce long-lasting protection. Early live vaccines were attenuated usually by repeated *in vitro* passaging. Advances in biochemical and molecular biological techniques have allowed the engineering of mutant and recombinant live viral vectors, which avoids the dangers inherent in spontaneously attenuated viruses by lessening the possibility of reversion to virulence, yet confers some of the advantages of live vaccines.

### II. ADVANTAGES OF ADENOVIRUS-VECTORED VACCINES

Engineered adenovirus (Ad) vectors offer a number of attractive features for vaccine design (for reviews, see Refs. 1–4). Adenoviruses are independent of host cell division for virus replication. They infect a variety of postmitotic cells and have a broad tissue tropism, including the respiratory tract, eye, intestine, liver, skeletal muscle, brain, and heart. They can be easily administered intranasally or orally, and their replication in the epithelium of the upper respiratory track and gut elicits mucosal immunity essential for the prevention of mucosally and sexually transmitted infections. During infection, up to  $10^4$  progeny virions are produced per cell, and are easily purified to titers of  $10^{12}$  particles per milliliter. As naked viruses, Ads are more stable than enveloped viruses, an important feature for vaccines to be used worldwide in underdeveloped areas. They also exhibit genetic stability. They do not integrate into the host genome, but persist extrachromosomally [5], minimizing risks of insertional mutagenesis and cellular gene activation. Because Ad has been studied extensively as a model of RNA processing and gene expression in mammalian cells, its molecular biology and host interactions are well understood.

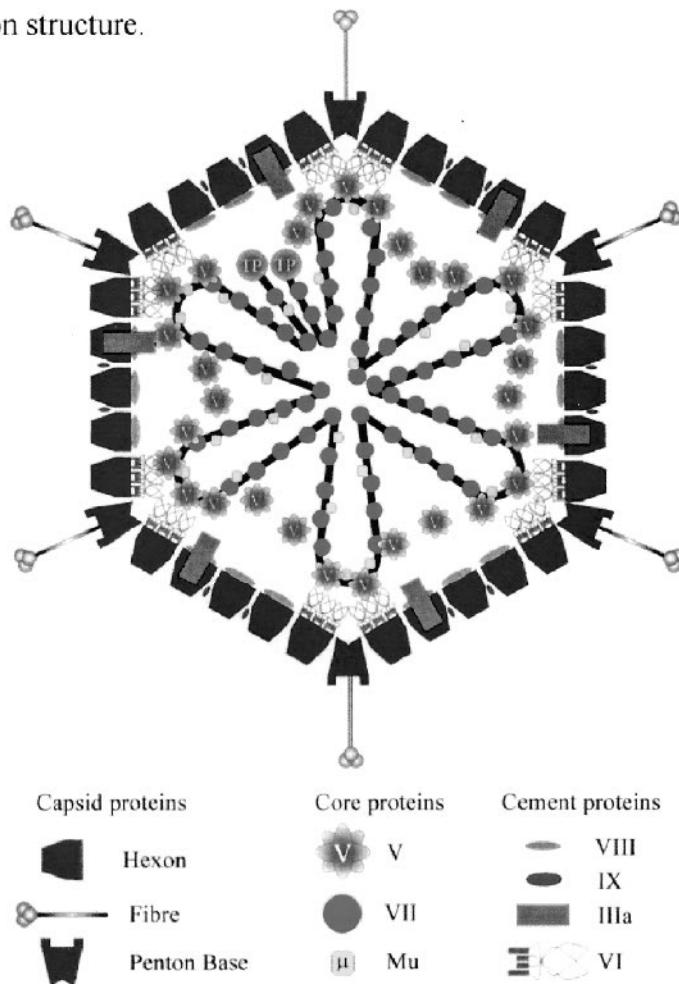

### III. ADENOVIRUS BIOLOGY AND MOLECULAR BIOLOGY

Adenoviruses were initially isolated from human pediatric adenoid tissues and respiratory secretions [6,7], and subsequently from tissues of monkeys, birds, pigs, horses, and cows [8]. Human Ads are the etiological agents for diseases ranging from pharyngitis to pneumonia, conjunctivitis, hepatitis, and acute hemorrhagic cystitis [9,10]. However, only one third of all Ad serotypes causes disease, and most Ad infections are subclinical. Only 3–7% of febrile illnesses in the civilian adult population are attributable to Ads, and a slightly higher 5–10% in children [9].

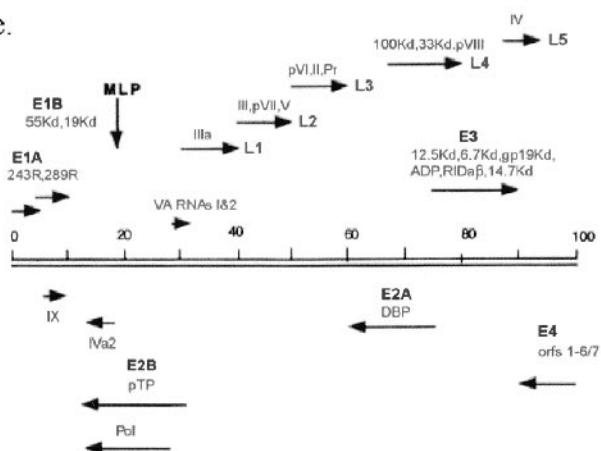

The Ad virion forms a characteristic 70- to 100-nm icosahedral particle, which lacks a lipid envelope (Figure 1A). The outer capsid is made up of the hexon, penton, and fiber proteins, in addition to a number of minor cement proteins. The core contains Ad DNA, closely associated with proteins of varied function [1,8]. The Ad enters cells via a receptor-mediated pathway, binding to the coxsackie/adenovirus receptor (CAR) via the protruding fiber protein [1, 11,12]. Subsequently, internalization is mediated by specific binding of the penton base to cellular integrins [13], which help define Ad tropism. Integrin  $\alpha v\beta 5$  is expressed at the major sites of primary Ad infection *in vivo*, including bronchial and intestinal epithelium [14]. All human Ads bind to CAR except subgroup B Ads, which recognize a different receptor [15].

Other than chimpanzees, few animal models exist for the study of human Ad infection, as most Ads are species-specific. Group C Ads replicate in the lungs of cotton rats, allowing the study of Ad-induced pneumonia [16]. Although Ads do not replicate in mice, high-dose infection of mice results in virus entry and early gene expression [17], providing a model for assessment of gene transduction, expression, and immunogenicity. An Ad5 host range mutant, with a point mutation in the DNA-binding protein, replicates in

**Figure 1** Schematic of the Ad virion and the Ad genome. In (B), the arrows indicate directional transcription of Ad genes. “E” designates early mRNA products (E1–E4), whereas late mRNAs are denoted as L1–L5. MLP = major late promoter. VA RNAs (1 and 2) are not translated and play a role in regulating host defense mechanisms. IVa2- and IX-expressed proteins are transcriptional activators of the MLP. (From Ref. 1.)

simian cells [18], allowing preclinical study of Ad recombinant vaccines in nonhuman primates.

The association of Ad12 with tumor production in rodents [19] suggested that Ads might be oncogenic for humans. Although human Ads are able to transform cultured rodent cells, only a few subtypes cause tumor formation in rats and hamsters [8]. A recent report, as yet unconfirmed, suggested that Ad oncogenicity in rodents was due to a “hit-and-run” mechanism, with Ad being required for initiation but not for maintenance of the transformed state [20]. Importantly with regard to vaccine safety, despite their long use as wild-type vaccines, Ads have never been associated with human cancer [21].

The Ad genome is a linear, double-stranded DNA of around 36 kb with an inverted terminal repeat (ITR) at each extremity. The left ITR contains an origin of replication, and a required *cis*-acting packaging sequence is located in its immediate vicinity. The replication cycle of Ad (reviewed in Ref. 8) consists of early and late phases, before and after the onset of viral DNA replication, respectively. In the early phase, viral regulatory genes are expressed noncontiguously from five early transcription units: E1A, E1B, E2, E3, and E4 (Figure 1B). E1 genes, essential for replication, encode the predominant regulatory proteins and are required for the activation of all other early expressed genes. Two E1A polypeptides are expressed first and modulate the transcription of early Ad genes and some cellular genes, rendering the cell susceptible to viral infection [1,3]. Interactions with the tumor suppressor protein, pRB, lead to disruption of normal cellular control processes and quiescent cells begin synthesizing DNA. E1B encodes the E1B-55 kDa protein that binds the tumor suppressor p53, blocks its normal function, and thus contributes to cell cycle progression. Together with the E1B-55 kDa protein, the E1B-19 kDa protein blocks E1A-induced apoptosis, thereby contributing to cell growth.

A DNA-binding protein, preterminal protein, and polymerase, all required for DNA replication, are encoded by the E2 region. The E3 region, in contrast, is nonessential for virus growth, but its gene products are important for regulation of host antiviral immunity. The best characterized 19K protein binds MHC class I molecules with high affinity and retains them in the endoplasmic reticulum, thereby blocking transport to the surface and antigen presentation to T cells [22,23]. The 14.7K protein inhibits tumor necrosis factor (TNF)-mediated lysis of Ad-infected cells [24].

The E4 region (reviewed in Ref. 25) orchestrates the transition from early to late gene expression and down-regulates host cell gene expression in preparation for virion assembly [3]. E4 gene products have complex functions impacting transcriptional regulation, mRNA transport, and DNA replication. Of six identified E4-encoded polypeptides, E4 Orf3 and Orf6 proteins are of special interest. Both increase viral late protein production, facilitating accumulation of cytoplasmic mRNA posttranscriptionally. In addition, Orf6 complexes with the E1B-55K protein to increase nuclear export of mRNAs while inhibiting cellular mRNA export. Both Orf3 and Orf6 stabilize unprocessed nuclear late RNA, thus increasing RNA available for maturation and transport. Both proteins are important for splicing events, and both participate in Ad DNA replication. Impor-

tantly, the E4 Orf6 protein binds p53 [26] (thus blocking p53-induced apoptosis) and, together with E1A, transforms rodent cells [27]. The Ad9 E4 Orf1 protein also appears to have transforming properties and has been correlated with mammary tumorigenesis in rodents [28].

Overall, E4-deleted Ad vectors might be safer. In addition to loss of transforming potential, they induce significantly less vector toxicity and inflammation *in vivo* [29]. But E4-deleted Ads also poorly express transgenes from exogenous promoters [29,30]. E4 gene complexity must be carefully considered in vector design. Provision of selected E4 Orf genes in packaging cells, rather than vectors, may supply important functions for transgene expression while avoiding safety concerns.

The late phase of Ad infection is initiated by activation of the major late promoter (MLP) following DNA replication. This transcription unit is processed to generate five families of late mRNAs (L1–L5) and then is translated into viral structural proteins, leading to assembly and maturation of infectious virus. In permissive cells, the early phase of infection may take about 6–8 hr, whereas virus production occurs after another 4–6 hr in the late phase. Cell lysis begins to occur 24–72 hr after infection [9].

#### IV. EVOLUTION OF ADENOVIRUS RECOMBINANT VECTORS

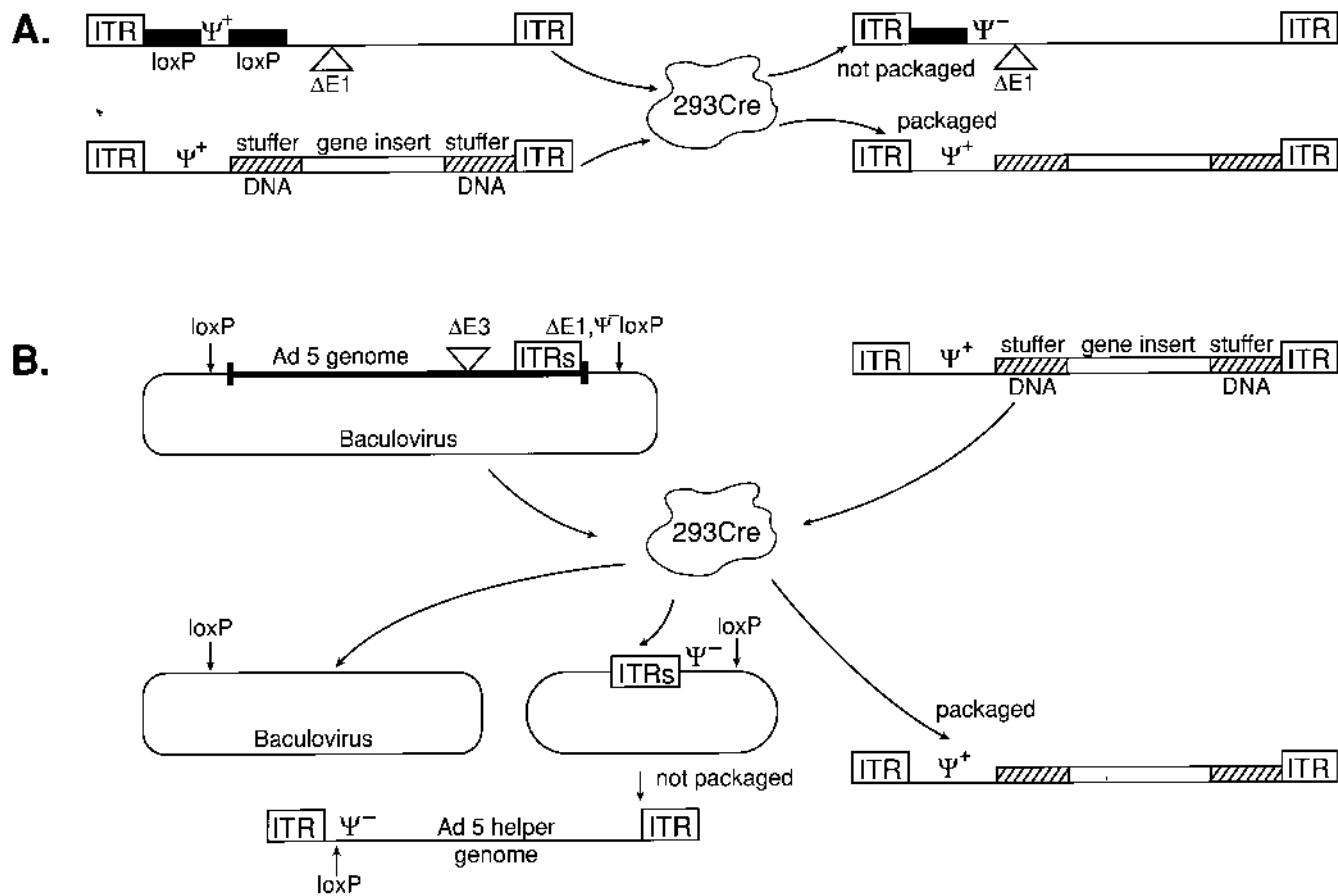

Gene therapy research has yielded much of what is known about Ad vectors and complementing cell lines. Thousands of Ad vectors have been generated, most of them derived from either Ad2 or Ad5, the genomes of which are well characterized. Because its icosahedral capsid is rigid, Ad can package DNA only up to 105% of its genome size [31]. Adenovirus late proteins provide the structural framework of the virion particle and are essential. Therefore, deletion of Ad early region genes has been generally exploited to create a variety of Ad vectors with increased cloning capacity.

Most recombinant Ads are generated by insertion of foreign genes into deleted E1 or E3 regions, resulting in Ad vectors with different natures (Table 1): replication competent E3-deleted vectors and replication-defective E1-deleted vectors. To express transgenes from replication-defective Ad vectors, an expression cassette is introduced with the transgene under the control of an exogenous promoter.

E3-deleted replication-competent Ad vectors can accommodate a transgene of 3–4 kb, large enough for most foreign gene inserts. Replication-defective vectors lacking both E1 and E3 regions can accommodate larger inserts up to 7–8 kb. Deletion of additional early genes can further increase cloning capacity and may also lessen host immunity to the Ad vector, thus leading to greater persistence of transgene expression. Replication-defective Ad vectors with additional deletions in the E2a, E2b, or E4 region allow inserts up to 10 kb [32–35]. They exhibit reduced expression of early and late virus proteins and, in some cases, extended persistence of transduced liver cells [35–37]. Conflicting results, however, have shown that mice, which received vectors defective in E1, E3, and E4 or E1, E3, and E2A and lacking a transgene, exhibited similar vector persistence and anti-

**Table 1** Characteristics of Replication-Competent and Replication-Defective Ad Vectors

Characteristic	Replication competent	Replication defective		
		First generation	Second generation	"Gutless"
Deletion	E3	E1, E3	E1, E2, E3; E1, E3, E4; E1, E2a, E3, partial E4	All but ITRs and $\psi$
Clone capacity (kb)	3–4	7–8	~10	~35
Effective dose	$10^5$ – $10^7$	$10^9$ – $10^{11}$	$10^9$ – $10^{11}$	$10^9$ – $10^{11}$
Helper virus	Not required	Not required	Not required	Required
Packaging cells	Not required	293 (HEK + Ad5 bases 1–4344) [71,72] 911 (HEK + Ad5 bases 79–5789) [74] PER.C6 (HER + Ad5 bases 459–3510) [75] GH329 (HeLa + Ad5 bases 511–3924) [76]	E2T (293 + E2a; tetracycline regulated) [103] IGRP2 (293 + E4 Orf6 and Orf7; dexamethasone-inducible MMTV-LTR) [104] 293 Orf6 (293 + E4 Orf6; Zn <sup>2+</sup> -inducible metallothionein promoter) [77] C7 (293 + Ad polymerase + pTP) [105] A70.S54 (A549 + Ad5-E1, Ad5-E2a, Ad5-E4; dexamethasone-inducible) [106]	293-Cre [41], 293FLP [107,108]

**Figure 2** Strategies for production of HD-Ad. (A) Reprinted in slightly modified form. (From Ref. 41.) (B) Reprinted in slightly modified form. (From Ref. 42.)

viral immune response compared to a simple E1- and E3-deleted vector [38]. Furthermore, in the absence of transgene expression, mouse cellular immunity played a minor role in eliminating the Ad vector [38].

Persistence of transgene expression is influenced by host immunity to both the transgene and the vector. A completely “gutless” Ad vector has been proposed to combat the latter. In addition to reducing immunity to vector components, a gutless vector would provide the greatest possible cloning capacity and would theoretically be safer, as all viral genes except the ITRs and packaging signal would be eliminated. This strategy is not without problems, however. To maintain the optimal packaging size of approximately 75% of the wild-type genome length [39], “stuffer” DNA, which can significantly influence persistence of transgene expression [40], is required. Furthermore, gutless Ad vectors depend on helper virus to supply structural components of the virion. Production of helper-dependent Ad vectors (HD-Ads) has been complicated by difficulties in separating HD-Ad recombinant virus from the helper. Among several strategies, the best known uses Cre recombinase to remove the helper virus packaging signal between engineered *loxP* recognition sites (Figure 2A) [41], producing HD-Ad recombinants containing approximately 0.1% helper virus. A modification of this strategy, using baculovirus, lacks a packaging signal in the helper component (Figure 2B) and is reported to completely eliminate helper contamination [42]. This approach, however, requires further development of alternate packaging cells lacking overlap in the E1 region, in order to avoid eventual emergence of replication-competent adenovirus (RCA).

## V. ISSUES IN APPLICATION OF ADENOVIRUS VECTORS FOR VACCINE DEVELOPMENT

Desirable features of Ad vaccine vectors differ from optimal gene therapy vectors. A critical decision in vaccine design is use of a replication-competent or replication-defective Ad vector. Comparative studies with regard to vaccine efficacy and immunogenicity have yet to be carried out. Further characteristics of these vectors are summarized in Table 1. Vector choice is influenced by the expression and persistence of the transgene, safety, and potential to propagate the vector at levels necessary for manufacture and use. Other elements of Ad vector design concern the choice of serotype, and whether vector targeting is desired.

Replication-competent Ad vectors have been used for immunization where viral replication is desired to increase the amount of immunogen [9]. They provide higher levels of gene expression than replication-incompetent vectors because the Ad MLP, which controls transgene expression, is greatly enhanced by a *cis*-acting function linked to Ad replication itself, resulting in a potent promoter. Importantly, these vectors continue to generate large amounts of viral mRNA with each infection cycle. In contrast, transgene expression of replication-defective vectors with a dormant MLP is limited, as its expression is solely dependent on a heterologous promoter.

Strong immune responses result from highly expressed transgenes. Cytotoxic T lymphocytes (CTLs) develop against

both transgenes and Ad antigens, and eventually clear Ad-infected cells. Replication-competent Ad recombinants, because they spread from cell to cell, may persist longer, thereby inducing a more potent and long-lasting CTL response. Although replication-defective Ad vectors have demonstrated high levels of transgene expression *in vitro*, expression is short-lived *in vivo*. This may relate to their inability to initiate new infections *in vivo*, resulting in rapid elimination by CTL.

Avoidance of toxicity and immunopathological responses is critical for vaccines that will be administered to healthy people. Oral wild-type Ad4 and Ad7 vaccines were used for over 25 years to protect against acute upper respiratory disease in military personnel. Over 100 million people were vaccinated safely and effectively [43]. With this extensive safety profile, replication-competent Ad vectors with simple E3 deletions would seem to be vectors of choice. They can be easily constructed and manufactured. Moreover, they may elicit better CTL activity compared to wild-type virus, as their ability to down-modulate MHC class I is impaired. However, intranasal administration of Ad5-E3-deleted vector to cotton rats has elicited greater lung pathology compared to wild-type Ad5 [44], raising safety concerns. Effects of E3 region gene products are not always predictable, however. Cloned expression of the E3-19 kDa protein failed to suppress either CTL or natural killer (NK) cell responses to vaccinia virus in infected mice [45]. In addition, E3-deleted bovine adenovirus vaccines showed no enhanced pathogenic effect when administered to cattle [46]. We examined lung pathology in cotton rats following intranasal administration of candidate Ad4-HIVenv and HIVgag vaccines [47]. Although Ad4 did not replicate in the rats, only Ad early gene expression is sufficient to induce immunopathology due to host inflammatory cytokine and virus-specific CTL responses [17,48]. The increased lung pathology elicited by the Ad4-E3-deleted vector compared to wild-type Ad4 was abrogated when HIVenv or HIVgag was inserted into the E3 region. The responsible mechanism remains to be elucidated, but could be related to immune-suppressive properties of the inserted HIV genes [47].

These results bode well for the use of replication-competent Ad recombinant vaccines. Oral and intranasal administration of Ad-E3-deleted recombinant vaccines to nonhuman primates and people has not caused any significant clinical sequelae [49–58]. This, in part, reflects the low doses sufficient to elicit desired immune responses. Ad4 and Ad7 wild-type vaccines typically were administered orally at doses of  $10^7$  TCID<sub>50</sub> [59]. The Ad4 vaccine has been given intranasally to Ad-seropositive and Ad-seronegative people at doses of  $2 \times 10^5$  and  $4 \times 10^4$  TCID<sub>50</sub>, respectively [60], with no serious side effects.

In contrast to the benign sequelae observed following low-dose administration of replication-competent Ad vaccines, clinically significant inflammatory responses in humans have resulted following treatment with replication-defective Ad recombinants at high dose to achieve desired levels of transgene expression [61]. In animals, doses of  $5 \times 10^{10}$  plaque-forming units (pfu) or more replication-defective Ad recombinants are necessary for transgene expression [62]. Dose-dependent toxicity includes an acute-phase re-

sponse with rapid release of inflammatory cytokines and recruitment of host cell defenses [63–65]. The CTL- and NK-mediated responses subsequently elicit late-phase toxicity [63]. High doses of Ad can also elicit toxicity via induction of multiple signaling cascades upon interaction of numerous virions with Ad receptors on many cell types. In addition, at high multiplicity of infection, replication-defective Ad vectors may self-replicate, leading to greater tissue inflammation [1]. Many cells have E1-like proteins able to activate Ad-E2 genes, facilitating Ad replication and late protein synthesis [66–68].

Vector toxicity is also dependent on route of administration. High-dose immunization via the upper respiratory tract, desirable in a vaccine to induce mucosal immunity, is problematical. Repeated intranasal doses of  $10^9$  pfu of replication-defective Ad recombinant have been safely tolerated [69,70]. An intranasal dose of  $10^{10}$  pfu, however, produced local mucosal inflammation. Overall, a delicate balance between immunogen expression and Ad-associated toxicity must be achieved.

The availability of permissive cell lines for vector propagation is another important consideration in the design of Ad-vectored vaccines. Replication-competent Ad vectors can grow in many cell lines of epithelial origin, including HeLa (human cervical carcinoma), A549 (human lung carcinoma) cells, and primary cells. However, E1 gene functions must be provided in trans for growth of replication-defective Ad vectors. Historically, transformed human embryonic kidney 293 cells containing the first 4344 bp of the Ad5 genome [71,72], which express the E1 gene products, have been used. The 293 cells have good growth characteristics, produce extremely high yields of E1-deleted Ad recombinant viruses, and are easily transfected by DNA plasmids. However, the extensive homology between the Ad5 genomic sequence in 293 cells and standard E1-deleted Ad vectors provides a substantial risk of generating RCAs that have recovered E1 genes by recombination during viral production [73]. Recently, human embryonic retinoblasts (HERs) were transformed by Ad [74], and cell lines containing smaller portions of the Ad5-E1 region that prevent RCA were developed [75,76]. However, appropriately matched Ad vectors are also required to prevent RCA development during Ad recombinant production.

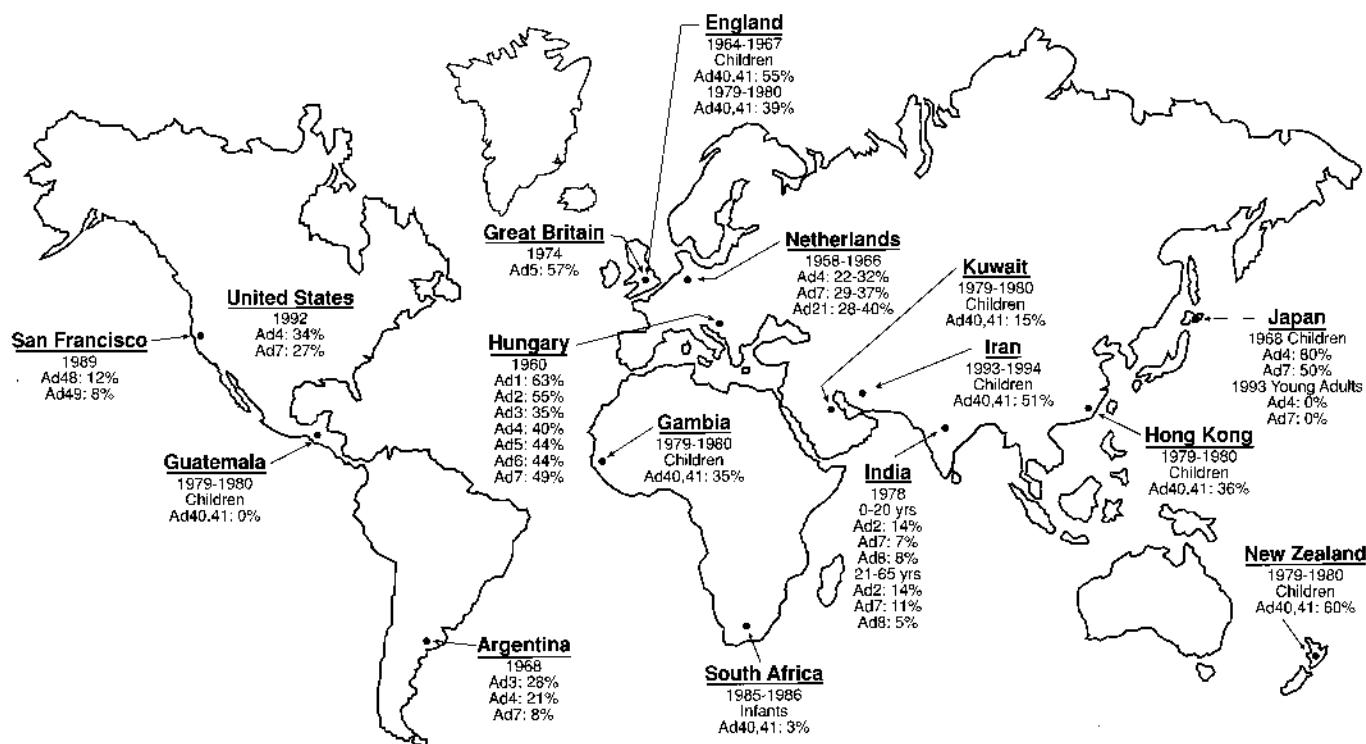

With design of second-generation and gutless Ad vectors, additional packaging lines became necessary to complement functions of deleted early region genes (Table 1), or to provide a helper virus function. In some cases, expression of early region gene products was toxic for cells, and these were introduced under the control of inducible promoters. The extent to which replication-defective Ad vectors based on different serotypes will require packaging lines with serotype-matched inserts is not known. The 293 Orf6 cells, for example, containing the Ad5-E1 and Ad5-E4 Orf6 genes, support the growth of Ad7 replication-defective vectors [77]. The choice of producer cells is critical for vaccine development. Weighing the risk–benefit of live vaccines for healthy people elicits greater caution than gene therapies for patients, where potential treatment success may outweigh associated cell line risks. These include potential oncogenicity and undetected exogenous or endogenous viruses or viral

sequences. To avoid such risks, vaccines must be produced in well-characterized cells and shown free of contaminating cellular DNA.

A further consideration in Ad vector design is the Ad vector subtype. At issue is whether preexisting immunity in the population to the vector will preclude effective immunization. Repeated administration of Ad recombinants in gene therapy trials led to loss of transgene expression, due to rapid elimination of the Ad recombinant by host immune responses. For vaccination, repeated frequent immunizations may not be optimal for induction of strong, persistent immune responses, including memory cells [78]. Moreover, preexisting immunity to Ad does not necessarily limit the response to the transgene. Two sequential immunizations of rhesus macaques with an Ad5 host range mutant expressing SIV gene products were able to boost cellular immune responses to the expressed proteins [56] (J Zhao, Y Lou, LJ Patterson, N Malkevitch, M Robert-Guroff, unpublished observations). Immunization of cattle with preexisting high antibody titers to Ad with a bovine Ad3 bovine herpes virus recombinant successfully elicited strong immune responses and protected the animals from a subsequent bovine herpes virus challenge [46].

There are currently 49 recognized Ad serotypes and two additional subtype candidates, Ad50 and Ad51 [79]. However, little is known concerning current Ad seroprevalence worldwide. Most serological studies in healthy individuals were carried out in the 1960s on Ad subtypes 1–7 (Figure 3). Later studies focused on the enteric Ads, subtypes 40 and 41. Virus isolations from patients in the 1960s and 1970s showed that Ad2 and Ad1 were most prevalent [80]. Whether these patterns hold today is unknown. However, the great variety of Ad serotypes provides a means for sequential immunization with Ad vectors of different subtype, should preexisting immunity be a problem. Our HIV vaccine studies have used sequential immunizations with Ad5, Ad7, and Ad4-HIV recombinants in chimpanzees [52–54]. Gene therapy experiments have also established the feasibility of this approach [81,82]. After cessation of the Ad4 and Ad7 US military vaccination program, 88% of new recruits lack protective antibodies to both Ad4 and Ad7 [83]. Thus, these subtypes are reasonable choices for Ad vector development. Animal Ad vectors may also circumvent preexisting immunity to human Ads. A replication-defective chimpanzee Ad68 vector with little homology to human Ads is under development [84].

A final consideration in the design of Ad vaccine vectors concerns targeting desired cell types. Delivery of Ad to potent antigen-presenting dendritic cells has been achieved by targeting cell surface CD40 with a bispecific antibody [85]. A chimeric virus made by switching the less permissive subgroup C Ad5 fiber with one from subgroup B (Ad35) gave 100-fold better transgene expression [86]. Similarly, substitution with fibers from Ad40 or Ad41 that infect primarily gut tissue may help target Ad vaccines to mucosal inductive sites. Ad recombinants with knobless fibers, replaced with a moiety to provide the fiber trimerization function and a targeting ligand, can also alter viral tropism and retarget vectors to specific cell types [87]. Generation of Ad recombinants independent of CAR for

**Figure 3** Worldwide seroprevalence of adenovirus subtypes. Seroprevalence in healthy individuals without symptoms of upper respiratory tract or gastrointestinal infection is reported. Dates provided are from the cited references or date of publication. (From Refs. 83,109–118.)

cell entry, including retargeting complexes composed of the CAR ectodomain fused to targeting ligands, were recently reviewed [88].

## VI. ADENOVIRUS VACCINE APPLICATIONS

It is beyond the scope of this chapter to summarize the innumerable vaccine strategies to which Ad recombinants have been applied, including those designed for veterinary use. Studies with Ad recombinants that targeted a broad array of viruses causing human disease and resulting in protection were recently reviewed [2]. Nonviral diseases, such as malaria, have also been targeted effectively by Ad recombinant vaccines [78]. We will conclude, rather, with brief comments on two areas under intensive efforts of vaccine development: HIV/AIDS and cancer immunotherapy.

For HIV/AIDS vaccines, significant progress has been made using replication-competent Ad recombinants. The rationale is based on chimpanzee studies, which suggested that better replication of Ad-HIV recombinants *in vivo* leads to enhanced immune responses and greater protection [52–54]. Overall, a combination approach of Ad-HIV or Ad-SIV recombinant priming followed by boosting with envelope protein has elicited humoral, cellular, and mucosal immunity [49–57]. The vaccinated chimpanzees, in particular, showed persistent potent immune responses with significant protec-

tion against homologous and heterologous HIV challenges and provided the basis for moving forward into Phase I human trials. Other groups are utilizing replication-defective Ad recombinants deleted in E1 and E3 [89–92]. Recently, application of the chimpanzee Ad68 vector has been described [93]. In lieu of second-generation vectors, improved expression of HIV/SIV-inserted genes has been achieved by removing instability elements from targeted genes [94], or by altering codons to those preferentially utilized in mammalian cells [92]. Combination DNA priming, followed by Ad recombinant boosting, has led to enhanced immune responses, recently demonstrated with Ad-SIV vaccines in monkeys [92]. The potential of this approach is further exemplified by the synergistic immune responses seen in monkeys primed with an Ebola virus DNA vaccine and boosted with an Ad-Ebola recombinant. The animals were completely protected against a lethal Ebola virus challenge [95].

Adenovirus recombinant vectors are also being applied in the rapidly growing area of cancer vaccine development. Adenovirus recombinants can effectively deliver various therapeutic immune modulators, but recently have been used to immunize against tumor components themselves. Among the earliest strategies, mice immunized with Ad recombinants expressing the melanoma antigens MART-1 or gp100 were protected from a murine B16 melanoma challenge [96]. The safety of this approach was later con-

firmed in Phase I human trials [97]. Enhancement of immunity to melanoma antigens has been demonstrated by immunization of mice with Ad-gp100-transduced dendritic cells [98]. In other approaches, protection against B-cell and T-cell lymphomas has been described using Ad-B-cell lymphoma idiotypes [99] and an Ad-chimeric T-cell antigen receptor [100], respectively. An Ad-prostate-specific membrane antigen recombinant induced an immune response in people, thereby breaking tolerance to a self-antigen [101]. Ad-HPV16 vaccines have suppressed the growth of tumors in mice [102]. The use of vaccine strategies shown to enhance immune responses against infectious agents will undoubtedly have benefit in the cancer vaccine field.

## VII. CONCLUDING REMARKS

Overall, live Ad recombinants have a broad potential for vaccine strategies against both infectious diseases and cancer. The long history of safety and efficacy of wild-type vaccines, the flexibility afforded by the numerous subtypes, the vast body of knowledge accumulated through gene therapy studies, and the already extensive accumulation of appropriate vectors and associated cell lines should stimulate and facilitate their further development for vaccine use.

## RNA Virus Replicon Vaccines

Nancy L. Davis and Robert E. Johnston

*University of North Carolina, Chapel Hill, North Carolina, U.S.A.*

### I. INTRODUCTION

Expression systems based on single-stranded RNA viruses offer exciting prospects for their application as vaccines. The relatively recent development of cDNA-based genetic systems for a substantial number of these viruses has made possible the directed manipulation of RNA virus genomes, the discovery of substantial genomic plasticity in these virus systems, and their reconfiguration as vaccine vectors. While not directly germane to a discussion of vaccines, pioneering work with infectious clones of poliovirus [1], positive-strand RNA plant viruses [2,3]), and rabies virus [4] was key in guiding the subsequent development of analogous reverse genetic systems for other RNA viruses and vaccine vectors derived from them.

Single-stranded RNA virus vectors can be conveniently divided into those based on positive- or negative-stranded genomes. Positive-stranded genomes have the same sequence as mRNA. The first step in genome replication, the translation of the replicase enzymes from the parental RNA genome, directly occurs upon introduction of the genomic RNA into cells. Therefore when the RNA genome alone is introduced into a cell by any one of a number of transfection methods, it is infectious without the need of any exogenous viral proteins. For genetic manipulation of a positive-strand RNA genome, cDNA clones may be constructed with the viral sequences downstream of a phage RNA polymerase promoter. Linearization of the plasmid downstream of the viral sequences and *in vitro* transcription with the cognate phage RNA polymerase result in the production of positive-strand RNA replicas of the viral genome which are infectious after transfection into cells.

Negative-stranded RNA genomes carry their genetic information in the complementary sense relative to mRNA. Therefore successful virus propagation requires that the viral replicase/transcriptase enzymes active in the earliest stages of intracellular replication be introduced into the cell along with the genome. In systems designed for reverse genetics of negative-stranded viruses, *in vitro* transcripts from cDNA clones (usually transcripts which are the positive sense

complement of the genome) are introduced into cells where the replicase proteins are being expressed from a second expression system (often the vaccinia T7 system).

With either positive or negative sense RNA genomes, the systems used to regenerate infectious viruses from cDNA clones have also been employed to add immunizing genes from target pathogens to the viral genomes. This results in a fully infectious and propagation competent virus vector which expresses an exogenous immunogen in addition to a full complement of viral proteins in the successive cells it infects. A second iteration on this theme is the substitution of an immunogen gene for one or more of the structural protein genes of the vector virus. The resulting RNA genome is self-replicating inside an appropriate cell, thus the term "replicon." The replicon expresses the immunizing gene and can be packaged into "replicon particles" when the structural proteins are produced *in trans* within the same cell. When inoculated into an animal or human, the replicon particles target to those cells normally infected first by the complete virus, the replicon genome expresses the immunizing gene, but the infection cannot be propagated to additional cells because of the absence of the structural protein genes from the replicon genome. Thus replicon particles can provide safe and effective immunization against a variety of pathogens.

### II. REPLICON VACCINE VECTORS DERIVED FROM POSITIVE-STRAND RNA VIRUSES

#### A. Propagation Competent Vectors

##### 1. Alphaviruses

Propagation competent vectors express an immunizing gene in the context of a complete virus genome. For instance, the alphavirus promoter for transcription of the subgenomic mRNA has been defined by deletion and point mutation analysis [5], and a second copy of this promoter can be inserted into the genome either immediately upstream of the original subgenomic promoter or between the end of the

structural protein genes and the beginning of the 3' untranslated region [6,7]. As alphaviruses contain an icosahedral nucleocapsid, which presumably limits the total genome size, the size of exogenous RNA that can be added is also limited. Genes of up to 2.3 kb have been inserted and successfully used in murine immunization experiments [8], although genes in the 1-kb range are more stable upon passage of the virus [9]. Increased stability also may be associated with insertion at the upstream site [9].

## 2. Coronaviruses

Coronaviruses express their genes from a 3' coterminally nested set of mRNAs in which sequences at the 5' end of the genome are fused with the beginning of each mRNA immediately upstream of the coding sequence for each of the coronavirus genes. Although the precise mechanism whereby this occurs remains a matter of some controversy, the necessary *cis*-acting signals at the beginning of each gene have been well defined. An exogenous immunizing gene may be inserted between native coronavirus genes, and the gene will be expressed if the *cis*-acting intergenic region signals are included at its 5' end [10].

## 3. Picornaviruses

In picornavirus propagation competent vectors, short, foreign epitope sequences have been substituted for external loops on the poliovirus capsid structure, resulting in an immune response to those epitopes following infection with the chimeric poliovirus [11]. In a second iteration, the immunizing gene is placed either upstream of the major capsid genes or at the P1/P2 junction, maintaining the genomic open reading frame (ORF). As picornavirus genes are expressed as a single ORF, an additional internal ribosome entry site is utilized [12], or additional viral protease cleavage sites are placed as appropriate to excise the expressed protein from the polyprotein precursor [13]. Immunization with such vectors protected mice against a model tumor challenge [14]. Crotty et al. [15,16] overcame the inherently limited insertion size in such vectors by expressing a population of relatively short overlapping coding sequences from genes many times larger than the insertion maximum. Immunization of macaques with the population of vector viruses resulted in significant immunity to simian immunodeficiency virus (SIV), and significant protection upon challenge.

## 4. Flaviviruses

Flaviviruses have also been modified in a manner analogous to picornaviruses. A malaria epitope has been inserted into the E protein of the yellow fever vaccine strain, 17D [17], and 17D has been utilized to express a model tumor antigen and protect against tumor challenge [18]. The 17D virus, as well as attenuated dengue fever virus subtypes, has been utilized for the production of flavivirus chimeras in which the prM and E genes of a flavivirus to be vaccinated against are exchanged for the same genes in one of the vaccine virus backbones [19,20]. The goal is to take advantage of the attenuating mutations embedded in the vaccine backbone to

create alternative live virus vaccines for the agents supplying the exogenous prM and E genes. Early stage clinical trials of this concept are underway [21].

## 5. Advantages and Disadvantages of Propagation Competent Vectors

Propagation competent vectors are essentially live virus vaccines and share some of their advantages and disadvantages. Because they are propagation-competent, they should be inexpensive to produce, and amplification in the vaccinee should allow immunization at a relatively low dose. The biological characteristics of the parent virus backbone also contribute to the characteristics of the vector. For example, in the case of poliovirus vectors, oral vaccination and induction of mucosal immunity are potentially significant advantages of this approach. However, the ability of propagation competent vectors to amplify in the host also imposes several challenges. The first of these is the necessity of maintaining an attenuated phenotype. In most of these systems, the insertion of the exogenous gene is itself a strongly attenuating mutation, and this can be supplemented with other defined attenuating mutations to make reversion a rare event. Second, the stability of the inserted gene is critical to the ability to immunize with the vectored gene. Third, inclusion of all the viral genes in addition to the vectored gene limits the size of the heterologous sequence that may be accommodated within the viral capsid, especially icosahedral capsids. Finally, the inclusion of all the viral genes in these vectors means that immunization will induce strong vector-specific immunity, perhaps limiting the ability of such vectors to be used for boosting or to be subsequently used in the same individuals for immunization against additional pathogens. In those instances where an existing human vaccine is utilized as the vector, the ability to vaccinate with the exogenous gene may be limited by preexisting immunity to the vector itself.

## B. Replicon Vectors

Replicon vectors derived from positive-strand RNA viruses are essentially self-replicating machines designed to amplify the mRNA for the exogenous genes that they carry. By substituting an immunizing gene for one or more viral structural protein genes, the immunizing gene can be expressed to high level. The replicon genome can be packaged into virions by supplying the structural proteins in trans, thus producing a replicon particle capable of delivering the replicon genome to the same target cells as those normally infected by the wild-type virus. Because replicon genomes typically do not carry the genes for structural proteins, they are suicide vectors incapable of propagation beyond the initially infected cell.

RNA replicons based on poliovirus, the alphaviruses [Semliki Forest (SFV), Sindbis (SIN), Venezuelan equine encephalitis (VEE), and South African Arbovirus 86 (S.A.AR86)], the flavivirus Kunjin and the coronavirus transmissible gastroenteritis virus have been produced and tested for their ability to induce protective immune responses

in experimental animals, including nonhuman primates in some cases. A human Phase I clinical trial with a VEE replicon expressing the human immunodeficiency virus (HIV) clade C gag gene has been initiated.

### 1. Alphaviruses

The antecedents of alphavirus replicon systems are found in the work of the Rice, Schlesinger, and Strauss laboratories, which constructed the first cDNA clones of alphaviruses, mapped the *cis*-acting signals required for alphavirus RNA replication and encapsidation, and showed that alphavirus RNAs could be modified to express exogenous genes [5–7,22–27]. Replicon expression systems have now been derived from several alphaviruses including SFV [28,29], SIN [30], VEE [31,32], and S.A.AR86 [33]. A replicon system based on a related Togavirus, rubella, also was recently described [34].

The structural protein genes, normally expressed to high level from a subgenomic mRNA, are deleted from alphavirus replicon systems and replaced by the immunizing gene. Thus, the gene of interest is expressed in replicon infected cells to levels approaching 20% of the total cell protein. In the SFV and SIN systems, high-level expression depends on the presence of a translational enhancer sequence extending from the subgenomic mRNA start site through approximately 200 nucleotides into the capsid gene [35,36]. Although the cells are eventually killed as a result of replicon infection, the absence of the structural protein genes prolongs the period of maximal expression [37]. Moreover, mutant alphavirus replicons have been selected which are capable of persistent infection and expression [38–41].

Packaging of alphavirus replicon genomes into replicon particles has been accomplished either by coelectroporation of in vitro replicon and helper structural protein transcripts [29,30,32], or by the establishment of stable cell lines constitutively expressing transcripts for the structural proteins [42]. In either case, the helper transcripts contain the *cis*-acting 5' and 3' ends of the cognate alphavirus, a deletion in the nonstructural gene region (deleting replicase function and the *cis*-acting packaging signal), and the native subgenomic promoter followed by the structural protein genes. Therefore in the presence of the cognate alphavirus replicon transcript, the structural protein helper RNAs are replicated, and the structural protein genes are expressed from the native 26S promoter. In the packaging cell lines, the helper transcripts are constitutively expressed but are not translated until introduction of the replicon RNA, either by electroporation or by infection with previously packaged replicon particles. Complementation occurs between the replicase functions inherent in the replicon RNA and the structural proteins supplied by the helper RNAs in these transfected cells, and replicon particles are assembled. These contain only the replicon RNA as a result of the absence of a packaging signal on the helper RNAs.

Alphavirus RNAs are capable of low-level recombination [43], and alphavirus particles can copackage multiple RNAs [30]. In the context of alphavirus packaging systems, either can result in the production of propagation competent

genomes. Expressing the capsid and glycoprotein genes from separate helper RNAs significantly reduces the generation of propagation competent virions contaminating replicon particle preparations [32,42,44].

Replicon particles provide an efficient system for delivery of the replicon genome into cells *in vivo*. The effectiveness of the VEE replicon system may be attributable in part to the ability of VEE replicon particles to target and replicate within dendritic cells in lymph nodes of mice [45] and primates (West et al., personal communication). The SIN variants, selected from laboratory adapted strains for increased ability to target dendritic cells, may improve the ability of SIN replicon particles to induce immune responses [46]. However, other studies suggest that wild-type SIN itself targets efficiently to dendritic cells *in vivo* [47]. The SFV replicon particles also appear to target lymphoid tissue [48].

Replicon RNAs derived from alphaviruses have also been directly delivered into animals [49–53], although degradation of the RNA prior to entry into cells may limit this approach. Alternatively, cDNAs driven by eukaryotic promoters have been used to express self-replicating replicon RNAs [54–57]. In the case of cDNA delivery, the efficiency of transcription in and exit from the nucleus may limit effectiveness in a vaccine context [58].

Alphavirus replicon particle vaccines have been tested in a variety of animal models of disease. Humoral, cellular, and mucosal immunity have been demonstrated in mice, and in primates there is clear induction of both antibodies and cytotoxic T cells. Pushko et al. [32] described the protection of mice from intranasal (IN) influenza challenge by using VEE replicon particles expressing the hemagglutinin (HA) protein of influenza strain A/PR/8/34. Challenge virus replication was reduced by greater than 4 logs in the nose and could not be detected by *in situ* hybridization (Davis et al., personal communication). VEE replicon particle immunization against the A/HK/156/97 HA protected mice and chickens against challenge with the human pathogenic Hong Kong origin H5N1 virus [59]. Protection with VEE replicon particles has also been reported for equine arteritis virus in horses [60,61] and for rodent models of Lassa fever, Ebola, and botulinum toxin [62–64]. In primates, partial protection against simian immunodeficiency virus challenge has been demonstrated [65], and complete protection of primates against a high-dose challenge of Marburg virus was achieved [66]. Immunization with VEE replicon particles expressing the E7 protein from human papilloma virus 16 completely protected mice against tumor establishment in a murine model and led to eradication of established tumors in 67% of the animals [67].

The SIN- and SFV-based replicon vectors, either as naked RNA, as DNA-launched replicon genomes, or as replicon particles, have also induced varying degrees of immune response and protection in animal challenge models. These include influenza in mice [53,68–71], infectious bronchitis and infectious bursal disease viruses in chickens [72,73], flaviviruses in mice and sheep [53,74,75], herpes simplex in mice [57], tumor immunotherapy [76–83], immunodeficiency virus models in rodents and macaques [84–90], hepatitis C in conventional and HLA-A2.1 transgenic mice [91–93], *Plas-*

*modium falciparum* in mice [52,70], and respiratory syncytial virus in mice [53,94].

## 2. Picornaviruses

Kaplan and Racaniello [95] identified the sequences not essential for replication of poliovirus RNA, setting the stage for Ansardi et al. [96], who devised a poliovirus replicon system in which immunizing genes replace the P1 segment of the polio genome. Transfection of the replicon RNA and coinfection with vaccinia expressing the substituted poliovirus structural protein genes results in the production of poliovirus replicon particles, as well as the vaccinia helper. The polio replicon particles may be amplified by continued passage of the mixed population followed by separation of the much larger vaccinia virions from the polio replicon particles. This system has been utilized for immunization against a variety of bacterial and viral pathogens (e.g., *Helicobacter pylori* [97]; HIV/SIV [98–101]; tetanus toxin C-fragment [102]), and for tumor immunotherapy and viral induced lysis of tumors [103,104]. Following the poliovirus example, other picornaviruses, such as rhinoviruses, also are being developed as vaccine vectors [105].

## 3. Flaviviruses

Flavivirus genomes are organized as a single long ORF encoding the structural proteins at the 5' end and the replicative nonstructural proteins in the 3' portion of the genomic RNA. Replicons of Kunjin virus have been constructed in which the structural proteins are replaced with the gene of interest in a cDNA clone of the virus genome [106]. Much like the poliovirus replicons, electroporation of in vitro transcripts from the modified cDNA results in synthesis of the heterologous gene. Packaging of the Kunjin replicon genome into flavivirus-like particles is accomplished by supplying the structural proteins in trans from an SFV replicon [107]. Whether delivered into an animal as a naked RNA, as a cDNA placed behind a eukaryotic promoter, or as a Kunjin replicon particle, this system induces humoral and cellular immune responses to heterologous antigens [108]. A noncytopathic version of the Kunjin replicon has also been developed and may improve the capacity for immunization and/or enable gene therapy applications [109].

## 4. Coronaviruses

Coronavirus replicons are in the early stages of development but they hold promise as vaccine vectors because of their potential for expression of large gene cassettes. Heterologous genes have been inserted into the genome of transmissible gastroenteritis virus after deletion of genes required for either virus replication or assembly. The required genes are supplied in trans by a helper virus [110], or by an alphavirus replicon expressing the helper genes [111].

## 5. Advantages and Disadvantages of Replicon Vectors

Replicon vectors combine some of the features of live virus and subunit vaccines. They initiate a partial replication cycle in vivo, which allows the production of immunizing genes in

the context of viral replication, much as what would occur with a live virus. The major product of that replication, however, is one or more protein subunits derived from the target pathogen. In a sense, replicon vectors represent the implantation of a subunit vaccine factory into the vaccinee, using the vaccinee's own cells for in situ production of the subunit vaccine. The absence of viral structural protein genes in the replicon RNA allows immunization with the vectored immunogen without raising high levels of immunity to the replicon particles themselves, facilitating booster inoculations as well as the sequential immunization of the same individual with the same vector expressing genes from other pathogens. Positive-strand RNA replicon vaccines can be delivered as self-replicating naked RNAs or as cDNAs from which self-replicating RNA replicons can be transcribed by cellular polymerases. This feature may facilitate the rapid development of new vaccines, as Good Manufacturing Practice (GMP) production of DNAs is straightforward and DNA vaccines will have been well characterized. The deletion of the vector's structural protein genes has two implications. First, it leaves room for larger inserted sequences than the related propagation competent vectors, and second, it makes replicon vectors inherently safe. Additional safety features can be built into the system, e.g., by using helper systems which reduce or eliminate the possibility of regenerating a propagation competent virus, including known attenuating mutations in the replicon genome and/or the structural protein genes used for packaging into replicon particles, and developing sensitive assays for the detection of propagation competent viruses in replicon particle preparations. However, a number of practical questions remain. No results of human trials are yet available for any of these systems, and for some, primate experiments have yet to be initiated. The GMP production of replicon particles may be problematic, with low relative yields in approved cell substrates and no packaging cell lines yet established in cell substrates likely to be approved for GMP production. These difficulties will be magnified in adapting these processes to commercial scale. Notwithstanding these issues, replicon vaccines derived from positive-strand RNA viruses have shown tremendous promise in experimental systems and certainly merit continued effort to resolve these potential limitations.

A number of review articles have been published on expression systems derived from positive-strand RNA viruses [112–124].

## III. REPLICON VACCINE VECTORS DERIVED FROM NEGATIVE-STRAND RNA VIRUSES

Negative-strand viruses share advantages with positive-strand viruses when configured as vaccine vectors. Both have evolved mechanisms for high-level protein expression, and neither directs the integration of foreign genetic material into the genome of the host. However, now that systems have been established for the efficient recovery of recombinants of several negative-strand RNA viruses, and specific signals for gene expression have been defined, members of this group of viruses offer these additional advantages. First, viruses with

segmented genomes and/or filamentous nucleocapsids are able to accommodate additional whole gene segments, or large gene insertions. Second, many are infectious by the intranasal (IN) route and deliver heterologous immunogens to the respiratory mucosa. Third, multiple serotypes exist in many cases, which facilitates effective booster strategies. Finally, in several cases, safe and effective vaccine strains have been reproduced as full-length cDNA clones and are available as the starting point for development of vaccine vectors.

### A. Influenza Virus

Influenza virus is a member of the orthomyxovirus family, with a genome of eight segments of negative-sense RNA. These encode 10 viral proteins, the three polymerase proteins, PB2, PB1, and PA, the nucleoproteins, NP and NEP (NS2), the nonstructural protein, NS1, the membrane associated proteins, M1 and M2, and the transmembrane spike glycoproteins, neuraminidase (NA) and hemagglutinin (HA). Fifteen distinct hemagglutinin subtypes and nine different NA subtypes have been identified, which could be alternated in sequential immunizations for improved boosting (see Section 3.2 below). Influenza virus differs from other RNA viruses in that genome replication and transcription occur in the nucleus of infected cells, although the life cycle does not involve a DNA intermediate. M1 and M2 are both expressed from the same genome segment by way of an unspliced (M1) or a spliced (M2) mRNA, as are NS1 and NS2. NS1 protein, which regulates mRNA export from the nucleus [125] and its translation in the cytoplasm [126], and inhibits the host interferon response [127], is the only non-structural protein, and the only protein not required for viability. It has been possible, by using techniques described below, to generate viable viruses that contain more than eight segments.

Strategies for genetic engineering of influenza virus have been recently reviewed by Neumann and Kawaoka [128], and will be only briefly summarized here. Recombinant DNA technology has been a part of the study of influenza virus since the first system was described in 1989 by Luytjes et al. [129]. This initial technique was helper-virus-dependent. It combined the *in vitro* transcription and reconstitution of an influenza viral ribonucleoprotein (RNP) segment with RNP transfection. This was followed by helper virus superinfection and counterselection of helper virus to produce a pure stock of viable recombinant virus. The first published demonstration included the modification of influenza virus to drive the expression of chloramphenicol acetyltransferase (CAT), and influenza virus-based expression vectors were born [129]. The construction of RNA polymerase I-driven expression plasmids to produce all eight influenza vRNA segments, followed by cotransfection with influenza protein expression plasmids allowed generation of recombinant influenza virus entirely from cDNA, eliminated the need for helper virus, and opened up all 10 genes to genetic analysis [130–132].

Several approaches have been used to express foreign genes from influenza virus (reviewed in Refs. [133,134]). In an approach called epitope grafting, peptides were inserted

to produce chimeric HA or NA proteins. Influenza vectors in which foreign peptides replaced the antigen B site of HA were used to immunize mice, and elicited serum antibodies, mucosal immune responses and/or CD8+ T cell responses against several disease agents, such as HIV [135–138], malaria [139,140], and *Pseudomonas aeruginosa* [141].

The stalk region of NA can also accommodate foreign sequence, and although this site may not efficiently present B cell epitopes [133,142], it has been used to induce specific CD8+ T cell responses against lymphocytic choriomeningitis virus [143], model tumor antigens [144], and malaria [145]. The strategy of epitope grafting is limited with respect to the amount and character of the foreign sequence that can be inserted without detrimental effects on the viability of the recombinant vector.

Efficient incorporation of a third, heterologous transmembrane glycoprotein into both the plasma membrane of infected cells and the envelope of recombinant virus has been demonstrated by Zhou et al. [146]. This was accomplished by helper virus rescue of a ninth genome segment expressed from an RNA polymerase I-driven plasmid that encoded a chimeric protein (the HA cytoplasmic region fused to the transmembrane anchor and ectodomain of classical swine fever virus (CSFV) E2 protein). The initial proportion of recombinant virus was maintained on passage because of the inclusion of an upregulated viral promoter on the engineered ninth genome segment. The performance of this vector as a vaccine for CSFV has not yet been reported.

The NS1 gene presents an attractive site for the insertion of foreign sequences. It is a true nonstructural protein which varies in size among different isolates, and thus may have fewer size constraints than a structural protein. It is abundant in influenza-infected cells. In infected animals, both NS1-specific antibody [147] and cytotoxic T lymphocytes (CTLs) [148] have been reported. Finally, the abrogation of its function as an interferon antagonist has been shown to significantly attenuate influenza virus virulence [127,149,150]. A recombinant NS genome segment was engineered to express a truncated NS1 protein fused to a self-cleaving foot-and-mouth disease virus (FMDV) protease domain followed by an HIV-1 Nef-derived polypeptide. This segment was rescued into viable virus by using a high-efficiency helper system for NS mutants [151]. The engineered NS-Nef virus replicated as well as the parent virus in most *in vitro* culture conditions, and was stable through five serial passages. In mice, IN inoculation of the NS-Nef virus produced no clinical signs and no virus replication in the nose or lung, which represented a significant reduction in virulence compared to the parent virus. However, the attenuated virus vector did replicate sufficiently to induce Nef-specific serum antibody and CD8+ T cells in the spleen and in lymph nodes of the respiratory tract and urogenital tract. A successful booster immunization was achieved by using a second analogous vaccine vector with a distinct HA subtype.

It has been possible to engineer influenza genome segments for expression of bicistronic mRNAs in which two open reading frames are separated by a mammalian internal ribosomal entry site or IRES. Garcia-Sastre et al. [152] constructed two such altered NA segments that contained (5' to 3') the HA signal sequence, a part of the HIV-1 gp41 ecto-

domain, a transmembrane region and cytoplasmic tail derived from either gp41 or HA, a BiP IRES, and the intact NA gene. The recombinant viruses, whose viability was dependent on the translation of the NA gene downstream of the IRES, grew to 0.5–1.5 log lower titers than the wild-type virus. Cells infected with both viruses contained the predicted gp41-related polypeptide, and the presence of the HA transmembrane region and cytoplasmic tail resulted in efficient transport of the foreign protein to the plasma membrane for incorporation into the virion envelope. Tests of the immune response to this vector have not been reported. A similar vector was constructed for *P. falciparum* and shown to induce specific CD8+ CTLs [140]. Improvements in this type of vector might include the use of a different, more efficiently replicated genome segment, such as HA, or the identification of a more active IRES.

Vaccinia-T7-based [153] and plasmid-based [154] systems have been established for the production of nonpropagating influenza virus-like particles (VLPs). An RNA polymerase I-driven plasmid was engineered to express a vRNA with an antisense copy of green fluorescent protein. The VLPs containing the synthetic vRNA were packaged by cotransfection of plasmids expressing the influenza structural proteins. By analogy to replicon particles of positive-strand viruses, single-cycle vector particles that contain a vRNA expressing a gene of interest as well as vRNA segments for PA, PB1, PB2, and NP (required for transcription and replication of the foreign sequence) would deliver the foreign gene to influenza virus susceptible cells for in vivo expression, but be unable to spread in the host. Also, a nonpropagating influenza virus vaccine vector could be based on the work of Watanabe et al. [155], who engineered an NS2-knockout virus that is replication-defective and highly immunogenic in mice.

## B. Rhabdoviruses

The best known members of the Rhabdovirus family are vesicular stomatitis virus (VSV) and rabies virus, both of which have been exploited as vaccine vectors. Rhabdoviruses contain nonsegmented, negative-sense RNA genomes and are classified with Paramyxoviruses and Filoviruses in the order Mononegavirales. Genomic RNA is approximately 11 kb in length, and encodes the nucleocapsid protein (N), phosphoprotein (P, previously NS, a cofactor in viral RNA synthesis), matrix protein (M), spike glycoprotein (G), and RNA-dependent RNA polymerase (L). All five viral proteins are found in the virus particle. Sequential transcription of these five genes by the viral transcriptase complex occurs on the nucleoprotein-encapsidated genome and is regulated by *cis*-acting signal sequences, including the 3' polymerase entry site and gene-start, polyadenylation, and gene-stop sequences flanking each gene. The level of gene expression is directly related to gene position relative to the 3' end of the RNP template, such that rearrangement of the viral genes leads to slower growth in cultured cells and attenuation of virus virulence in the animal host [156]. These rearranged genomes are stable on passage, as homologous recombination does not occur. There are three known serotypes of VSV, but only a single serotype of rabies virus. Specific mu-

tations in both the VSV and rabies virus glycoproteins have been shown to attenuate virulence, and there is a live attenuated vaccine for rabies that is safe in many animal species. Although VSV is cytopathic in cell culture, rabies virus does not shut off host protein synthesis in cultured cells. VSV has a wide host range, from insects to man, and causes a mild, flu-like illness in humans. Laboratory animals can be infected by subcutaneous, intracranial or IN routes.

Vesicular stomatitis virus RNA transcription has been characterized in depth by elegant in vitro reconstitution studies. Further insights into the virus life cycle were gained by using cells infected with defective deletion mutants and transfected with virus protein expression plasmids, or by using cells cotransfected with cDNAs expressing either deletion mutant genomes or synthetic minigenomes and virus proteins. Schnell et al. [4], working with rabies virus, first demonstrated cDNA-based replication of a full-length recombinant rhabdovirus genome, by using the transfection of T7-driven RNA expression plasmids for transcription of both the complete genome complement (or antigenome) and the mRNAs for the N, P, and L proteins, followed by infection with vaccinia virus expressing T7 bacteriophage RNA polymerase. In the 8 years since this signal success, this strategy has been successfully used to produce recombinant VSV and several paramyxoviruses (see below). More recently, vaccinia virus-free systems for both rabies virus and VSV have been developed [157,158].

Functional gene-stop and gene-start signal sequences were inserted into the rabies virus genome sequence and recovered in viable virus as part of the demonstration that a recombinant rabies virus could be produced from cDNA [4]. Shortly thereafter, stable expression of a reporter protein from a sixth VSV gene flanked by minimal start and stop signals and inserted between the G and L genes was obtained [159]. This basic strategy has been used in the construction of several expression and vaccine vectors (some of which are described in Schnell et al. [160]), which have allowed the characterization of this system.

It was expected, based on the well-known ability of VSV to incorporate heterologous glycoproteins into its virions, that heterologous glycoproteins expressed from VSV vectors would become part of analogous mosaic virions or pseudotypes. Viable viruses carrying genes for CD4, measles virus hemagglutinin (MH) or measles virus fusion protein (MF) were produced from cDNAs and were shown to contain varying amounts of the foreign protein inserted into their virion envelopes. The additional gene increased the length of the bullet-shaped particles, presumably because of the increased length of the filamentous ribonucleocapsid, and reduced, to varying degrees, the level of virus replication in cultured cells. In many but not in all cases, no VSV-specific sequence was needed to drive incorporation of the additional glycoprotein into the virion envelope. The efficiency of VSV G incorporation into virions was not affected, suggesting that the new membrane protein occupied extra space in the envelope. By electron microscopy, each virus particle contained both proteins. This type of replication-competent VSV vaccine vector has been tested in animal models against measles virus [161], influenza virus [162,163], respiratory syncytial virus [164,165], HIV-1 (see below), and bovine vi-

ral diarrhea virus [166]. The VSV vector expressing measles virus H protein was used to vaccinate cotton rats intranasally in a measles virus challenge experiment [161]. In contrast to the attenuated live virus measles vaccine, the VSV vaccine vector was able to induce protective levels of serum neutralizing antibody even in the presence of maternal antibody. *In vitro*, virions carrying both VSV G and measles H protein on their surface (at 30% the level of G) were easily neutralized by VSV-specific antiserum, but required very high titers of measles-specific serum for neutralization. Thus the additional envelope glycoprotein is highly immunogenic, but is nonfunctional in the vector replication cycle, and when bound to moderate amounts of cognate antibody, does not interfere with G-driven VSV infection. This vaccine vector approach is promising in cases such as measles, where vaccination in the presence of maternal antibody is needed to prevent dangerous early childhood infections.

Haglund et al. [167] demonstrated that viable VSV vectors could express two foreign proteins from two additional mRNAs with only a threefold reduction in titer. The HIV-1 *gag* gene was positioned between M and G, and the *env* gene between G and L in the same recombinant VSV genome. HIV virus-like particles (VLPs) as well as VSV vector particles were produced. HIV gp160 was incorporated only into VLPs, while VSV G was found in both.

A cocktail approach, mixing vaccine vectors expressing either SIV Gag or an HIV Env/VSV G chimeric protein, was used in a SHIV89.6P challenge experiment in macaques [168]. HIV-specific neutralizing antibody was induced, and cellular immune responses were detected against both proteins in most vaccinated monkeys. All the vaccinated animals were infected upon SIV 89.6P challenge, but were able to control their virus loads and remain disease-free for several months.

Two concerns surround the use of propagation competent VSV vectors: (1) the febrile, flu-like illness associated with human infection [169], as well as residual reactogenicity in mice of IN-administered vaccine vectors; and (2) induction of levels of antivector antibody that prevent effective booster immunizations [163,170]. Some improvements of propagation competent vectors have been explored. Recombinant VSV mutants carrying deletions in the cytoplasmic tail of G that were significantly attenuated relative to the parent virus have been described, and vaccine vectors carrying these mutations and expressing influenza HA showed comparable immunogenicity in mice to the parent vector [163,171]. In addition, effective boosting in the presence of anti-VSV antibody has been achieved by constructing vaccine vectors with G proteins of three alternate serotypes [170].

In an alternate approach, both vector virulence and antivector immunity are addressed by the use of nonpropagating G-deleted vectors. It is possible to engineer a recombinant virus whose G gene is replaced with that for a heterologous glycoprotein. This virus can be maintained on cells that provide G in trans. However, following a single passage through normal cells, nonpropagating virions carry primarily the heterologous envelope protein. When such vectors were constructed with influenza HA, RSV G, or RSV F, each of the three proteins was incorporated into vi-

rions that did not spread in cell culture. However, RSV F did function to produce syncytia in vector-infected cells. In mice, the vectors inoculated IN produced no clinical signs, and gave complete protection against disease [171,165]. In contrast, the analogous vector lacking the VSV G gene and expressing an HIV-1 gp160 chimeric protein with the VSV G transmembrane and cytoplasmic domains was infectious. Gp160 substituted for G in the virus envelope to produce a “surrogate virus,” which was able to grow efficiently in HIV-susceptible cells [172]. This was also true, in reverse, for vectors expressing cellular CD4 and CXCR4, which mediated entry of vector particles into HIV-infected cells with gp160 on their surface [173]. The utility of this approach may depend, therefore, on the ability of the heterologous glycoprotein to produce a propagation-competent recombinant virus, and its resulting biological properties.

Vaccine vectors have also been based on rabies virus. Advantages of this vector system include the availability of a vaccine strain shown to be safe in many animal species, the less cytopathic nature of infection in cultured cells, and the possibility of oral immunization [174]. A vector in which HIV-1 gp160 was inserted between the G and L genes was inoculated intraperitoneally (IP) into mice and primed a neutralizing antibody response to HIV [174] and a cross-reactive anti-HIV CTL response [175]. The IP immunization of mice with an analogous vector expressing HIV-1 Gag induced HIV gag-specific CD8+ CTLs. G-deficient rabies virus vectors expressing a chimeric HIV-1 gp160-G protein (with the rabies virus G protein cytoplasmic domain) contained gp160 in their envelope, showed reduced replication *in vitro* compared to G-containing vectors and displayed the cell tropism of HIV-1 [176].

### C. Paramyxoviruses

The Paramyxovirus family includes two subfamilies, the Paramyxovirinae subfamily, with the respiroviruses (e.g., Sendai virus, human parainfluenza, and bovine parainfluenza), the rubulaviruses [New Castle disease virus (NDV) and simian virus 5 (SV5)], and the morbilliviruses (measles and rinderpest viruses), and the Pneumovirinae subfamily, with the pneumoviruses (human and bovine respiratory syncytial viruses) and the metapneumoviruses. Paramyxoviruses contain nonsegmented negative-sense RNA genomes in filamentous ribonucleocapsids enclosed in polymorphic envelopes. They share patterns of gene expression and regulation with the simpler rhabdoviruses, but carry additional genes. For example, all paramyxoviruses have two distinct glycoprotein spikes, one for attachment and the other for fusion with the host cell membrane. Several recombinant paramyxoviruses have been recovered from genomic cDNA clones by using techniques analogous to those described for rhabdoviruses. Reverse genetics systems have been reported for measles virus, respiratory syncytial virus, Sendai virus, Rinderpest virus, human parainfluenza type 3 (hPIV-3), and simian virus 5 (SV5) (reviewed by Roberts and Rose [177]). More recently, recombinant bovine PIV-3 [178] and New Castle disease virus (NDV) [179] have been recovered. Work with these systems has made significant contributions to the understanding of the replication cycles of these viruses and,

in some cases, has allowed determinants of attenuation to be mapped and candidate vaccine vectors to be constructed.

A large body of work with genomic cDNA clones of RSV and PIV3 has been previously summarized [180]. The ability to rescue recombinant human and bovine RSV spurred the development of candidate live attenuated RSV vaccines (reviewed in Collins et al. [181]). These were constructed by introducing single and multiple mutations originally identified in cold-passaged and/or chemically mutated strains [182–188], by deleting genes not required for growth in cultured cells [181,189,190,191,192,193] or by replacing the G and F genes of recombinant bovine RSV with human RSV G and F [194].

The RSV genome was engineered to express the CAT reporter gene by linking its coding sequence to flanking RSV gene-start and gene-stop signals and inserting them between the G and F genes of the cDNA encoding the RSV antigenome. Expression was maintained on passage in spite of the fact that the additional small gene reduced virus yield in vitro by 20-fold [195]. A dual-specificity, propagation-competent RSV vaccine candidate was produced by inserting the RSV subgroup B G protein between the F and M2 genes of recombinant subgroup A RSV [196]. This virus vector showed a 1 log<sub>10</sub> reduction in peak titer in vitro and both glycoproteins were expressed in infected cells. However, insertion into virion envelopes was not assayed.

In 1997, two groups reported the recovery of human PIV3 from full-length cDNA [197,198]. By analogy to RSV, recombinant hPIV3 has been used to test attenuating mutations for inclusion in a live, attenuated vaccine [199–202]. Bovine PIV3 shows restricted replication in human cells and in the primate respiratory tract, and is attenuated in humans [203,204]. Three recombinant human and bovine PIV3 chimeras have been constructed and tested for attenuation. Two were based on hPIV3 cDNA with its N gene [205], or F and HN genes [206] replaced by those from bovine PIV3. The third was based on a bovine PIV3 cDNA with its F and HN genes replaced by those from hPIV3 [178,206]. The reverse genetics system for human PIV3 also has been used as a starting point for development of vaccine candidates against the closely related human pathogens, hPIV1 [207–210], and hPIV2 [211].

Dual-specificity paramyxovirus vaccine candidates have been produced by adding genes to a full-length cDNA as described for RSV subgroups A and B above. In this strategy, the original recombinant virus becomes a vaccine vector, and an attenuated bivalent or trivalent vaccine strain is produced. In initial experiments with recombinant hPIV3, the insertion of an additional transcribed but noncoding sequence between the HN and L genes was shown to contribute in and of itself to attenuation in hamsters [212]. The insertion of the coding sequence for measles virus HA protein at any one of several intergenic sites in the hPIV-3 cDNA was similarly attenuating [213]. When administered intranasally, this bivalent vaccine candidate induced a protective immune response against hPIV challenge in hamsters, and a level of measles virus neutralizing antibody in excess of that known to protect humans. The IN administration may allow the successful immunization of infants against these two respiratory pathogens even in the presence of maternal

antimeasles neutralizing antibodies in the serum. A similar approach was taken by using the attenuated bovine–human PIV3 chimera (F and HN genes of hPIV3 in the bovine PIV3 backbone). The insertion of either the RSV G or F protein as the first gene transcribed, upstream of the PIV3 N gene, produced a bivalent vaccine that protected hamsters against challenge with both hPIV3 and RSV [214]. This result was the basis for construction of two recombinant PIV3 chimeras containing G and F genes from either RSV subgroup A or B, and a test in monkeys [215]. The levels of neutralizing antibody against both PIV3 and RSV were comparable to those induced by RSV infection or by infection with the bovine–human PIV3 vector. These studies describe an attractive strategy for mucosal vaccination against two of the most important respiratory pathogens of infants.

Reverse genetics for measles virus has led to the rescue of recombinant measles virus expressing several heterologous reporter proteins and immunogens [216,217]. This work is based on a full-length cDNA of the Edmonston B vaccine strain, which has a long history of safe and effective human use. In addition, the targeting of measles virus to macrophages and dendritic cells may be important in induction of immune responses to a vectored immunogen. Recombinant measles virus expressing the surface antigen of hepatitis B virus induced antihepatitis B virus antibody in a mouse model for measles virus infection [218], and measles virus vectors stably expressed immunogens of simian immunodeficiency virus with only a minor effect on growth kinetics [219]. A vaccination strategy based on recombinant measles virus has been proposed that would replace the current early-life measles vaccine with a cocktail of vectors expressing heterologous immunogens.

Simian virus 5, although it can infect and replicate in most cultured cell lines, induces very little cell death in most cell lines tested, and can persistently infect cultured cells. This property was exploited by Parks et al. [220] to produce a recombinant SV5 vector for controlled cell killing. SV5 was engineered to express the herpes simplex thymidine kinase gene inserted between its HN and L genes, and shown to replicate in several cell lines without extensive cytopathic effect. However, infection coupled with treatment with acyclovir or gancyclovir, drugs that become toxic when phosphorylated by TK, led to extensive cell death. The use of this virus vector for targeted killing of cancer cells depends on the ability to engineer the SV5 HN protein for specific cell targeting *in vivo*. More recently, induction of a strong cellular immune response by recombinant SV5 has been demonstrated [221].

There are many reminders that the vaccine vector approach is an empirical one. For example, expression of mumps glycoproteins by a measles virus vector was unexpectedly very deleterious to virus growth [219]. Also, expression of foot-and-mouth disease genes by an attenuated recombinant rinderpest virus did not induce any detectable immune response to FMDV, nor did it protect cattle against FMDV infection [222], in spite of the fact that vaccination with an analogous rinderpest virus vaccine vector for influenza HA was highly immunogenic in cattle [223].

A vaccine vector based on a full-length cDNA of the Newcastle disease virus (NDV) veterinary vaccine strain,

Hitchner B1, was described by Nakaya et al. [179], who tested for the expression of either CAT or influenza HA from genes inserted between the P and M genes. The expressed HA protein was incorporated into the infected cell plasma membrane and virion envelope, and viral titers were reduced 20-fold. The addition of the HA gene attenuated even further the virulence of the NDV vaccine strain for embryonated eggs. The intraperitoneal or intravenous immunization of mice induced HA-specific serum antibody and protected against a lethal influenza virus challenge. NDV vaccine vectors present the possibility of bivalent poultry vaccines, as well as human use vaccines.

A vaccine vector for SIV was based on recombinant Sendai virus. Macaques were immunized intranasally with SIV Gag-expressing Sendai virus, either alone or following an initial immunization with a DNA vector, and then challenged with pathogenic SHIV. The Sendai vector contributed to induction of a protective immune response when used as a booster [224]. A nonpropagating Sendai virus-based vector also has been reported. This defective recombinant virus does not carry a functional gene for F, the fusion protein, and can be propagated only in cells that provide F protein in trans, but is able to enter susceptible cells, replicate its RNA genome and express the heterologous gene to high levels [225]. It cannot spread either by production of infectious virus progeny or by cell-to-cell fusion.

#### IV. CONCLUSION

RNA virus genomes, reconfigured to express heterologous antigen genes, have great potential as vaccine vectors. Levels of expression are generally high, the plasticity of RNA genomes will allow innovative use of their coding capacity, knowledge of virulence determinants will insure safety, and the variety of potential vaccine vectors will obviate problems of antivector immunity. However, this field is relatively young, and significant hurdles must be surmounted as RNA virus vectors progress from the laboratory to human use vaccine products. Few of these concepts have moved from tests in mice to experiments in nonhuman primates, and fewer still have progressed to human trials. In addition, some of these laboratory-derived systems are not particularly well suited for GMP production at commercial scale. Nevertheless, the potential of RNA virus-based replicon strategies for improvement of existing vaccines and for derivation of new ones places these rapidly developing vaccine concepts at the leading edge among new vaccine technologies.

## Attenuated *Salmonella* and *Shigella* as Live Vectors Carrying Either Prokaryotic or Eukaryotic Expression Systems

James E. Galen, Marcela F. Pasetti, Marcelo B. Sztein, Eileen M. Barry, and Myron M. Levine

University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.

### I. INTRODUCTION

A vaccinology strategy that has generated much optimism in recent years is the use of attenuated strains of bacteria to carry protective antigens of foreign, unrelated pathogens and to deliver those heterologous antigens to the immune system, thereby resulting in protective immune responses [1,2]. Initially, the strategy focused on engineering the attenuated strains to express foreign proteins and polysaccharide antigens directly [3–7]. Subsequently, bacterial live vectors were modified to carry DNA vaccine plasmids (i.e., foreign genes on plasmids controlled by eukaryotic regulation elements) [5,6,8–13]. In this approach, the bacteria deliver the DNA vaccine plasmids to the host cells, particularly antigen-presenting cells [e.g., dendritic cells (DCs), macrophages, and B lymphocytes] where the foreign antigen is subsequently expressed.

An array of bacteria has been utilized as live vectors [4]. These include attenuated strains derived from wild-type pathogens such as *Salmonella enterica* serovar *Typhi* (*S. typhi*) [14–18] and *S. enterica* serovar *Typhimurium* (*S. typhimurium*) [19–21], *Shigella* [22–25], *Vibrio cholerae* [26–28], *Listeria monocytogenes* [29], *Mycobacterium bovis* (Bacille Calmette Guerin, BCG) [30], and *Yersinia enterocolitica* [31]. Other investigators have chosen to utilize as bacterial live vectors nonpathogenic strains derived from normal flora such as *Streptococcus gordoni* [32] or other sources such as *Lactobacillus casei* [33] and *Lactococcus lactis* [34].

Attenuated strains of *Salmonella* and *Shigella* are particularly versatile because they can deliver to the mammalian immune system foreign antigens produced either by the vectors themselves (by means of prokaryotic expression systems), or by eukaryotic cells (by means of eukaryotic expression plasmids). In addition, such strains are administered by mucosal rather than parenteral routes, an approach that can increase vaccination compliance and can avoid problems of injection safety that are associated with the use of parenteral immunization in developing countries

[35,36]. Moreover, *S. Typhi* and *Shigella* live vector vaccines are amenable to relatively economical manufacture compared to tissue culture-based, conjugate, or purified subunit vaccines. This review will focus on the use of *Salmonella* and *Shigella* as live vectors. We will first briefly describe common themes of virulence and regulation in *Salmonella* and *Shigella* to provide a context for emerging strategies in the engineering of prokaryotic expression systems. We will also summarize recent progress in live vector delivery of DNA vaccines and will review the immunology of *Salmonella*-based and *Shigella*-based live vectors carrying either prokaryotic or eukaryotic expression systems.

### II. VIRULENCE AND REGULATION IN *SAFMONELLA* AND *SHIGELLA*

To be fully pathogenic, both *Salmonella* and *Shigella* require a variety of virulence genes, which are scattered throughout the chromosome as well as residing on large virulence plasmids in the case *S. Typhimurium* and *Shigella*. Because the genomic sequences of *S. Typhi* [37] and *S. Typhimurium* [38] have recently been described, we will focus on the organization of virulence determinants within these genomes and draw parallels to *Shigella* where possible.

Controlled expression of genomic virulence factors is accomplished at several different levels, the most basic of which involves the clustering of virulence functions into large pathogenicity islands which can be up to 134 kb in size. Analysis of the genomes of *S. Typhi* and *S. Typhimurium* has revealed the presence of at least nine [37,38] and perhaps 12 [39] *Salmonella* pathogenicity islands (SPIs) common to both serovars. If one considers the pathogenesis of *Salmonella* in terms of biochemical events occurring prior to eukaryotic cell invasion and those following invasion, the functions encoded by the SPI-1 and SPI-2 islands are immediately seen to play key roles. The SPI-1 locus encodes a contact-dependent type III secretion system, which specif-

ically targets effector molecules to eukaryotic target cells, thereby allowing invasion to proceed [40]. Once inside a eukaryotic cell, a number of factors are required for intracellular survival and colonization of deeper tissues. Synthesis of these factors involves coordinated expression from several SPIs [41], including the SPI-2 locus, which encodes a second contact-dependent type III secretion system that delivers many of these molecules [42,43]; a detailed study of the mechanisms of such effector molecules is currently underway.

A type III secretion system also resides within the virulence plasmid of *Shigella*. The complete sequence of the 214-kb virulence plasmid from *S. flexneri* serotype 5 [44] reveals a 31-kb *virB-spa40* island encoding the type III secretion apparatus and IpaA–D effector proteins, as well as additional pathogenicity factors distributed around the plasmid. Analysis by Parsot and Sansonetti [45] reveals significant homology between the IpaA–D effector proteins and SPI-1-encoded effector proteins; in addition, extensive homologies between both secretion apparatuses were noted.

### III. ATTENUATED SALMONELLA AND SHIGELLA AS LIVE VECTORS DELIVERING HETEROLOGOUS ANTIGENS

With increasingly detailed knowledge of *Salmonella* and *Shigella* genomics and mechanisms of pathogenicity, precise mutations were introduced, resulting in the development of attenuated vaccine strains with minimal reactogenicity and yet highly protective against disease (see Levine et al., Chapter 43 and Kotloff et al., Chapter 61 of this volume). It was also attractive to use such attenuated strains as live vectors to present foreign (heterologous) antigens from unrelated human pathogens, creating a multivalent vaccine that could elicit both homologous and heterologous protective immune responses.

Heterologous antigen expression within live vector strains may involve either chromosomal or plasmid loci, and a wide variety of plasmid-based expression technology are now available for achieving the appropriate expression levels required to elicit the appropriate and relevant immune response(s). However, often overlooked in live vector engineering is the effect that expression plasmids (and the heterologous antigens they typically encode) can exert on the fitness of a live vector. The notable burden placed upon live vectors carrying multicopy plasmids is the cumulative result of a metabolic cascade triggered by two processes: (1) the replication and maintenance of expression plasmids [46–48], and (2) the transcription and translation of the various plasmid-encoded functions including the heterologous antigen(s). It is therefore not surprising that plasmid-bearing bacteria grow more slowly than plasmidless bacteria [49–53], and this explains why growth rate decreases as copy number increases [46,47]. Reduced growth rate is the inevitable consequence of metabolic burden, which in turn is the cumulative result of a number of physiological perturbations. Because this creates a selective pressure for loss of resident plasmids in the absence of selection, significant loss of expression plasmids from live vectors may occur after

immunization, accompanied by reduced immunogenicity and reduced protective efficacy. Clearly, spontaneous plasmid loss would remove any metabolic burden and allow plasmidless bacteria to quickly outgrow the population of plasmid-bearing bacteria. Such a shift in antigen expression within a population of live vector bacteria would be expected to reduce the efficiency of stimulating immune responses specific to the foreign antigen.

#### A. Chromosomal Expression Systems

Several approaches have been applied to reduce metabolic burden while ensuring consistent immunogenic levels of expression for a given heterologous antigen. Chromosomal integration of expression cassettes into nonessential loci has been successful for the expression of otherwise toxic eukaryotic antigens from *Plasmodium falciparum* and *Leishmania mexicana* within *S. Typhi* live vectors, but expression levels resulted in modest immune responses [54,55]. In a clever attempt to increase heterologous antigen expression levels while still minimizing toxicity, Santiago-Machuca et al. [56] introduced expression cassettes onto multicopy plasmids in which transcription of the heterologous gene is controlled by the extremely powerful bacteriophage T7 promoter; expression of the cognate T7 polymerase was encoded within a *S. Typhi* chromosomally integrated expression cassette, controlled in turn by a promoter responding to an environmental cue (anaerobiosis), likely to be encountered within immunized hosts. Expression levels in vitro were tightly regulated with high induction ratios, but the immunogenicity of such constructs has not yet been tested.

One further variation on the theme of chromosomally integrated transcriptional control elements driving expression of plasmid-based antigen cassettes was recently reported in *S. Typhi* by Qian and Pan [57]. They described the construction of a chromosomally encoded tetracycline repressor (*tetR*) used to control the expression of a plasmid-encoded 42-kDa merozoite surface protein 1 fragment (MSP-1<sub>42</sub>) from *P. falciparum*, under the control of a tightly regulated tetracycline response promoter; in the absence of the anhydrotetracycline inducer, antigen expression is quantitatively shut down. Although antibodies against MSP-1<sub>42</sub> were not observed in mice immunized intraperitoneally (i.p.) (possibly due to improperly folded cytoplasmic antigen expression), a greater concern for this approach is the need to coadminister an antibiotic with the inoculum to achieve regulated antigen expression. However, *tetR* mutants, which activate transcription in the absence of tetracycline inducer while maintaining tight regulation of the target antigen cassette in the presence of inducer, are now available [58].

#### B. Plasmid-Based Expression Systems

Nonchromosomally regulated expression of multicopy heterologous antigen cassettes can be achieved either at the level of transcription, translation, or both. Work done by Chatfield et al. [19] clearly demonstrated that constitutive expression in *S. Typhimurium*, using the powerful *tac* promoter ( $P_{tac}$ ) to express fragment C of tetanus toxin (fragC) from a

multicopy plasmid, resulted in no detectable anti-fragC antibodies. Isogenic expression using the reengineered *nirB* promoter  $P_{nir15}$ , which responds to the environmental signal of low oxygen, elicited protective anti-fragC responses after challenge with 50 LD<sub>50</sub> of tetanus toxin [19]. It was further demonstrated that plasmids carrying the constitutive  $P_{tac}$ -fragC cassette were rapidly lost in vivo from bacteria colonizing deep tissues [19].

This concept of using “in vivo-induced” expression cassettes to enhance the stability of multicopy plasmids, thereby improving relevant immune response(s), was soon expanded to include eukaryotic antigens from parasites such as *Schistosoma* [59] and *Leishmania* [60]. Elegant work by Bumann [61] clearly demonstrates that regulated expression of foreign antigens strongly influences the immunogenicity of live vectors by affecting colonization levels of the live vector. When comparing constitutive expression of green fluorescent protein (GFP) fusions from  $P_{tac}$  vs. regulated expression from the PhoQ/PhoP-controlled  $P_{pagC}$ , Bumann showed that although both constructs induced comparable cellular immune responses, doses almost 1000-fold lower were sufficient for live vectors expressing antigen from  $P_{pagC}$ . Using two-color flow cytometry, Bumann [62] has gone on to quantitate the in vivo induction ratios of various promoters controlling *Salmonella* virulence, including  $P_{phoP}$ ,  $P_{pagC}$  (positively controlled by PhoP and induced within macrophages [63,64]),  $P_{sicA}$  (from SPI-1),  $P_{ssaH}$  (from SPI-2), and  $P_{sifA}$  (controlled by SPI-2 [65]). Such work raises the possibility of influencing the host’s immune response by using well-characterized promoters of differing strengths to deliver antigen to different compartments of an immunized host and to influence the immune response.

Further refinements to expression plasmid stability have addressed the inheritance of these plasmids within a population of dividing live vectors. To prevent plasmidless daughter cells from overtaking a growing population, conditionally lethal systems were engineered such that plasmid loss quickly led to cell death. In one variation, mutations were engineered into chromosomal loci encoding critical metabolic enzymes such as aspartate β-semialdehyde dehydrogenase (Asd), which were complemented by plasmid-encoded genes [66]. Therefore, plasmid loss removed the capacity to synthesize necessary metabolites resulting in cell lysis. Another variation involves expression plasmids, which encode a toxin–antitoxin system in which the protective antitoxin is unstable and requires constant synthesis from resident expression plasmids; plasmid loss activates the toxin, again leading to cell lysis [50,67,68]. To remove the random partitioning of multicopy plasmids during cell division, plasmid segregation functions were also introduced to ensure nonrandom inheritance of plasmids into all daughter cells [68].

However, it is not enough to optimize in vivo expression levels and plasmid stability to secure an appropriate immune response [69]. Problems with inherent antigen toxicity may diminish the colonizing ability of live vectors and lower the levels of antigen delivered to immunological induction sites. In addition, proper folding may be required for conformationally specific epitopes to trigger protective serum antibody responses. For example, neutralizing serum antibodies

against the critical 19-kDa carboxyl terminal domain of MSP-1 are only observed when the six disulfide bridges of the terminal domain are properly folded [70,71]; this is unlikely to efficiently occur for antigens made within the reducing environment of the live vector cytoplasm.

In attempts to address potential toxicity and folding problems, various antigen export technologies have been developed for surface or extracellular secretion of foreign proteins. Impressive success has been achieved using a novel surface display technology based on engineering of expression cassettes derived from the *Pseudomonas syringae* ice nucleation protein (Inp); the versatility and the promise of this approach are illustrated by recent reports of the display of properly folded eukaryotic antigens such as the human immunodeficiency virus type 1 glycoprotein gp120 on the surface of *Escherichia coli* [72], and the construction of an immunogenic multivalent hepatitis B surface antigen/hepatitis C core protein displayed on the surface of the licensed *S. Typhi* vaccine strain Ty21a [73].

In addition to surface display, secretion of heterologous antigens out of *Salmonella* live vectors has been reported by several groups to enhance the immune response to a foreign protein. Hess et al. [74] reported that cytoplasmic expression of the protective T-cell antigen listeriolysin O (LLO) within recombinant *Salmonella* vaccine strains did not confer protection in mice against lethal challenge with virulent *L. monocytogenes*. However, in-frame insertion of LLO within a truncated form of the *E. coli* hemolysin A (HlyA) allowed extracellular secretion of this fusion in the presence of the coexpressed *E. coli* HlyB/HlyD/TolC export apparatus, and resulted in protection against lethal challenge with *L. monocytogenes*.

Similar results were reported by Russmann et al. [75] wherein secretion via the SPI-1-encoded type III secretion system of an eight-amino-acid immunodominant epitope from the murine lymphocytic choriomeningitis virus (LCMV) conferred a protective class I-restricted cytotoxic T lymphocyte (CTL) response against an intracerebral lethal challenge with virulent LCMV, not observed for the cytoplasmically expressed epitope. This type III secretion-mediated approach was recently used to improve upon the protective immune response in mice against lethal challenge with *L. monocytogenes*, using the heterologous *Yersinia* outer membrane protein E (YopE) as a carrier for carboxyl-terminal fusions of LLO and p60 domains consisting of >300 residues [76]. As of this writing, the use of SPI-2 mediated secretion to enhance the immunogenicity of heterologous antigens delivered within target cells such as macrophages has not yet been reported.

### C. Shigella Live Vectors

Use of attenuated *Shigella* as live vectors is rapidly advancing. Initial attempts at using *Shigella* as a live vector employed the  $\Delta aroD$  *S. flexneri* vaccine strain SFL124. Heterologous antigens from the related *S. dysenteriae* were successfully expressed from chromosomal cassettes, including surface-expressed O-antigenic determinants, as well as a Shiga toxin B subunit (Stx1<sub>B</sub>) fusion secreted from SFL124 through a chromosomally encoded *E. coli* HlyA type I

secretion operon [77,78]. Multicopy expression plasmids have also been used in *Shigella* for the expression of foreign antigens in various subcellular locations. Colonization factors from enterotoxigenic *E. coli* (ETEC) [79], as well as fragC of tetanus toxin [24], have been cytoplasmically synthesized, whereas rotavirus VP4 was expressed as a fusion with *E. coli* maltose-binding protein and localized either to the cytoplasm or periplasmic space [80]. Outright secretion through the *Shigella* type III secretion system of a poliovirus VP1-neutralizing epitope was accomplished using IpaC–C3 hybrid protein fusions [81]. In addition, stabilized expression plasmids developed for *Salmonella* live vectors have recently been used in *AguaBA* *S. flexneri* 2a live vectors to express several ETEC fimbrial colonization factors plus LT antigens from a single expression plasmid [23,25].

#### IV. IMMUNE RESPONSES INDUCED BY *SAFMONELLA* AND *SHIGELLA* EXPRESSING HETEROLOGOUS ANTIGENS

Attenuated *Salmonella* and *Shigella* strains have remarkable potential as mucosal live vectors expressing heterologous antigens, as they can stimulate a wide array of humoral and cellular immune responses. Serum IgG antibodies, secretory IgA (sIgA), T-cell proliferation, cytokine production, and MHC class I-restricted CTL responses have been demonstrated in animal models [16,24,25,82,83] and humans [84–86]. It is likely that the tropism of these bacteria for dendritic cells and macrophages allows “direct delivery” of antigens into professional antigen-presenting cells (APCs) at inductive sites of the immune system.

Mucosal and systemic responses against bacterial and foreign antigens have been demonstrated with *S. Typhimurium*-expressing fragC [19,87–89], *Y. pestis* F1 capsular antigens [90], influenza A nucleoprotein [75], ETEC fimbria [91], *M. tuberculosis*- and *M. bovis*-secreted T-cell antigen ESAT-6 [92], *L. major* gp63 [60,93], *Plasmodium* spp. sporozoite and merozoite surface proteins [94], *Helicobacter pylori* urease [95], *Streptococcus* spp. antigens [96], hepatitis B antigen [97], and herpes simplex [98] and measles virus B and T epitopes [99]. *Salmonella* infection induces activation of macrophages and DCs by increasing surface expression of MHC class I, MHC class II, and costimulatory molecules as well as cytokine production. These immunoregulatory activities are believed to enhance the ability of APC to activate specific T cells during the initial stages of the immune response, including antigen processing and presentation, as well as the subsequent lymphocyte expansion and generation of memory T cells. [100]. Antigens expressed by recombinant *Salmonella* strains can be presented by DCs in the context of MHC class II and MHC class I molecules, thus inducing both Th1-type and Th2-type cell-mediated responses. For example, it has been shown that bacterial live vectors expressing foreign antigens can induce CTL responses [101], which proved critical to confer prolonged protection [101]. Antigen-specific long-term memory mucosal responses have also been described [102].

As mentioned above, *S. Typhi* strains have been engineered to express a variety of heterologous antigens. *S. Typhi*

strains CVD 908, CVD 908-*htrA*, and CVD 915 expressing fragC elicited high levels of serum IgG antitetanus toxin and fragC antibodies when delivered to mice intranasally (i.n.) [16,103–105]. In addition to humoral responses, CVD 915 expressing fragC induced antigen-specific T-cell proliferation and Th1 cytokines [103]. Mice immunized intranasally with CVD 908 expressing pertussis toxin subunit S1 fused to fragC developed serum pertussis-neutralizing antibodies [15]. Lee et al. [73] adapted *S. Typhi* strain Ty21a to express HBsAg and HCV antigens on the cell surface and demonstrated induction of high levels of serum antibodies against both antigens in intranasally immunized mice. *S. Typhi* strain CVD 908 expressing *L. mexicana* gp63 given to mice orally elicited a broad antigen-specific T-cell-mediated immunity, including T-cell proliferation, IL-2 secretion, and CTL responses, which conferred significant protection against wild-type strain of *L. mexicana mexicana* challenge [55].

Immunization using *Shigella* as a mucosal live vector has also been successful. Mice immunized intranasally or intravenously (i.v.) with *S. flexneri* 2a SC602-expressing IpaC–C3 neutralizing epitope of the poliovirus VP1 as hybrid protein elicited serum IgG and local IgA and IgG anti-C3 and Ipa [81]. *S. flexneri* 2a CVD 1203 expressing *E. coli* (ETEC) colonization factor CS3 fimbriae (CFA) induced sIgA and serum IgG anti-CS3 in mice and guinea pigs immunized orally and intranasally. Of note, the nasal route was shown to be more efficient in inducing significantly higher immune responses in both animal models [79]. Using a similar approach, Altbaum et al. [23] coexpressed ETEC CS2 and CS3 fimbriae in *S. flexneri* 2a CVD 1204 and showed the presence of sIgA and serum IgG against *Shigella* LPS, CS2, and CS3 antigens in guinea pigs immunized intranasally. In both reports, the animals were protected following conjunctival challenge with virulent *S. flexneri* 2a [23,79]. *S. flexneri* 2a CVD 1204 carrying fragC was able to induce potent serum IgG responses to fragC (neutralizing tetanus toxin in vivo) as well as serum IgG and sIgA against bacteria LPS that protected them from ocular *S. flexneri* challenge [24]. Koprowski et al. [25] adapted *S. flexneri* CVD 1204 to coexpress ETEC CFA/I and genetically detoxified ETEC heat-labile toxin derivatives LThK63 or LThR72, showing the production of IgG and sIgA anti-CFA/I and LTh antibodies in guinea pigs immunized intranasally, which also produced sIgA and serum IgG anti-*S. flexneri* 2a LPS.

This impressive array of immune responses induced by bacterial live vectors carrying foreign antigens provides a strong rationale for the continuing evaluation of this approach in the development of vaccines for human use against a wide variety of pathogenic organisms.

#### V. ATTENUATED *SAFMONELLA* AND *SHIGELLA* AS LIVE VECTORS DELIVERING DEOXYRIBONUCLEIC ACID VACCINES

DNA vaccines, in general, consist of plasmid vectors that encode foreign antigens under control of a eukaryotic promoter. In animal studies and in the few clinical trials, DNA

vaccines have been traditionally given intramuscularly (i.m.) or adsorbed to gold particles and inoculated intradermally (i.d.) with a gene gun; either route has produced strong cellular as well as humoral responses, particularly in animal models. A major disadvantage of this approach is that large amounts of DNA are required as the efficiency of the DNA uptake is low and dose-dependent. In addition, parenteral DNA delivery does not induce strong mucosal responses, and the manufacturing of highly purified DNA vaccines can be extremely expensive [106].

Bacterial live vectors represent an attractive alternative to limitations encountered with purified DNA vaccines [8, 13,107]. In this approach, DNA vaccine plasmids are delivered by the live vector to host APCs after cell invasion, where encoded heterologous antigens are expressed using the cellular machinery. Thus, this strategy combines the advantages of mucosal delivery of a live carrier with efficiently targeted DNA vaccination. This can be particularly relevant to elicit cell-mediated immunity against intracellular organisms that gain access through the mucosal surfaces. Moreover, bacterial components such as unmethylated CpG motifs in the bacterial DNA [108] and lipopolysaccharide can serve as adjuvants, thus potentiating the immunogenicity of the foreign antigen. The possibility of selecting sophisticated gene expression systems [109], or the coadministration of immunomodulators such as cytokines and costimulatory molecules [108], makes live vector-mediated DNA vaccination an appealing approach to tailor immune responses [6]. As with prokaryotic systems, antigen expression cassettes could be manipulated to specify transport to a particular eukaryotic cellular compartment, or to influence their processing, thus enhancing immunogenicity [110].

*Shigella* appears to be particularly efficient in the delivery of DNA vaccines, as many strains retain a functional IpaB that allows the bacteria to break out of the phagolysosome and enter the cytosol. Upon death and disruption of the attenuated bacteria, the DNA vaccine plasmid is released and can enter the nucleus of the eukaryotic target cell. In the first report of live vectors used to deliver a DNA vaccine, Sizemore et al. [111,112] showed that *S. flexneri* 2a can successfully deliver a DNA vaccine encoding  $\beta$ -galactosidase and can induce specific serum antibodies and T-cell proliferation. Subsequently, Fennelly et al. [113] used a similar strategy to deliver a DNA vaccine encoding measles virus antigens and demonstrated induction of specific antibodies and T-cell proliferation. Anderson et al. [24] used *S. flexneri* 2a CVD 1204 to deliver a DNA vaccine encoding tetanus toxin fragC and observed potent serum responses to fragC in guinea pigs immunized intranasally. Devico et al. [114], Shata and Hone [115], and Shata et al. [116] reported the induction of CD8 $^{+}$  T-cell responses and protective antiviral immunity using *S. flexneri* 2a CVD 1203 delivering DNA plasmids encoding HIV gp120 and gp140. Examples of in vivo studies using *Salmonella* and *Shigella* as gene delivery systems are summarized in Table 1.

Despite the fact that *Salmonella* remains in the phagosomal compartment and does not escape into the cytoplasm as do *Listeria* or *Shigella*, several groups have demonstrated the delivery of DNA vaccines and immunogenicity of DNA-encoded antigens. In fact, *Salmonella* delivering these eu-

karyotic expression vectors have been shown to induce cellular and humoral immune responses against bacterial pathogens [117,118] and their toxins [103], viruses [113,119,120], as well as tumor antigens [121]. Interestingly, *Salmonella*-mediated delivery of DNA vaccines appears to be more effective at inducing mucosal cell-mediated immune responses than intramuscular immunization with purified DNA [119]. *Salmonella* DNA delivery can even be more efficient at induction of both cellular and humoral systemic immune responses when compared with prokaryotic antigen expressions [103,118].

Although it is unclear how the plasmid DNA is transported from the phagosomal compartment into the nucleus, it has been suggested that plasmids released from lysed bacteria may reach the cytoplasm of the host cell by leakiness from the atypical vacuolar compartment in which the live vector resided [6]. This has been supported by the observations that bacterial invasion is necessary but not sufficient for efficient gene transfer and, in fact, escape of bacteria or plasmid DNA from the primary vacuole is required for gene transfer to occur [107]. In this context, different strategies have been devised to facilitate DNA delivery to the cytosol to improve immunogenicity of DNA live vector vaccines [122]. Gentschev et al. [123] constructed a *Salmonella* strain equipped with the Hly secretion system, which disrupts the phagosomal membrane and releases the *Salmonella* into the cytosol; this construct exhibited an enhanced ability to transfect mammalian cells. DNA delivery via recombinant *Salmonella* strains in the presence of phagosomal escape properties was successfully used to direct macrophage presentation of DNA-encoded antigen within MHC class I and to stimulate specific CD8 $^{+}$  T cells in vitro [124].

It has also been observed that efficient DNA delivery can be achieved by inducing programmed bacterial lysis, which would enhance the release of DNA constructs into the eukaryotic cytosol [125]. Thus, Sizemore et al. [111] and Vecino et al. [126] used an attenuated *Shigella* strain that cannot synthesize diaminopimelic (DAP) acid, an essential cell wall component. In vivo starvation for DAP eventually causes bacterial cell lysis and DNA release. Recently, Jain and Mekalanos [127] showed that the incorporation of lambda phage S and R in an inducible lysis system for *S. Typhimurium* can be useful to finely regulate bacterial lysis within mucosal tissue or APC and more efficiently release DNA vaccines. It is puzzling, however, that wild-type intracellular bacteria (without mechanisms to favor cell lysis or DNA release) can still deliver DNA into mammalian cells [107]. It is possible that a yet unidentified specific phagosome-to-cytosol transport process could exist for the translocation of the plasmids molecules across the phagosomal membrane; such a pathway was recently reported for protein antigens in DC [128]. Another hypothesis raises the possibility that *Salmonella*-induced apoptotic macrophages containing antigenic material might be engulfed by bystander APCs, mainly DCs, facilitating antigen presentation by crosspriming [129].

In a recent publication, Vecino et al. [126] investigated the ability of *S. flexneri* 15D, *S. Typhi* Ty21a, and *S. Typhimurium* SL7207 given intranasally to deliver DNA plasmids encoding HIV gp120 and SIV Nef and to induce

<sup>a</sup> Ty21a was developed using chemical mutagenesis and therefore has many other mutations besides the three listed.

<sup>b</sup> Serum vibriocidal antibody.

<sup>c</sup> Cell-mediated immune responses.

<sup>d</sup> Two subjects manifested serum antibody responses (ELISA against purified protein or indirect immunofluorescent assay against whole sporozoites). One subject mounted a specific MHC class I-restricted, CD8<sup>+</sup> cytotoxic lymphocyte response.

<sup>e</sup> Results in subjects lacking tetanus antitoxin at baseline.

<sup>f</sup> Serum antibody.

<sup>g</sup> IgA antibody secreting cell response.

<sup>h</sup> IgG antibody secreting cell response.

immune responses, in comparison with the traditional intramuscular DNA vaccination. Among the three strains evaluated, *S. flexneri* induced the highest responses, measured by CD8<sup>+</sup> IFN- $\gamma$ -secreting T cells, in spleen after three doses. These responses were comparable to those induced by intramuscular immunization. Of note, mucosal IgA responses were higher in the *S. flexneri* group than following intramuscular immunization.

Despite the evidence that *Salmonella* and *Shigella* can successfully deliver DNA vaccines in animal models, it is unclear whether this approach will be effective in humans. A more precise understanding of the mechanisms involved, further evaluation of ways to optimize the DNA delivery, and safety issues (including the possibility of DNA integration into the host cell genome or induction of autoimmunity) need to be carefully addressed before this vaccine strategy can be evaluated in volunteers.

## VI. HUMAN CLINICAL TRIALS WITH ATTENUATED SALMONELLA AND SHIGELLA EXPRESSING FOREIGN ANTIGENS

Although studies in murine, guinea pig, and other animal models with attenuated *Salmonella* live vectors expressing foreign antigens have clearly demonstrated the feasibility of this vaccine strategy, heretofore, only a few Phase I and Phase II clinical trials have been carried out in humans. Clinical trials with *Shigella* live vectors have not yet been initiated but are imminent. Salient results of these trials are summarized in Table 2.

Early studies with Ty21a expressing *S. sonnei* O-poly-saccharide or *V. cholerae* O1 Inaba lipopolysaccharide established that *S. Typhi* live vectors bearing foreign surface antigens could stimulate relevant immune responses (*S. sonnei* O-antibody and Inaba vibriocidal antibody) and could confer protection against experimental shigellosis and cholera, respectively. However, the efficacy of the Ty21a construct expressing *S. sonnei* was inconsistent [130,131] and the level of protection (25% efficacy) of the Ty21a construct expressing Inaba LPS was low [132], impeding further development of those vaccines.

Oral immunization of young adults with two doses of *S. Typhi* live vector CVD 908 expressing the circumsporozoite protein of *P. falciparum* set two milestones [54]. First, this construct documented that *S. Typhi* live vectors could elicit antibody responses to a protein antigen in humans. Second, this *S. Typhi* live vector stimulated CD8<sup>+</sup> MHC class I-restricted cytotoxic lymphocytes that recognized targets bearing CSP, demonstrating that *Typhi* live vectors could elicit relevant cell-mediated effector responses in humans [54].

Immunization of adults with a single oral dose of CVD 908-htrA carrying a plasmid-encoding fragC of tetanus toxin elicited enhanced proliferative responses and stimulated protective levels of tetanus antitoxin in a seronegative subject [133]. The importance of the latter observation is to demonstrate that a single oral dose of a *S. Typhi* live vector can elicit a type of protective immune response that is generally thought to require parenteral immunization. Re-

cent clinical trials have illuminated the influence of the specific live vector on the immune response to a given heterologous antigen. In a Phase I clinical trial of an attenuated *S. Typhi* Ty800 live vector expressing *H. pylori* urease A and B from stabilized expression plasmids, no immune response was observed against the heterologous antigen despite a strong response against live vector antigens [134]. When this urease antigen was expressed from the identical expression plasmid introduced into an attenuated *S. Typhimurium* live vector, vaccination stimulated strong responses to the live vector as well as antiurease antibodies in three of six subjects, but this live vector was not well tolerated clinically [135]. However, a recent preliminary report by McKenzie et al. [136] using CVD 908-htrA to express *H. pylori* urease resulted in impressive and encouraging dose-dependent responses to both live vector and heterologous antigen; when immunizing with 5×10<sup>9</sup> colony-forming units (cfu), urease-specific IgG ASC responses were detected in seven of eight subjects, and urease-specific fecal IgA responses were detected in 50% of vaccinees.

Clinical trials with other live vector constructs have given generally modest results [17,134,137–139]. In some of these clinical trials, the *S. Typhi* live vectors failed to elicit a detectable immune response to the foreign antigen, despite immunogenicity of the identical (or homologous *S. Typhimurium*) constructs when tested in preclinical animal models. Regrettably, none of the human clinical trials with *Salmonella* live vectors, heretofore, has utilized constructs that would be considered optimal.

### I. INTRODUCTION

Compared to other conventional vaccine technologies, such as adjuvanted protein, recombinant vector, and attenuated pathogens, the concept of DNA vaccination is relatively simple. A specific gene of interest from a particular pathogen is cloned into a plasmid containing a powerful promoter active in eukaryotic cells and, upon injection into vaccinees, the antigen is produced *in situ*. The expressed protein is then processed and presented to the immune system by the MHC class-I restricted pathway for CTL induction, the MHC class-II restricted pathway for the induction of helper T (Th) cell responses and to B cells for the induction of antibodies. It has been known for quite some time that direct inoculation of linear or plasmid DNA could result in gene expression *in vivo* [1,2]. The power of this technology for inducing potent immune responses and its potential for vaccine application was demonstrated by Tang et al. [3], Ulmer et al. [4], Fynan et al. [5], Wang et al. [6], and many others in different animal models. Using the gene gun to deliver plasmid DNA into the skin of mice, Tang et al. [3] demonstrated the induction of antibody responses. Ulmer et al. [4] first demonstrated the induction of CTL responses and proof of principle for protective efficacy of a DNA vaccine encoding influenza nucleoprotein (NP). Specifically, these animals were protected from both morbidity and mortality upon lethal challenge with a heterosubtypic strain of influenza A virus. While substantial antibody responses were also generated against NP, protection was demonstrated to be cell mediated [4]. Later that same year, DNA vaccine studies were extended to other diseases such as HIV [6], rabies virus [7], and hepatitis B [8]. These early studies established several important features of DNA vaccines: 1) both antibody and cellular immune responses can be induced; 2) immune responses can be induced by different routes of immunization (intramuscular and epidermal); and 3) it is possible to express foreign genes *in vivo* with proper structure and confor-

tion, as judged by the induction of neutralizing antibodies. Since then, DNA immunization has been used successfully to induce immune responses in animal species from mice to humans with DNA encoding antigens from various sources such as HIV [9–14], herpes simplex virus-1 (HSV-1) [15–18], HSV-2 [19–21], rabies [7,22–24], hepatitis C [25,26], tuberculosis [27–30], malaria [31–34], mycoplasma [35], toxoplasma [36–40], rotavirus [41–43], Ebola virus [44–46], and many others. In addition to infectious diseases, the DNA vaccine strategy has been shown to be potentially a very powerful tool in animal models of allergy, asthma, and cancer.

This review will focus on the ability of DNA vaccines to induce humoral and cellular responses against a wide variety of infectious agents, and the current approaches being developed to enhance the efficacy of DNA vaccines.

### II. HUMORAL IMMUNE RESPONSES

Antibodies against viral proteins induced by DNA vaccines were first demonstrated by intramuscular injection of DNA encoding influenza NP and hemagglutinin (HA) [4]. The ability of DNA vaccines to induce appreciable antiviral antibodies was subsequently confirmed by several other investigators with other genes from influenza [47–52], HIV [53–58], rabies virus [7,23,59–61], and hepatitis B virus [62]. Since then, the DNA vaccine approach has been used extensively to induce antibody responses against various viral, bacterial, parasitic, fungal, tumor, and eukaryotic proteins.

In general, the antibodies induced by DNA vaccination are predominantly of the IgG subtype with lower levels of serum IgA and IgM [52,63]. The quantity and quality of the antibody responses induced by DNA vaccination appear to be influenced by the nature and type of immunogen, animal species, and also by the method and site of DNA delivery. First, as with protein-based vaccines, the inherent antigenicity of the protein expressed by DNA vaccines in part

determines the potency of the immune responses induced. However, increased antibody responses can be achieved by expressing antigens as secreted proteins, or as fusion proteins with other antigens or helper T-cell epitopes [64–66]. Second, antibodies induced by DNA vaccines in small animals such as mice are durable and long lasting as shown with influenza [67,68], hepatitis B [69], hepatitis C [25], plasmodia [70–72], leishmania [73–75], and other animal models. In general, though, antibodies induced in nonhuman primates by DNA vaccination are of lower titer and rather short-lived [76,77]. However, this is partly due to a species-related phenomenon, because even potent protein subunit vaccines induce short-lived antibodies in primates [76]. Finally, it has been shown that DNA vaccines can successfully be delivered via different routes, such as intramuscular, intravenous, intranasal, oral, intraepidermal, intrarectal and intravaginal [57,68,78–83], and more recently intrasplenic [84] and intrahepatic [85]. However, the most common routes are intramuscular needle injections and gene gun-mediated epidermal delivery. The nature of how DNA vaccines are delivered with these two modes of vaccination is fundamentally different. After i.m. injection, myocytes are the primary cells transfected, and uptake of DNA is passive and very inefficient [86]. Whereas the gene gun propels DNA-coated gold beads directly into cells of the dermis and epidermis, including antigen presenting cells (APCs). As a consequence, less DNA is required for induction of immune responses by the gene-gun route [5,87,88]. But there is currently a limitation on the mass of DNA that can be delivered by the gene gun and the difference in immune priming can be overcome simply by injecting more DNA. Interestingly, the type of helper T-cell response induced by the gene gun is sometimes qualitatively different. For example, in almost all cases, i.m. injection of DNA induces dominant Th1-type responses, as shown by the induction of IgG2a antibody responses in mice, increased levels of IFN- $\gamma$  production, and little IL-4 production [88–90]. In contrast, gene gun-mediated epidermal delivery of DNA has been shown in some instances to induce more of a balanced Th1/Th2-type response, as shown by the induction of IgG1 antibodies, increased levels of IL-4 production, and lower levels of IFN- $\gamma$  production [88,89,91]. The reason for these differences is not yet known, but it may involve the site of antigen production (i.e., myocytes versus skin cells) or differential stimulation of the innate immune system (e.g., via immunostimulatory CpG sequences).

For many infectious diseases caused by pathogens that enter the host through mucosal surfaces, such as HIV, induction of mucosal immunity may be desirable for effective prophylaxis. So far, intramuscular injection, gene gun-mediated delivery, or mucosal delivery of naked plasmid DNA have been rather limited in their ability to induce secretory mucosal IgA responses. However, mucosal delivery of formulated plasmid DNA, such as with cationic lipids [92], monophosphoryl lipid A [93], QS-21 [94], encapsulation in ploy(lactide-coglycolide) (PLG) microparticles [95–98], macroaggregated polyethyleneimine-albumin conjugates [99], and biodegradable alginate microspheres [100], is effective at inducing secretory IgA responses at mucosal sites. This increased effectiveness was likely due to protection of DNA from digestion and more efficient delivery of DNA

into cells of the mucosal immune system. Using a different approach, Wang et al. reported the induction of strong mucosal immunity against simian immunodeficiency virus in primates using DNA expressing intact noninfectious virions [101]. The levels of secretory IgA observed in the rectal secretions of the immunized primates were even higher than the levels achieved through the natural infection. Thus development of DNA vaccine technologies capable of enhancing local IgA responses will be important for the prevention of infectious diseases.

### III. CYTOTOXIC T-CELL RESPONSES

One of the potential advantages of DNA vaccines, compared to certain other types of vaccines, is their ability to induce cellular responses. DNA vaccines induce potent long-lasting cellular responses mediated by MHC class-I restricted CD8+ cytotoxic T lymphocytes (CTL). Effector CTL recognizing appropriate MHC-restricted peptides have been demonstrated in mice immunized with DNA encoding NP from influenza A virus [4,49,66,102–104], hepatitis B surface [105] and core antigen [106], and HIV Env [107–109] and gag antigens [109–111], and many others. DNA vaccine-induced CTL were also capable of killing virus-infected targets, thereby demonstrating recognition of endogenously processed epitopes. It has been shown that CTL induced in mice by DNA vaccination can persist for more than 2 years after immunization [67,112,113], demonstrating the longevity of CTL responses. In addition, the ability of DNA vaccines to prime CTL in nonhuman primates has been demonstrated, where long-lived and broad responses can be achieved [76,114–118]. In several independent experiments, one or two intramuscular injections of plasmid DNA encoding HIV env or gag genes induced MHC-class 1-restricted CTL in primates [114]. For example, anti-Env CTL was detected for at least 11 months after the last immunization [114] and gag DNA induced CTL against multiple discrete epitopes [110], demonstrating the longevity and breadth of these responses. Also, gene gun-mediated immunization of rhesus macaques with plasmid DNA encoding simian immunodeficiency virus (SIV) Env and Gag induced Env-specific CTL [110]. Intramuscular and intravenous administration of the same plasmids combined with gene gun-mediated immunization induced Env- and Gag-specific CTL responses. The efficiency of DNA vaccines for the induction of potent CTL responses, like antibodies, is also influenced by the route and site of immunization, as well as on the immunization regimen. In general, multiple immunizations are necessary to induce strong responses; however, the number and frequency appear to be important. Fuller and Haynes [91] have shown that gene gun-mediated delivery of HIV-1 env DNA vaccine induced strong CTL and weak antibody responses after one, two, or three immunizations. However, a fourth immunization caused a significant drop in CTL levels with a significant increase in antibody titers. A corresponding decrease in IFN- $\gamma$  and increase in IL-4 was also observed along with this change in the nature and profile of immune response. However, other investigators demonstrated that repeated immunization boosted the CTL levels against

influenza NP [119] and HIV Env [109,114], and in both these instances the nature of response remained of Th1 type [89]. Thus the optimum dose and regimen may be different for different DNA vaccines. In addition, differences with the quality and quantity of T-cell responses observed with different routes of DNA administration may be due to fundamental differences in how antigens are processed and presented to the immune system. After i.m. injection, CTL are primed mainly via cross-presentation [120], where expression of antigens directly by APCs is important for CTL priming by the gene gun [121].

DNA vaccines have been tested in human clinical trials for initial safety and immunogenicity. Clinical trials using DNA vaccines either alone or in combination with a live vector boost have been conducted for herpes, influenza, hepatitis B, HIV, malaria, and several cancers. For example, Phase I clinical trials were initiated to evaluate the safety and immunogenicity of HIV-1 *env/rev* DNA constructs in infected and uninfected human subjects [122–126]. The uninfected human subjects that received the highest dose of DNA vaccine induced antigen-specific lymphoproliferative responses and antigen-specific production of interferon- $\gamma$  and  $\beta$ -chemokines [124]. In the infected individuals, HIV-1 *env/rev* DNA vaccine construct modestly boosted the env-specific antibodies; however, no consistent effect was observed on cellular responses to HIV. In a separate study, HIV regulatory genes such as rev, nef, and tat were also evaluated in a Phase I clinical trial. Immunization of infected individuals with these genes resulted in enhanced cellular responses without any consistent changes in lymphocyte subsets or viral load [122,123,125,126]. The DNA vaccines were well tolerated in a broad dose range from 20  $\mu$ g up to 2500  $\mu$ g, as no significant local or systemic reactions were observed in human subjects [123,127].

In a Phase I clinical trial for a malaria DNA vaccine, it has been shown that three intramuscular immunizations of a *Plasmodium falciparum* circumsporozoite (PfCSP) construct induced antigen-specific, genetically restricted CD8+ T-cell-dependent CTL. The cellular responses were directed against multiple epitopes and were restricted by six HLA class I alleles [32]. In the same study, despite induction of significant CTL responses, DNA vaccination failed to induce detectable antigen specific antibodies in any of the volunteers [127]. Phase I trials have also been conducted with the gene gun, where DNA encoding hepatitis B surface antigen induced both humoral and cellular immune responses (CD4+ and CD8+ T cells) [128]. A Phase I trial of an experimental HIV vaccine was recently initiated in Kenya, which involved a DNA vaccine encoding an HIV subtype A *gag* gene as a fusion with several discrete CTL epitopes from other HIV genes [129]. The DNA vaccine was administered by the gene gun and was the first component of a prime-boost vaccination strategy, which will be followed by a recombinant vaccinia virus vector [130]. In addition, Phase I clinical trials have been initiated in healthy and HIV-infected human volunteers to perform a head-to-head comparison of HIV DNA vaccines delivered as naked DNA and/or by a recombinant adenovirus [131]. Phase I/II trials are also ongoing using DNA immunogens as potential immunotherapies for cancer, including carcinoembryonic antigen

(CEA) for colon cancer, human follicular lymphoma, and a T-cell receptor V $\beta$  for cutaneous T-cell lymphoma. The next year or two should reveal in detail the potency of new DNA vaccine technologies for inducing immune responses in humans.

#### IV. PROTECTION BY DNA VACCINES IN PRECLINICAL DISEASE MODELS

The influenza virus model was used to demonstrate that immune responses induced by DNA vaccination could protect mice against a lethal viral challenge [4]. The protection observed was due to NP-specific cellular responses, as passive transfer of immune serum from the immunized mice did not protect naïve mice against the challenge infection, although the serum contained high levels of specific antibodies to NP. In addition, adoptive transfer of splenocytes from the immunized mice protected naïve mice against lethal challenge infection [132]. Furthermore, both CD4+ and CD8+ T cells played a role in protection [102]. In addition to influenza, the protective efficacy of DNA vaccines has been demonstrated against many other diseases such as herpes simplex virus [16,18,133], rabies virus [22–24], cottontail rabbit papilloma virus [113], hepatitis B virus [128,134], Plasmodia [31,70,135,136], SIV/SIV [58,137–140], rotavirus [97], LCMV [141], and others.

Strong CTL responses were induced by DNA vaccines encoding HIV-1 Env and SIV Gag in primates and these animals were successfully protected from challenge with chimeric SHIV virus [117,118,142,143]. However, strong antibody responses are not induced by DNA vaccines alone. Thus considerable attention has been focused on prime/boost strategies involving recombinant proteins or vectors to induce protective immune responses in primates. Along these lines, Amara et al. have demonstrated that priming of rhesus macaques with plasmid DNA encoding multiple proteins of SIV (Gag, Pol, Vif, Vpr) and HIV (Env, Tat and Rev) and boosting with recombinant modified vaccinia Ankara expressing SIV Gag and Pol and HIV Env induced potent CTL but weak antibody responses [117]. These animals were protected from AIDS upon mucosal challenge with highly pathogenic SHIV. In a separate study, protection from SHIV challenge has been induced in primates primed with an HIV-1 *env* DNA and boosted with recombinant oligomeric gp140 protein [142]. Barouch et al. have demonstrated the enhanced efficacy of DNA vaccine in inducing CTL and humoral responses by coadministration of HIV-1 Env- and SIVmac239 Gag-encoding plasmids with a plasmid encoding IL-2/Ig in rhesus macaques [118]. Upon challenge with pathogenic SHIV-89.6, these animals were able to control their viremia and were also protected against clinical AIDS. Finally, recombinant adenovirus vectors have successfully been used to boost CTL responses and protection in primate models of SIV [143] and ebola virus [46].

The efficacy of DNA vaccines for inducing protective responses in diseases where protection is mediated by antibodies has been shown against influenza [5,47,52,76], rabies [23], HSV [15,144], human papilloma virus [113], Ebola virus [46], and others. The effectiveness of DNA vaccines at

inducing protective levels of antibodies is perhaps surprising, given the very low level of antigen produced by cells of the vaccinated host. This is particularly true for proteins that are poorly expressed (e.g., major capsid protein of papilloma virus) [113]. Possible explanations could include the duration of protein expression and the potential for preservation of conformation-specific epitopes by production of antigen *in situ*. In a DNA prime-protein boost study, Barnett et al. demonstrated the induction of strong neutralizing antibody responses in rabbits and rhesus macaques by intramuscular and intradermal injection of plasmid DNA encoding an oligomeric form of HIV-1 Env (o-gp140) followed by boosting with Env protein (o-gp140ΔV2 SF162) [53]. These antibodies neutralized both homologous and heterologous primary isolates, and initially protected rhesus macaques from challenge with pathogenic SHIV SF162P4 [142]. In this study, the primary control of the viremia was likely exerted by antibodies as the animals were depleted of CD8+ T cells prior to challenge.

The requirements for the expression, folding, and intracellular transport of bacterial and parasite proteins compared to viral proteins are different. Nevertheless, the DNA vaccine approach is quite effective at inducing protective responses in preclinical models of bacterial and parasitic diseases. In some of these models, protection is thought to be mediated by T cells, such as tuberculosis [27,145], *Mycoplasma pulmonis* infection [35], malaria [70,135,136,146], and leishmaniasis [147]. In these cases, processing and presentation of DNA-encoded antigens to T cells are unlikely to be affected by the source of the antigen (i.e., virus versus bacteria). In contrast, expression of bacterial antigens in cells of the eukaryotic host, where posttranslational modification and folding of the protein may be different than in the organism, may have an effect on the quality of antibody responses. Nevertheless, it is possible to induce protective immunity based on antibody responses with DNA encoding bacterial antigens, such as tetanus toxin C fragment [148] and *Salmonella typhi* OmpC porin [149].

In general, DNA vaccines are effective at inducing CTL, but less so at inducing T-helper responses and humoral responses, as compared to other means of immunization (e.g., adjuvanted recombinant protein, inactivated virus). To overcome these limitations, several approaches have been used to increase the potency of DNA vaccines, such as 1) optimization of vectors and genes of interest, in order to achieve higher levels of expression of antigen; 2) coadministration of plasmid DNA encoding immunologically active proteins such as chemokines, cytokines, costimulatory molecules, in order to enhance immune responses against encoded antigens; and 3) targeted DNA delivery into cells by either formulated DNA, physical delivery technology or vector systems, in order to overcome some of the barriers to effective transfection of cells *in situ*.

## V. VECTOR AND GENE OPTIMIZATION

Expression studies using reporter genes indicate that only picogram to nanogram quantities of protein are expressed *in vivo* after administration of plasmid DNA [2,150]. While

only small amounts of antigen may be sufficient for presentation to MHC class-I molecules for induction of potent CTL responses, this may be a limiting factor in inducing potent humoral responses. To compound this problem, certain antigens from pathogens are not efficiently expressed by mammalian cells. For example, codon usage, mRNA instability, and dependence on coexpression of other genes (e.g., *rev*-dependence in HIV) can lead to suboptimal levels of expression of prokaryotic genes in eukaryotic cells. Therefore increasing gene expression by DNA vaccines is a reasonable strategy for increasing the potency of immune responses, and several approaches have been successful. First, the choice of promoter, enhancer, intron, polyadenylation, and transcriptional termination vector sequences can affect gene expression. The promoter/enhancer element of cytomegalovirus (CMV) is most commonly used in DNA vaccines and offers a high level of gene expression in a variety of cells. However, one potential disadvantage of the CMV promoter is that its activity may be downregulated by high levels of IFN- $\gamma$  and TNF- $\alpha$  [151], which may be produced locally in response to DNA vaccines. Second, Haas et al. demonstrated that optimizing the nucleotide sequence of HIV genes to reflect the preferential codon usage in the mammalian cells can result in higher levels of gene expression [152]. Using codon optimization and also by removing certain inhibitory sequences, zur Megede et al. increased HIV gag expression by 1000-fold *in vitro*, with a corresponding substantial increase in immunogenicity in mice and primates [111]. Third, fusion of poorly expressed sequences with highly expressed heterologous proteins can increase the production of the target gene. For example, Wu and Barry showed that HIV env gene fused to the "C" termini of GFP or human protein alpha1-antitrypsin resulted in better anti-Env immune responses [153]. In addition to expression levels, localization of the encoded protein can affect the quantity and quality of DNA vaccine-induced immune responses. In general, secreted forms of the antigens compared to those targeted to the cytosol or plasma membrane are more effective at inducing antibody and helper T-cell responses, whereas cytosolic targeting may be preferred for CTL induction. However, this is not always the case, as membrane-bound antigens can induce high levels of antibodies [144] and secreted antigens can be effective for CTL [154]. The effectiveness of DNA vaccines for inducing CTL responses also may be enhanced by inducing rapid degradation of antigen by proteasomes, which can sometimes be achieved by expression as a fusion protein with ubiquitin [155,156]. In addition to intracellular targeting of antigen, extracellular targeting also can be effective. For example, expression of the gene of interest as a fusion protein with ligands such as CTLA4 [65,157], L-selectin [157,158], IgG-Fc [159], and chemokines [160], which target the cell surface receptors of APCs, have been shown to enhance both cellular and humoral immunity of DNA vaccines. In a related approach, expression as a fusion protein with a heat-shock protein increased potency [161], possibly by facilitating cross-priming via delivery of antigen to and activation of APCs. These previous examples have focused on the production of most or all of the antigens. This allows for determinant selection of T-cell epitopes by the vaccinated host.

In order to focus the immune response on specific T-cell epitopes, DNA vaccines encoding minimal epitopes [49, 162,163], strings of epitopes [49,104,129,164], and epitopes in the context of other proteins [49,165] have all shown to be effective at priming MHC class I- and class II-restricted responses. Therefore for efficient induction of cellular and humoral immunity by a given DNA vaccine the form of antigen should be evaluated on a case-by-case basis.

## VI. ADJUVANTS FOR DNA VACCINES

To modulate or enhance immune responses induced by DNA vaccines, coadministration of biologically active molecules such as cytokines, chemokines and costimulatory molecules have been used extensively. The role of these biological or genetic adjuvants for DNA vaccines has been reviewed in detail [166]. Following are a few examples to demonstrate the potential of this approach. In general, coadministration of IL-2, a potent stimulator of cellular immunity that induces the proliferation and differentiation of T cells, B cells, and NK cells, enhances both cellular and humoral immune responses against DNA vaccine antigens [26,167]. For example, Barouch et al. have shown that coadministration of IL-2 as a fusion protein with the Fc portion of immunoglobulin G significantly enhanced the DNA vaccine-induced protective immune responses against HIV and SIV antigens in mice and rhesus macaques [12,168]. Intramuscular and intranasal coadministration of DNA encoding another cytokine, IL-12, has enhanced cellular and T-helper responses and downregulated humoral responses induced by DNA vaccines against various antigens [169–173]. In addition, Iwasaki et al. have shown that coadministration of IL-12 can overcome unresponsiveness of certain antigens [174]. DNA encoding other Th-1 inducing cytokines, such as IL-15 and IL-18, were also evaluated for their capability to modulate immune responses induced by DNA vaccines [169]. Interestingly, in contrast to IL-2 and IL-12, coadministration of IL-15 and IL-18 with DNA vaccines significantly enhanced antibody and proliferative responses but had little effect upon cellular responses [169,170,175]. In general, coadministration of DNA encoding Th-2-type cytokines, such as IL-4, IL-5, and IL-10, as might be expected significantly enhanced the magnitude of antibody responses induced by DNA vaccines [68,175]. In addition, IL-4 DNA inhibited cellular responses [68], which may limit the application of this cytokine as an adjuvant for antiviral vaccines. Coadministration of DNA encoding GM-CSF, a pro-inflammatory cytokine, has been shown to enhance antigen-specific cellular, humoral, and T-helper responses [176,177], as has been observed with antigens from HIV [92,178,179], influenza [174], HCV [26], encephalomyocarditis virus [180], rabies [90], and plasmodia [181,182]. Furthermore, coinjection of GM-CSF DNA has also improved the protective efficacy in models of rabies [90] and malaria [181,182]. The effect of GM-CSF DNA appears to be dependent upon the mode and route of DNA delivery, as no enhancement was seen with gene gun-mediated epidermal delivery [183]. Other pro-inflammatory cytokines, such as TNF- $\alpha$  and TNF- $\beta$ , also were effective at enhancing the

antibody and proliferative responses in rodents [175]; however, only TNF- $\alpha$  DNA was effective for CTL [175].

Another strategy to enhance the potency of DNA vaccine is coadministration of DNA encoding costimulatory molecules such as B7.1 (CD80), B7.2 (CD86), and CD40. For example, coinjection of CD86 DNA resulted in a substantial increase in CTL responses against influenza NP [174] and HIV-1 antigens [184,185]. Whether these effects are a consequence of rendering non-APCs capable of priming CTL or of further activation of professional APCs already expressing these costimulatory molecules remains to be determined.

In summary, DNA encoding many cytokines or costimulatory molecules have increased the potency of DNA vaccines. Further development of these genetic adjuvants will require careful evaluation of the safety of potential long-term intracellular expression of these biologically active molecules. So far, GM-CSF DNA has been evaluated in nonhuman primates and human clinical studies with a malaria DNA vaccine.

## VII. IMMUNOSTIMULATORY ACTIVITY OF DNA VACCINES

The inherent immunostimulatory activity of bacterial DNA has received widespread attention, particularly in the context of DNA-based adjuvants for proteins. It has been shown that oligonucleotides containing particular sequences surrounding CpG dinucleotides can stimulate B cells to proliferate and secrete immunoglobulins, activate APCs, and stimulate the production of cytokines [186,187]. These CpG sequences signal the innate immune system through Toll-like receptor 9 [188–191], and their role in the potency of DNA vaccines is illustrated as follows. First, plasmid DNA vaccines containing extra CpG motifs can induce stronger antibody and CTL responses [192]. However, this does not always result in more potent DNA vaccines, suggesting that context may be important. Second, methylation abrogates DNA vaccine potency [193]. This likely reflects a means by which the innate immune system recognizes pathogen-derived DNA as distinct from host DNA. Finally, the potency of plasmid DNA can also be enhanced by coadministration of noncoding plasmid DNA [194], presumably by providing additional CpG motifs. Efforts to codeliver plasmid DNA with CpG oligonucleotides, however, resulted in reduced DNA vaccine expression and immunogenicity [195], suggesting competition between the plasmid and the oligonucleotide. Thus appropriate DNA delivery or formulation will be required to take full advantage of CpG oligonucleotides for enhancing the potency of DNA vaccines.

## VIII. DNA VACCINE DELIVERY SYSTEMS

Conventional methods of DNA vaccine delivery include direct intramuscular injection of plasmid DNA into muscle and gene gun delivery into skin, neither of which provides optimal immune responses. Intramuscular injection is suboptimal because only a small fraction of muscle cells are

transfected due to inefficient uptake of DNA by cells. Antigen presenting cells can also be transfected but the efficiency is very low. Using fluorescently tagged plasmid DNA, Dupuis et al. demonstrated that after intramuscular injection 1) distribution of DNA within the injected tissue was rather limited; 2) uptake of DNA by myocytes and APCs was low; and 3) the majority of labeled DNA was phagocytosed and degraded by macrophages [86]. Therefore approaches to facilitate distribution of DNA throughout the tissue, increase transfection of muscle cells or APCs, prevent DNA degradation, or enhance the release of DNA out of endosomes may all be of help in the enhancing potency of DNA vaccines. With regard to DNA delivery, three promising general approaches have been shown to enhance the potency of DNA vaccines: 1) physical methods of delivery of the plasmid DNA into cells; 2) particle-mediated delivery of plasmid DNA to APCs; and 3) viral or bacterial vectors.

## IX. PHYSICAL METHODS

Physical or mechanical methods have been used effectively to facilitate DNA delivery *in vivo*. The main technologies include the gene gun (previously discussed), needle-free devices, electroporation, and hydrostatic pressure. Needle-free devices (such as the Biojector) are commonly used for administration of various drugs and vaccines, and offer the advantages of less invasiveness (i.e., no needle) and better distribution of inoculum. For DNA vaccines, the Biojector has shown some effectiveness in enhancing immune responses in animal models [34,196] and is being evaluated in a clinical trial involving a malaria DNA vaccine. Recently, it has been shown that electroporation treatment of tissue *in vivo* after DNA vaccination results in higher gene expression [197] and markedly enhanced cellular and humoral responses in small and large animal models [198–200]. Electroporation has long been used to transfect cells *in vitro* due to a transient disruption of the plasma membrane, thereby facilitating uptake of DNA. The precise mechanism by which electroporation facilitates DNA delivery *in vivo* and the factors influencing the enhancement of the immune response are not clear but may involve an increased DNA distribution within the tissue (i.e., iontophoresis) and delivery directly through membranes (i.e., electroporation). It is also possible that an inflammatory response at the site of treatment may contribute to the enhanced immunogenicity of DNA vaccines. Because of the physical nature of the enhanced delivery of DNA by electroporation and the effectiveness in large animals, this technology holds much promise for use in humans. However, issues related to tolerability, safety, and feasibility will need to be examined and may limit its use, in the first instances, to therapeutic applications. Finally, increased DNA delivery can be achieved through brute force using hydrostatic pressure [201]. This is accomplished by i.v. injection of large volumes of DNA solution, followed by restriction of blood flow to the injected limb, and results in substantially higher levels of gene expression in endothelial and muscle cells. As such, this approach would seem to be best suited to gene therapy but could conceivably be considered for therapeutic vaccination.

## X. PARTICLE-MEDIATED DELIVERY OF DNA VACCINES

Ideally, one would prefer to have a simple formulation of DNA that could be administered by conventional means, without the need for a device. In theory, DNA formulations could provide the following: 1) increased DNA stability (i.e., protection from nuclease digestion in tissues); 2) a depot for slow-release of DNA over a period of days or weeks; 3) facilitated uptake of DNA by cells; 4) targeting of DNA to specialized cells (e.g., APCs); and 5) inclusion of adjuvants to stimulate immune responses. To this end, several polymers that condense or interact with DNA have been tried, with varying degrees of success. Some examples include poly(ethylenimine) [202], polyvinyl pyrrolidone [203], dendrimers [204,205], chitosan [206], and poly(DL-lactide-co-glycolide) (PLG) [95,207,208]. The best studied of these in the context of DNA vaccines is PLG, and the rationale is twofold. First, methods for encapsulation of compounds into PLG micro-particles are well established and these formulations have been used for slow-release delivery of various entities. Encapsulation of plasmid DNA in PLG microparticles has been shown to be effective for oral delivery of DNA vaccines, presumably by protection from degradation in the gut [95,96,209]. Second, PLG can be made into particles of uniform size and lends itself to formulation with DNA into or onto particles of ~1 μm in diameter, which should be readily internalized by APCs. Indeed, it has been shown that DNA vaccines adsorbed onto the surface of PLG micro-particles substantially increased humoral and cellular immune responses [207,210], and the mechanism appears to involve targeting DNA to APCs [211]. Potential advantages of surface adsorption are that it avoids the harsh conditions of encapsulation of DNA and allows for the rapid release of DNA from the surface once inside the cell, thereby acting as an efficient delivery system.

## XI. USE OF LIVE VIRAL AND BACTERIAL VECTORS FOR VACCINE DELIVERY

Use of live attenuated organisms is very effective at inducing potent immune responses. However, because of safety issues, this technology may be problematic for enhancing the immune responses against chronic deadly diseases such as HIV [212]. For example, it has been shown that an attenuated SIV can cause an AIDS-like disease in monkeys [213]. A potential alternative is to deliver genes encoding antigens using heterologous live viral or bacterial vectors. Some of the viral vectors that have been tested for DNA or RNA vaccine applications include vaccinia [116,117,129,214], canarypox [215–218], yellow fever-Japanese encephalitis [219], rabies [220], canine herpes virus [221], adenovirus [143,222,223], varicella-zoster [224], poliovirus [225,226], and alphaviruses [227–229]. However, because the antigens are encoded by the viral genomes, these vectors are not plasmid DNA delivery systems per se. Whereas various bacterial vectors have been used for such purposes. The ability of bacteria to readily enter cells of the respiratory and gastrointestinal mucosa provides an efficient delivery of DNA to immunologically

relevant cells. For example, *Shigella* spp. are Gram-negative bacteria that enter cells via phagocytosis. To facilitate delivery of plasmid DNA vaccines out of the bacteria and into the cytosol, Sizemore et al. engineered a strain of *Shigella* with an unstable cell wall, which was shown to be effective at inducing humoral and cellular immune responses [230,231]. *Listeria monocytogenes* is another Gram-positive bacteria that enters the cytosol of infected cells and has been successfully used to deliver plasmid DNA [232–234]. Yet another bacterial vector that has been shown to be effective for DNA delivery is *Salmonella* [235–238]. In this case, though, the bacteria remains in the phagosomal compartment of the host cell and it is not clear how the plasmid DNA is delivered to the cytosol. The use of certain bacterial vectors offers potential advantages, such as a substantial safety profile in humans (e.g., BCG, *S. typhi* TY21a), the possibility of inducing systemic and local responses, and they may provide synergy with DNA vaccines in a prime/boost regimen. However, as with viral vectors, preexisting immunity may limit the effectiveness of DNA delivery.

## XII. SUMMARY

In conclusion, a substantial amount of work has been done on DNA vaccines since 1990, only a fraction of which has been cited here. During this time, work in animal models has shed light on the limitations of DNA vaccines, how they work, and how one may be able to increase their potency. First-generation DNA vaccines (i.e., naked DNA) have so far demonstrated limited effectiveness in larger animals, including humans. However, substantial advancements have been made over the past several years on improved DNA vectors and delivery, and on the use of adjuvants (biologic and genetic). The potency of these second-generation DNA vaccines in humans remains to be fully determined, but they represent significant advancements toward the development of protective DNA vaccines for humans.
