Although gonococcal pili were originally thought to exist as a homopolymer, it is now accepted that a 110-kDa protein (PilC) associates with the pilus structure [84,96–98]. The gene for this protein, designated *pilC*, can exist within a single gonococcal strain as two distinct loci (*pilC1* and *pilC2*) that can undergo phase-variable expression [99,100]. More contentious is whether PilC functions as an adhesin oriented at the pili terminus, distal to the gonococcal cell surface, or whether PilC functions in the assembly, retraction (twitching motility), or genetic competence (transformation) associated with pilated gonococci as reviewed by Merz et al. [18].

**Contribution of Pili to Gonococcal Pathogenesis.** As originally reported by Kellogg et al. [86] and Cannon et al. [23], all primary clinical isolates are pilated (P<sup>+</sup>) upon isolation and nonpiliated (P<sup>-</sup>) variants are less infectious in human volunteers challenged intraurethrally. Three properties that likely contribute to these observations are efficiency of infectivity, adherence, and resistance to phagocytosis. More recent work has demonstrated that an engineered *pilE* deletion mutant can cause experimental urethral infection, albeit somewhat different than infection with wild-type gonococcal infection [23]. What is clear from these studies is that the expression of gonococcal pili confers an advantage for the colonization of the male urethral mucosa, presumably mediated by the ability to adhere to this tissue, but not necessarily exclusive of the contribution of the pilus structure to natural competence and twitching motility.

Adherence has been historically recognized as a function of gonococcal pili. When compared to nonpiliated isogenic variants of the same strain, pilated Neisseria are reported to agglutinate human erythrocytes [101], and attach to spermatozoa [102], cultured epithelial cells [103], and explanted fallopian tubes [104]. The eukaryotic antigen CD46 is largely regarded as the pilus receptor; it is widely expressed in epithelial and endothelial cells [21,105,106]. CD46 functions as the receptor for the complement regulatory protein C3b and is associated with the signaling events associated with pilus binding [105]. These observations suggest that pili promote gonococcal adherence to cellular surfaces, thus facilitating the early colonization phase of infection. Proof for this notion is somewhat indirect, however, because electron microscopy studies of infected human tissues seldom reveal convincing piluslike structures [107]. Pilus antigens are nonetheless expressed in some form during

the course of infection because pilus antibodies can be readily detected in the sera and vaginal fluids of patients convalescing from gonorrhea [108]. Finally, piliation has historically correlated with the resistance of gonococci to phagocytosis by human neutrophils [109,110].

Antigenic heterogeneity is characteristic of pilin proteins prepared from different gonococcal strains [111]. The antigenic variation of pili expressed by isogenic variants of the same strain also occurs *in vivo*, where it can be demonstrated using isolates of the same strain from sex partners [112] and from men with experimentally induced gonococcal urethritis [113,114]. Studies clearly demonstrate that (a) pilin variation occurs throughout infection; (b) multiple pilin variants are present at any point during infection; and (c) pilin variants are likely recombinants between previously expressed genes and the silent storage pilin copies, *pilS* [114]. These investigations and others all lead to the same conclusion—during infection, a large repertoire of pilins is produced. As a consequence of this antigenic variation and heterogeneity, gonococci may avoid host immune responses directed at or triggered by pilin proteins.

The genetic basis for gonococcal antigenic variation is beyond the scope of this review and is addressed by several excellent reports [115,116]. In general, most clinical isolates contain a single pilin expression locus [115]. Elsewhere in the gonococcal genome, multiple nontranscribed “silent” pilin (*pilS*) loci exist. Most gonococcal strains have more than a dozen *pilS* loci; each silent locus contains one to several truncated pilin structural genes lacking the 5' promoter region and the coding sequence for the N-terminal constant region of pilin. The pilin sequences in the silent loci primarily specify the semivariable and hypervariable C-terminal regions of pilin and, consequently, they contain information for the creation of new antigenic determinants that are clearly formed during the process of natural infection [113,114]. It has been proposed that the diversity of pilin variants approaches that of the B-cell repertoire of antigen-combining sites. An equally important property of gonococcal pili is that of “piliation phase syndrome” as first proposed by Brinton et al. [117] in reference to the presence or absence of pili expressed by any given gonococcal isolate. Switching between the P<sup>+</sup> or the P<sup>-</sup> states occurs at rates as high as one per one thousand cell divisions reversion to the piliated state also occurs, although at slower rates, greater than one per one million cell divisions reversions per generation [82]. Natural recombination events result in the deletion of the pilin expression site, and the upstream promoter sequences lead to a P<sup>-</sup> state that is capable of reversion to the P<sup>+</sup> state at very low frequencies or not at all. In other cases, pilin is expressed but is undetectable due to rapidly degraded truncated or unassembled pilins, also referred to as soluble pilin [118]. Soluble pilin may provide yet another source of gonococcal protein that antigenically diverts the host immune system during the course of gonococcal infection.

The remarkable structural and antigenic diversity of gonococcal pili deserves a footnote as one of nature’s oddities. This property is unique to *N. gonorrhoeae* and its evolution clearly contributes to the efficiency with which this organism causes disease, giving rise to the concept of infec-

tion by a “quasi-species” (i.e., a population of multiple clones), reminiscent of HIV-1 infection.

**“Afimbral” Adhesins: Opas.** A group of related proteins, historically referred to as Proteins II and now designated as Opas for *opacity associated* proteins, are variably expressed on the gonococcal surface. The term Opa is derived from the observation that gonococcal colonies, propagated on clear typing media and viewed through a stereomicroscope using light reflected from a mirror below the stage, exhibit an opacity phenotype ranging from transparent to opaque [119–121]. Colonies appearing transparent by this analysis generally, but not always, lack Opas. These proteins are not presented as part of an extended appendage such as a pilus; rather, they are intimately associated with the gonococcal outer membrane. Whereas pili appear to be crucial for the first contact of gonococci with host cells from rather long-range, Opas are thought to promote more intimate contact with host cells, resulting in subsequent cell signaling.

**Biochemistry of Opas.** Opas comprise a family of surface-exposed outer membrane proteins with apparent subunit molecular mass between 24 and 30 kDa. As a group, they are basic proteins with isoelectric points above 9.0 [28,122] and are heat-modifiable (i.e., when prepared at 37°C for SDS-PAGE analysis, they migrate with a higher relative mobility than when prepared at 60°C or 100°C). Organisms forming opaque colonies usually express one or more Opas that affect intergonococcal adhesion, giving rise to the opaque appearance of these colonies [120,123–126].

The predicted amino acid sequences corresponding to Opa structural genes contain a relatively conserved “semivariable” region near the N-terminus of the molecule and two hypervariable regions that differ markedly in amino acid sequence and length [127]. Both hypervariable regions appear to contribute to the antigenic and functional properties of individual Opa family members.

Opa expression is variable; different colonies isolated from a single strain may express none, one, or several serologically distinct Opas simultaneously [120]. Fluctuation between different Opa expression patterns *in vitro* occurs at rates as high as one per 1000 cell divisions [128]. When fully expressed, the Opa content of the outer membrane nearly equals that of PorB. The genetic basis for Opa phase and antigenic variation has been studied in great detail. Within individual strains, Opas are specified by up to 12 independent structural genes that are distributed throughout the gonococcal chromosome [119,127]. Opa protein expression is controlled at the level of translation by the presence of up to 28 identical, tandem pentameric repeats (CTCTT) encoding the signal peptide [129,130]. Intact Opas are produced only when the number of the repeat units places the initiator AUG codon in-frame with the mature protein coding sequence. A change in the number of repeats results from slipped-strand mispairing of the pentameric units during DNA replication and is independent of RecA activity. Translational regulation as described above accounts for the expression of serologically distinct Opas within a single strain. This antigenic diversity is further enhanced through the recombination between *opa* genes within and among

gonococcal strains resulting in chimeric *opa* structural genes with different combinations of hypervariable regions [121]. Sequence analysis of gonococcal and meningococcal *opa* genes suggests that horizontal genetic exchange and recombination between *N. gonorrhoeae* and *N. meningitidis* DNA occur in nature [131], as evidenced by the presence of at least one identical *opa* hypervariable locus in isolates of the two species.

**Contribution of Opas to Gonococcal Pathogenesis.** In addition to promoting interbacterial adhesion, Opa proteins have long been recognized as adhesins that facilitate gonococcal interactions with human epithelial and phagocytic cells [122,132–135]. The expression of certain Opa proteins favors the binding of gonococci to human polymorphonuclear cells but not human epithelial cells [136]. In another study, it was demonstrated that only a subset of Opa proteins could induce oxidative killing by human polymorphonuclear cells, whereas a different subset could induce oxidative killing by human peripheral blood monocytes [133]. Variability in Opa-mediated host cell binding and activation is likely a reflection of variation in host cell receptors and the intracellular pathways stimulated by specific Opa binding to these receptors.

Early studies of naturally infected patients suggest that Opa expression is strongly correlated with the clinical manifestation of gonorrhea. In women, recovery of opaque colonial variants is highly associated with endocervicitis occurring at midcycle. In men, Opa<sup>+</sup> gonococci are closely linked with uncomplicated urethritis, pharyngitis, and proctitis. By contrast, recovery of the transparent colonial morphology is associated with disseminated gonococcal infection, pelvic inflammatory disease, and endocervicitis during menstruation [30]. Antibodies to Opa proteins can be detected in the convalescent serum and vaginal fluid of patients treated for gonorrhea, indicating that these proteins are expressed and immunogenic in vivo [112]. In an analysis of 200 variants of a single strain isolated during an outbreak of penicillin-resistant gonorrhea, Schwalbe et al. [137] demonstrated variable Opa expression. Swanson et al. [121,126] demonstrated a transition to the opaque phenotype in vivo in males challenged by urethral inoculation with a transparent colonial variant.

In more recent studies employing the male urethral challenge model, volunteers were challenged with transparent gonococci followed by the characterization of the Opa protein expression of gonococci recovered from the urine, urethra, and semen [138]. The studies confirmed the strong selection for Opa proteins in vivo, which are expressed more rapidly, in greater number, and with more variation than the same strains passaged in vitro. However, no single Opa protein type was preferentially expressed during early infection in the male urethra, and different subjects inoculated with the same bacterial suspension developed infections with gonococci that varied dramatically in the Opas expressed.

Using isogenic gonococci differing only in Opa expression in conjunction with well-defined cell lines, two candidate host receptors have been identified. One receptor appears to be the heparan sulphate proteoglycans (HSPGs)

[132,139,140]. Certain Opa proteins that contain highly cationic surface-exposed loops bind strongly to HSPGs, resulting in invasion of certain epithelial cells such conjunctival cells. This binding is markedly reduced by competition with soluble heparin, heparan sulfate, or HSPGs. In addition, the serum proteins vitronectin and fibronectin, in conjunction with their integrin receptors (and other cell proteins), encourage HSPG-mediated binding [141–143]. Opa-mediated binding to HSPG receptors results in the stimulation of intracellular signaling pathways involving acid sphingomyelinases [144] and cytoskeletal rearrangement [145]. A convincing argument that these events facilitate invasion by gonococci has been made.

A second target for many Opas is the CEACAM (formerly called CD66) family of host cell receptors. These host cell surface antigens are represented by multiple isoforms, each with a different expression pattern on various epithelial and immune cells. This differential expression and subsequent Opa recognition may account for the tissue tropism exhibited by the isogenic gonococcal Opa variants. As in the case of binding to HSPG receptors, binding to CEACAM results in the activation of intracellular signaling cascades, including acid sphingomyelinases [144], protein tyrosine kinases [146], and cytoskeletal rearrangement [145]. Recent studies suggest that Opa<sup>+</sup> gonococci binding to CEACAM1 (also called CD66a or BGP) on CD4<sup>+</sup> T-cells [146] and to CEACAM3 (CD66d or CGM1a) on B-cells and neutrophils may result in the inhibition of host immune responses.

Opa expression is strongly correlated with the most basic aspects of host-parasite interaction. One interpretation of studies of Opa biology is that this family of proteins and the genetic mechanisms that underlie its phase and antigenic variation are essential to the ecology of the organism, if not for virulence per se. Studies in the male urethral challenge model do not indicate a “programmed” or “selected” Opa, or, for that matter, a pilin expression pattern. Rather, expression of these antigenic and phase-variable surface proteins during infection reflects a certain arbitrariness, placing an apparent premium on antigenic and attachment diversity. Opa expression may also play a role in active immune suppression by gonococci, consistent with the familiar picture of reinfection, even by *N. gonorrhoeae* of the same porin serotype [147].

### 3. Environmentally Regulated Nutrient Acquisition Proteins

**Transferrin-Binding Proteins—TbpA and TbpB.** Given the tight regulation of protein expression exhibited by other organisms in response to their growth environment, analysis of the molecular composition of gonococci grown on rich complex medium in a laboratory environment may not accurately reflect the composition of the organism in vivo. The natural environment of the human host is defined by many parameters; notable examples include extremes in temperature, pH [148,149], and growth-essential nutrients. The latter is of particular significance because natural environments are frequently limited in one or more essential nutrients due to depletion by the host and endogenous mi-

icrobial populations. Hence, nutrient insufficiency may be the most common environmental extreme to which a pathogen is exposed. Investigators have focused on potential gonococcal antigens expressed when this organism is propagated under conditions that simulate those of a less than hospitable host. For example, using continuous culture, Morse et al. [150] were able to modulate the structural and antigenic composition of gonococcal LOS using glucose as a rate-limiting nutrient. Other reports suggest that oxygen tension may influence the synthesis of novel proteins [36,151]. However, the most attention in this area has focused upon the influence of environmental iron concentration on the molecular composition of gonococci [152–154].

Within the human host, there is little free iron, most being complexed to human transferrin in serum and human lactoferrin in secretions [155]. Iron in the form of heme may be available, bound to proteins such as hemoglobin, haptoglobin, or hemopexin [153,156]. These host proteins represent the principal reservoir of growth-essential iron for pathogenic bacteria. In turn, the ability of pathogenic microorganisms to scavenge iron from their host environment and incorporate this element into proteins is a crucial requirement for the production of disease [157]. Many pathogenic bacteria employ soluble low-molecular-weight siderophores that compete for this iron source [158]. The inability to detect the secretion of a soluble siderophore by Norod et al. [159] for the gonococcus, and by Archibald et al. [160] for the meningococcus, was the first indication that these organisms employed a fundamentally different mechanism for iron acquisition from the canonical siderophore-mediated mechanisms of scavenging iron observed in other organisms. Ultimately, this was resolved using a classical experiment by Archibald et al. [160]. These investigators demonstrated that ferri-transferrin, sequestered within a dialysis bag and immersed in iron-limiting media, was able to support the growth of a siderophore-producing strain of *E. coli* but not *N. meningitidis*, leading to the conclusion that transferrin binding was required for meningococci but not for *E. coli*. Almost three decades after these original experiments were performed, the existence of a transferrin receptor-binding complex on the surface of pathogenic *Neisseria* is well accepted [156,161]. For a contemporary review comparing the different mechanisms of iron transport among gram-negative bacteria, the reader is directed to Clarke et al. [162].

All strains of *N. gonorrhoeae* obtained from clinical infections are able to utilize iron from human transferrin [163], whereas only subsets of gonococci are able to utilize iron from human lactoferrin and hemoglobin [164]. The key to this process is the expression of specific receptors that bind human transferrin, human lactoferrin, or hemoglobin at the bacterial surface. One further source of iron is an outer membrane receptor formerly referred to as FrpB [165], but now designated FetA for ferric enterobactin transport [166]. This receptor recognizes phenolate siderophores produced by other microorganisms. A common property of pathogenic *Neisseria* is the exploitation of endogenous host iron sources such as transferrin, lactoferrin, hemoglobin, or phenolate siderophores, without expending metabolic energy to make a scavenging (e.g., siderophore) compound.

The neisserial lactoferrin, hemoglobin, and enterobactin receptors all demonstrate some capacity for phase variation [156,167,168], allowing gonococci expressing these surface proteins to potentially escape immune responses directed at these proteins, and making these poor targets for vaccine development. On the other hand, the transferrin receptor is expressed by all gonococci and does not demonstrate phase variation, making it an attractive target for a vaccine. Thus, subsequent sections of this review on the biochemistry and contributions of iron to gonococcal pathogenesis are focused on the gonococcal transferrin receptor.

**Biochemistry of Transferrin-Binding Proteins.** The gonococcal transferrin receptor is comprised of a heterodimer transcribed from a bicistronic operon whose promoter is regulated by the iron-dependent transcriptional repressor “Fur” (for ferric uptake repressor) [169]. The first gene in this operon encodes a lipoprotein (TbpB) that is tethered to the gonococcal cell surface and imparts binding and recognition properties to the transferrin receptor oligomeric complex [170,171]. The second gene in this operon encodes an integral outer membrane protein (TbpA) that is proposed to function as a gated porin [172]. Sequence analysis of TbpA reveals homology with the TonB-dependent outer membrane siderophore receptors FepA, FecA, IutA, FhuA, and FhuE [162]. By SDS-PAGE, the molecular masses of the gonococcal TbpA and TbpB are estimated to be ~100 and ~85 kDa, respectively [154]. Structural and antigenic diversity is demonstrated for both TbpA [173] and TbpB [174], although the variability appears to be greater for the more surface-accessible TbpB.

The stoichiometry of TbpA to TbpB in the transferrin receptor complex does not appear to be fixed and may vary as a function of the degree of iron starvation of gonococci [172]. Under extreme conditions, there may be as many as 20 copies of TbpB to one copy of TbpA. The specificity of the neisserial TbpA/B receptor complex for transferrin of hominid origin has been well described and may explain why gonococcal infection is confined to humans [156]. The gonococcal transferrin receptor preferentially binds to ferri-transferrin over apo-transferrin [175,176]. TbpA or TbpB can bind human transferrin independently of each other; however, both are required for the efficient transport of growth-essential iron from human transferrin [170,177]. The mechanism by which the gonococcal receptor liberates iron from human transferrin is unclear; the dissociation constant of iron bound to transferrin is  $10^{-20}$  M.

**Contribution to Gonococcal Pathogenesis.** To accomplish its proposed function, the gonococcal transferrin receptor requires that it be surface-exposed. It has been proposed that human transferrin bound to the gonococcal cell surface may act as a bridging ligand to facilitate the attachment and invasion of organisms [178]. More recent studies using gonococcal invasion of transformed cells propagated in culture report that human epithelial cells infected with *N. gonorrhoeae* have reduced levels of transferrin receptor messenger RNA and cycling of human transferrin receptors, suggesting that infection alters epithelial cell transferrin–iron homeostasis at multiple levels [179]. The expression of a functional transferrin receptor is critical to growth

of gonococci in vivo. Cornelissen et al. [180] report that an engineered mutation inactivating the transferrin receptor, in a strain of *N. gonorrhoeae* that naturally lacks the lactoferrin receptor, rendered the bacteria unable to cause experimental urethral infection. These observations underscore the critical relationship between the ability to obtain iron from the host environment and the ability to efficiently cause disease.

#### 4. Other Surface-Exposed Structures

In addition to the well-described gonococcal surface antigens discussed above, recent work from Spence et al. [181] suggests that ribosomal protein, L12, is exposed on the surface of *N. gonorrhoeae* and is involved in the invasion of host cells in the female genital tract bearing the lutropin receptor. This rather surprising observation further emphasizes the complexity and redundancy of mechanisms for the attachment and invasion of host cells in this remarkably versatile pathogen.

### C. Experimental Models of Gonococcal Infection

#### 1. Cell Culture Models

Significant progress has been made in recent years with respect to the host cellular receptors and the signal transduction processes involved in neisserial adherence, invasion, and transcytosis. Transformed and well-defined primary cell cultures have provided the most controlled models to analyze gonococcal adherence, invasion, and influence on host cell biology [18,56,135]. These studies have defined CD46 as a receptor for pilus that allows adherence to epithelial and endothelial cells, HSPGs acting in cooperation with vitronectin and fibronectin as receptors for some Opa variants, CEACAMs as the receptors for other Opa variants, and the host cell asialoglycoprotein receptor for gonococcal LOS expressing an appropriate terminal sugar. Binding to these receptors initiates the process of transcytosis through epithelial, endothelial, and phagocytic cells. From these studies, it can be concluded that the surface variation exhibited by gonococci is adaptive, and may modulate tissue tropism, immune evasion and suppression, and survival in the multiple environments (e.g., cervix vs. male urethra) encountered by this organism.

#### 2. Fallopian Tube Culture Model

Explant cervical, urethral, and fallopian tissues have been used for the purpose of understanding the pathobiology of the gonococcus. McGee et al. [50,182,183] pioneered a fallopian tube model from premenopausal women undergoing oophosalpingohysterectomy. Fallopian tubes obtained from these volunteers can be maintained in tissue culture for several days, exhibiting normal ciliary motion and synthesis of local antibodies and cytokines [184]. Using this model, the temporal sequence of the interaction of the gonococcus with fallopian tube membranes has been defined [183]: Approximately 20 hr after inoculation of the fallopian tube mucosa

with pilated gonococci, scanning electron micrographs reveal attachment to nonciliated, low columnar cells. Although few microorganisms interact with the ciliated epithelial cells, many cilia begin to slough from the epithelial cell surface, probably as a result of TNF- $\alpha$  [50]. The attachment of organisms exclusively to the nonciliated columnar cells suggests a highly specific recognition event indicative of a receptor ligand-mediated binding process. Gonococcal adherence to the mucosal surface appears to occur at two levels: Initially, long-range adherence occurs, which is most likely mediated by pili. Subsequently, intimate association between the gonococcal outer membrane and the epithelial cell plasma membrane occurs, which may be mediated by afimbrial adhesins such as Opas and LOS. By 2 hr, invasion of epithelial cells by gonococci is evident. This process appears to begin with the retraction of gonococcal-bound microvilli that, in effect, encompass the organism, leading to its presence in a membrane-bound endocytic vesicle. By 40 hr, the membrane-bound vesicles are found to contain multiple organisms and are located close to the cytoplasmic face of the basal surface of the epithelial cell. Thus, transport of the vesicle from the apical to the basal aspect of the cell has occurred, accompanied by the replication of single organisms within vesicles or the coalescence and fusion of several vesicles leading, in either case, to the existence of larger vesicles containing multiple organisms. Fusion of the basal plasma and vesicular membranes ensues and is followed by exocytosis of gonococci onto the basement membrane and in the lamina propria of the subepithelial space, where they may multiply in a sterile environment devoid of competing commensal organisms. In addition, the gonococcus is positioned in close proximity to local lymphatics and blood.

Although the human fallopian tube culture closely mimics the interaction between host and the insulting gonococcus, it is critical to appreciate the differences between this simulated organ culture model and natural infection. The use of sera of nonhuman origin to sustain fallopian tube viability is not a condition typically encountered by gonococci. Furthermore, many inflammatory and immune processes of gonococcal pathogenesis cannot be studied in the fallopian tube organ model.

#### 3. Murine Models of Gonorrhea

Progressing from cellular models of gonococcal infection to animal models, gonococcal infection has been established in chambers implanted subcutaneously in mice [185]. Corbiel et al. [186] were able to initiate vaginal infection in mice. Two groups extended these early observations using 17- $\beta$  estradiol to establish the colonization of the vagina with gonococci. Arko et al. [187] investigated the parenteral vaccination of mice with gonococcal antigens and then challenged with live gonococci. Vaginal clearance of gonococci from mice parenterally primed with a gonococcal PIB synthetic peptide and then orally immunized with a  $\gamma$ -irradiated, Rmp-deficient gonococcal strain was significantly more efficient than in corresponding nonimmunized controls. Similarly, Plante et al. [188] used estradiol-treated female mice to study the vaccine potential of outer membranes. Mice receiving nasal immunization with gonococcal

outer membranes demonstrated a systemic and vaginal immune response against several outer membrane proteins. Immunized mice cleared gonococci in half the time observed in the control group. These experimental studies suggest that a vaccination approach for the management of gonococcal infection is feasible. Despite its limitations (e.g., inability of gonococci to multiply in mouse serum and the lack of classical symptomatology), the mouse model of gonococcal infection is likely to receive increased attention in coming years, especially as results demonstrate predictable results with the human challenge model.

#### 4. Primate Models of Gonorrhea

More relevant animal models are those that have been developed in primates. Some, but not all, primate tissues can be infected with gonococci *in vitro* [185]. Gonococci bind to chimpanzee epithelial cells. Furthermore, male chimpanzees inoculated with *N. gonorrhoeae* develop purulent urethral infection and transmit the organism to female chimpanzees. However, the cost and ethical issues of working with chimpanzees have limited the extent to which this experimental approach has been and can be used.

#### 5. Human Male Urethral Challenge Model of Gonorrhea

It has long been recognized that gonococci transmitted in urethral pus or grown *in vitro* can cause urethral infection. Historically, John Hunter first employed the human urethral challenge model experimentally in the now-infamous experiment in 1767 by inoculating himself with a urethral exudate from a patient suffering from gonorrhea. Unfortunately, the exudate was also infected with *Treponema pallidum* and Dr. Hunter tragically acquired the much more serious symptoms of syphilis. In the 1960s, Kellogg et al. [86] employed a human challenge model to detect differences in gonococcal infectivity related to colony morphology (manifested as a result of pilin expression, as described above). In this study, piliated gonococci were 1000-fold more infectious than non-piliated organisms. In the 1970s, Brinton et al. [80] used the male urethral challenge model to demonstrate protection to homologous challenge using a pilin subunit vaccine.

The male urethral challenge model of gonococcal infection, in its current form, involves the direct inoculation of gonococci 5 cm into the distal urethra through a small-diameter catheter in order to bypass the squamous epithelium (which is believed to be somewhat resistant to gonorrhea relative to the transitional epithelium). Only male subjects have been used in this model because possible complications to females in this model represent an unacceptable risk [189]. Furthermore, treatment of subjects prior to painful symptoms generally limits the model to the very early stages of gonococcal infection. The inoculum required to cause gonococcal infection in men depends on the strain used and the *in vitro* growth conditions used to prepare this inoculum. Typically,  $10^6$  organisms are required to attain an infectious dose in 100% of volunteers [189]. However, using organisms recovered from humans with experimental urethritis, infection has been attained with as few as 250 bacteria [190].

Pyogenic urethral discharge (generally asymptomatic) develops 1–3 days after inoculation and is typically preceded by the recovery of gonococcal colonies from the urine and an increased number of white cells in the urine. After infection is established, gonococci can be harvested and quantified within the semen. Experimental subjects excrete  $10^3$ – $10^4$  organisms per milliliter of semen whereas patients with natural infection excrete  $10^6$  organisms per milliliter of semen.

The human challenge model can be used for three purposes: (a) to define antigenic variation during infection; (b) to use isogenic mutants to determine gonococcal genes (and structures or enzymes) required to produce mucosal infection in men; and (c) to test a vaccine for efficacy. Using this model, antigenic variation in LOS, pilin, and Opa expression during experimental human infection has been described [113,114,126,128,189–191]. As inferred by the antigenically variable gonococcal surface antigens, recombination (generally facilitated by RecA) would be predicted to be an important property [192,193]. Contrary to this prediction, the inoculation of a RecA-deficient strain was virulent in spite of a single predominant pilin phenotype [193a]. Subjects infected with this strain frequently developed delayed or asymptomatic infection and, in some cases, the urine colony counts began to fall at the time of therapy, thereby suggesting an engagement of host defenses capable of eradicating the organism. From these studies, it is clear that gonococci do not follow a “programmed” order of surface antigen expression. Antigenic variation can be expected to help the organism evade host responses and to provide the organism a better chance to establish infection in the next host. Isogenic pilin, RecA, IgA protease, Opa, and transferrin receptor mutants have been examined [114,126,138,180,189,191,194,195]. Although some differences were observed when comparing mutant organisms to wild type, the results indicate that the transferrin receptor is absolutely required for infection in organisms that do not use lactoferrin as an iron source [180].

A characteristic of gonorrhea is that repeated infections often occur within an individual and, after clearance, subsequent infections are often caused by the identical organism responsible for the primary infection. This is referred to as gonococcal recidivism and begs the question as to why the infected human host does not mount an effective immune response to prevent subsequent infections as a result of exposure to the primary infection. The human challenge model has been used to determine whether experimental infection limits reinfection. Schmidt et al. [194] used a defined inoculum of Opa<sup>−</sup> gonococci to infect volunteers, and infection was allowed to progress to a symptomatic state. Two weeks posttreatment, subjects were challenged with a lower number (10%) of the identical gonococcal clone. This challenge infected the same number (ca. 50%) of previously infected subjects as naive controls, indicating that no broadly protective immunity resulted from the initial challenge. However, serological analyses from this small number of rechallenged subjects suggested that the presence of serum IgG antibodies against gonococcal LOS was associated with an increased resistance to reinfection with the lower inoculum. Whether these antibodies resulted from experimental

infection or previous community-based encounters could not be discerned.

### III. POTENTIAL GONOCOCCAL VACCINE STRATEGIES—PREVIOUS EXPERIENCE, FUTURE DIRECTIONS

#### A. The Immune Response to Gonococcal Infection

An antibody response that can be amplified by vaccination of the human host forms the basis for most of the bacterial vaccines described in this text. Indeed, the development of capsular vaccines protecting against systemic disease by common strains of meningococcal infection was developed based on landmark work correlating serum bactericidal antibodies with protection [196]. Unlike meningococci, gonococci do not make capsules and previous diseases do not protect from reinfection. Consequently, in the case of gonococcal infection, we are forced to understand a failed immune response rather than to capitalize on the success of the meningococcal vaccine.

The conventional view is that a successful gonococcal vaccine must ultimately induce a mucosal antibody response. Antibodies generated at mucosal surfaces are expected to (a) block bacterial attachment, (b) facilitate granulocyte killing by promoting ingestion, or (c) stimulate complement-mediated lysis. Accordingly, insight into the mucosal response to gonococcal infection is essential. Mucosal and invasive gonococcal infection induces serum antibodies directed against surface-exposed antigens [48,108]. These immune responses, in large part, represent the basis for the selection of existing vaccine candidates. In some studies, serum antibodies directed against some porin types [197] or Opa proteins [198] have been correlated with some levels of protection from infection.

More recently, Hedges et al. conducted quantitative studies of the mucosal immune response in female and male volunteers. In studies with cervical mucus and vaginal wash fluid, these investigators rarely detected the inflammatory cytokines (IL-1, IL-6, and IL-8), except in women with concomitant infections with several pathogens (e.g., gonococci, *Trichomonas*, and *Chlamydia*) [199,200]. Serum cytokines were detected in high levels in some of these subjects. Likewise, the concentration of antibodies detected in the urethral exudate or semen in men with gonorrhea was very low. However, the inflammatory response itself in men was confirmed by an increase in cytokines (IL-1, IL-6, IL-8, and TNF- $\alpha$ ) in semen of men with gonococcal urethritis compared to a control group. A similar cytokine profile was detected in the urine of subjects with experimental urethritis [200a]. These findings suggest that antibody formation is not a result of stimulation by interaction between exposed gonococcal antigens and local immune devices.

Studies of blood T-lymphocyte responses to gonococci have been reported. Massari et al. [201] demonstrated that peripheral blood CD4 $^{+}$  and CD8 $^{+}$  T-cells harvested from

patients with mucosal gonococcal infection have a demonstrable increased TH<sub>2</sub>-type response to porin antigens. In addition, increased numbers of CD4 $^{+}$  T-cells have been recovered from the cervicovaginal lavage of women experiencing gonococcal infection. However, the lymphocytic responses to gonococcal infection have not been studied in the context of vaccinologic protection.

Gonococci may exploit the innate metabolic and enzymatic functions of the host to limit the immune response to infection [52]. Examination of outer membrane proteins expressed during natural infection demonstrates that the organism can shift from an aerobic to an anaerobic environment [151,202]. Gonococci are capable of respiration sufficient to limit free radical formation of attacking neutrophils, at least in vitro [203].

Mucosal secretions contain all classes of antibodies, but secretory IgA1 and IgA2 are locally generated, whereas IgG concentration likely reflects transudation from serum. Gonococci (and meningococci) make a protease that can cleave secretory IgA1 (sIgA1) at the hinge region, uncoupling the specificity-determining region (Fab) of sIgA1 from its effector (Fc) region. From this, it is inferred that (a) sIgA is an important local defense, and (b) gonococcal IgA1 protease evolves to support infection [204]. The detection of serum and mucosal antibodies in people with meningococcal infection directed against IgA1 protease proves that this enzyme is generated in vivo [205]. However, it has not been possible to demonstrate a role for this enzyme in gonococcal pathogenesis. sIgA cleavage fragments typical of protease activity are not detected in cervical fluid of women with gonococci. IgA1 protease-deficient gonococcal mutants cause infection in both the fallopian tube model [184] and the urethral challenge model [206], comparable to control organisms. It is possible that the gonococcal IgA1 protease plays an alternative role. More recently, it has been demonstrated that this enzyme can cleave an important phagosomal protein (LAMP-1) and can facilitate intracellular survival and transcytosis [207–210].

#### B. Vaccine Candidates

*Delivery approaches.* Experience with both bacterial and viral vaccines suggests several potential approaches that include live attenuated vaccines, killed whole bacterial pathogen vaccines, outer membrane vesicles, purified subunit vaccines, and DNA vaccines. Given the propensity for gonococcal recidivism, a live attenuated vaccine is unlikely to be successful. A killed vaccine consisting of autolyzed gonococci was tested in the 1970s and demonstrated no protective effect [211]. Furthermore, gonococcal LOS limits the use of a live attenuated or killed pathogen. On the other hand, progress has been made in all the other approaches. Subunit vaccines have been tested, or are in clinical development. Outer membrane vesicles have been employed as potential meningococcal group B [27] and gonococcal vaccines [188] using murine models. The use of a gonococcal DNA vaccine using unique vectors has also been reported. Regardless of the delivery system, the key question remains: Can an immune response be directed to any known epitopes

that will stimulate a broadly protective immune response against the quasi-species inoculum typified by gonococcal infection? In this regard, three gonococcal subunit vaccines employing pilin, porin, and the transferrin-binding proteins have been focused on and deserve discussion.

### 1. Pilin Vaccines

*Previous Vaccine Experience with Pili.* The functional, structural, and serological properties of gonococcal pili described above strongly correlate gonococcal pathogenesis with antibodies to pili that block the attachment of gonococci to human cells and that promote phagocytosis [212, 213]. These antibodies can be found in the sera and genital secretions of individuals convalescing from gonorrhea. Based upon this rationale, a vaccine comprised of pilus filaments was prepared from one gonococcal strain by Brinton et al. [80], Tramont et al. [111,215,216], and McChesney et al. [214] and administered by intramuscular injection to two male volunteers. Approximately 3 months after the primary immunization, the vaccine recipients and three nonimmunized control subjects were challenged by intraurethral inoculation with increasing numbers of the homologous gonococcal strain. In this study, vaccination was associated with a 30-fold increase in resistance to gonococcal infection. One of the immunized volunteers was boosted 15 months later. Upon challenge, a 900-fold increase in resistance, when compared to the nonimmunized control subjects, could be demonstrated. These data led to a larger study of more than 100 subjects, which showed that a higher dose of gonococci was required to cause infection in pilus-vaccinated individuals when compared to a control group [80]. This study established that a parenteral gonococcal pilus vaccine could confer at least partial protection.

Studies of the local and systemic immune response to the same vaccine were performed by Tramont et al. [111,216]. After immunization, antibodies to pili were detected in the serum and genital secretions of 100% and 50% of the vaccine recipients, respectively; the antibodies generated were opsonic and blocked the attachment of gonococci to human buccal cells. The immune sera were assessed for cross-reactivity with pili prepared from several heterologous gonococcal strains and were found to be substantially more broadly reactive than the immune sera elicited by the same vaccine in rabbits and mice. Moreover, the human immune sera contained antibodies that recognized a common pilus epitope; these cross-reacting antibodies seemed to be functionally important, being able to block buccal cell attachment by heterologous strains. Based on this information, the U.S. Army carried out a double-blind, randomized, placebo-controlled field trial with the same vaccine preparation. Gonorrhea occurred in 108 of 1499 (7.2%) men receiving the gonococcal vaccine and in 101 of 1498 (6.7%) men receiving a placebo vaccine. Moreover, no relationship between serum antibody levels to pili and risk of infection could be demonstrated. Four possible reasons for failure of this vaccine include: (a) the number of gonococci encountered in nature may have exceeded the level of protection conferred by the vaccine; (b) the concentration of antibodies to pili in genital secretions may have been too low to provide

protection; (c) the antigenic diversity of pili expressed by the heterologous infecting strains may have been too great; and (d) antibodies elicited by the vaccine may have actually been selected for pilus variants unaffected by these antibodies.

*Current State of a Pilus-Based Gonococcal Vaccine.* The remarkable antigenic diversity of gonococcal pilin subunit has limited enthusiasm for its development as a subunit vaccine candidate. However, demonstrating that the minor pilus-related outer membrane protein, PilC, is a possible adhesin associated with the pilus tip [96,217] represents a significant finding in light of the observation that antibody to similar adhesions from *E. coli* urinary tract isolates significantly reduced infectivity [218]. The finding that PilQ (OMP-MC) is essential for pilus biogenesis and function is interesting because it is surface-accessible and common among diverse gonococcal isolates.

### 2. Porin Vaccine

*Previous Vaccine Experience with Por.* Antibodies to PorB are bactericidal [219–223] and opsonic [224]. Furthermore, antibodies are detected in the vaginal fluid and serum of patients convalescing from gonorrhea [48]. Virji et al. [225,226] reported that Por-specific monoclonal antibodies were broadly cross-reactive; two monoclonal antibodies recognized 94% of gonococcal strains tested. These antibodies showed a protective effect when assayed against relevant gonococcal strains by complement activation, opsonic activity, and the ability to protect against challenge to epithelial cells in tissue culture. Elkins et al. [227] presented evidence that bactericidal antibodies could be elicited to peptides derived from Por sequences presumed to be surface-exposed.

Some epidemiological studies have suggested that an immune response to Por could protect against gonococcal infection. Buchanan et al. [228] found that subsequent episodes of salpingitis by gonococci of the same Por serovar were uncommon, indicating that acquired serovar-specific immunity may exist. Rice et al. noted that pelvic inflammatory disease was more common in patients with a reduced ratio of Por/Rmp antibodies [79]. Similarly, a longitudinal study of a cohort of sex workers in Nairobi, Kenya by Plummer et al. [77] found that anti-Rmp antibodies correlated with gonococcal infection. These investigators also reported that particular Por serovars were associated with “specific” but “incomplete” protection against subsequent infection with a homologous serovar [197]. More recent studies in the United States showed no association with Por serovar-specific immunity acquired during the course of natural infection [229].

Blake et al. [211] examined the protection offered from a Por vaccine formulation that likely contained contaminating quantities of Rmp. These investigators noted no protection by the vaccine and more recently have demonstrated that the subjects had a high concentration of antibodies directed against Rmp, suggesting that blocking antibodies could have offset a Por vaccine benefit [79].

*Current State of a Por-Based Gonococcal Vaccine.* Genetic manipulation allows for the expression of Por in a Rmp-negative gonococcal background [65], or in a geneti-

cally altered strain of *E. coli* that does not express OmpA (OmpA is a homologue of Rmp that could elicit blocking antibodies). A purified and renatured Por-based vaccine is currently being evaluated by Wyeth-Lederle in human volunteers for safety.

### 3. Transferrin-Binding Protein Vaccines

*Previous Vaccine Experience with Tbps.* By virtue of their surface localization, contribution to gonococcal growth, and high level of expression during the course of natural infection, the transferrin receptor complex is a reasonable target for a candidate vaccine. The phase variation demonstrated by the lactoferrin, hemoglobin, and enterochelin receptors challenges their consideration as a vaccine candidate. A transferrin receptor complex approach is being pursued to produce a protein-based meningococcal vaccine that would be broadly protective across capsular serotypes [174,230,231]. A potential limitation of a Tbp-based vaccine is competition for binding of host transferrin to the receptors; levels of host transferrin exist at micromolar levels, concentrations predicted to saturate the transferrin receptor. Nonetheless, lessons derived from studies of meningococcal Tbp should be very informative for the development of a homologous gonococcal vaccine formulation.

*Current State of a Tbp-Based Gonococcal Vaccine.* The finding that deleting the transferrin receptor complex from a virulent strain of gonococci renders this organism unable to cause disease [180] is significant and underscores the importance of iron and growth in the host environment. One of the challenges that faces this vaccine approach is the specificity of the gonococcal transferrin receptor complex to human transferrin as a source of iron [156,161]. This limits testing to cell culture models that include human serum in place of sera from animal sources as typically is used, and the use of the human experimental challenge model for testing the efficacy of this vaccine candidate.

## C. Other Advances in the Development of a Gonococcal Vaccine

### 1. Mab2c7 Antiidiotype

Yamasaki et al. [232] demonstrated that a monoclonal antibody, Mab2C7, binds to more than 90% of gonococcal isolates. This antibody is bactericidal (even in the face of sialylation) and opsonic. These investigators have proposed an idiotype/antiidiotype approach to gonococcal vaccine development. This antiidiotype approach allows vaccine development against LOS epitopes without immunization with toxic LOS. However, given the antigenic diversity of LOS and the lack of antiidiotypic vaccines for the prevention of other important infectious disease, this vaccinologic approach should probably be considered more theoretical than practical at this time.

## IV. CONCLUSIONS

Regardless of small fluctuations in incidence and prevalence, gonorrhea remains a major global public health

problem. Given the challenges for developing a vaccine for the prevention of gonorrhea, in the short term, more aggressive methods of diagnosis and treatment can be employed to decrease the incidence of this disease. One of the major problems in this area is compliance of the infected, typically adolescent, population to undergo STD testing. A significant step toward preserving the privacy of the adolescent would be the implementation of vaginal swabs self-collection used to diagnose *N. gonorrhoeae*. In a study addressing this [233], it was demonstrated that 2% of female students in this age group tested positive for gonorrhea using sensitive polymerase chain reaction (PCR)-based methods. The study also found that self-collection of vaginal swabs was almost uniformly reported as easy to perform and preferable to a gynecological examination. Nearly all of the study participants indicated that they would undergo testing at frequent intervals if self-testing was available. A similar finding regarding the positive merits of self-testing was independently reported by another group of investigators [234]. Clearly one of the most effective ways of controlling gonorrhea is the rapid and private diagnosis of this disease. Self-testing is an option that would empower a high-risk population to detect gonorrhea, and other STDs, that would otherwise remain undetected and untreated. After diagnosis, administration of effective antibiotic treatment will be required, which represents its own challenges given the emergence of antimicrobial resistance by the gonococcus. Furthermore, treating gonococcal infection will not prevent facilitated AIDS transmission and may not prevent reproductive tract sequelae.

The only reasonable conclusion that can be reached is that in the long term, a vaccine for the prevention and management of gonococcal infection remains as important today as when the quest for a gonococcal vaccine began some 30 years previous. Although a vaccine that prevents infection would be ideal, one that reduces transmission from an immunized but still infected host to his/her sexual partner would likely be of equal significance—particularly coupled with effective diagnosis and treatment.

The introductory chapters in this book are devoted to describing the ideal nature of a vaccine for infectious diseases of human significance. In a perfect world, a vaccine for the prevention of gonorrhea could be developed, therefore dispensing with issues of the diagnosis and treatment briefly described above. However, the unique pathobiology of gonococcal infection, which includes surface antigen variation and transient intracellular survival, along with limitations of animal model testing, makes the implementation of a safe and effective gonococcal vaccine very difficult. The development of such a vaccine would represent a “quantum leap” in the management of gonorrhea. In spite of this, we have learned an enormous amount about the biology and immunology of gonococcal infection. These are the data required to develop a rational vaccine. The failure of natural infection to offer protective immunity likely rests in the very poor mucosal response elicited.

Our challenges are clear: (a) we must develop immune strategies that force a vigorous mucosal response, so we can test the hypothesis that such a response can prevent infection; (b) this hypothesis can be explored in a mouse model, imperfect as it is; (c) this hypothesis can be validated rapidly

in the human challenge model, a huge advantage to gonococcal vaccine development; (d) surface-exposed antigens are attractive vaccine targets, and the fact that gonococci demonstrate an absolute requirement for iron offers unique epitopes for focus; and (e) sequencing of the gonococcal genome offers access to neoantigens that may be important to the organism and that evoke no response; such conserved neoantigens may ultimately prove of value. Most importantly, we must not become terminally frustrated or perceive lack of a vaccine as lack of success. Vaccines against STD pathogens remain the best way to control their spread [235]. What we learn about one pathogen (whether HIV, HSV, or gonorrhea) is relevant to the entire STD vaccine effort. Accordingly, now is the best time for increased effort in the development of a gonococcal vaccine.

## Vaccines Against *Campylobacter jejuni*

David R. Tribble, Shahida Baqar, and Daniel A. Scott

Naval Medical Research Center, Silver Spring, Maryland, U.S.A.

### I. INTRODUCTION

Surveillance data indicate that *Campylobacter jejuni* is the most common bacterial agent associated with diarrhea in the United States and, on a global basis, is an important bacterial cause of both endemic and travelers' diarrhea (TD). Compared to noninvasive causes of diarrhea, *Campylobacter*-associated diarrhea is generally more severe, with a longer duration of symptoms and frequent occurrence of severe cramps, bloody stools, and fever [1–3]. Recognizing the significance of this disease threat to military personnel (particularly when deployed to tropical regions and developing countries) [4–6], the Department of Defense (DOD) has sponsored a *Campylobacter* research program headed by the U.S. Navy that includes vaccine development activities.

### II. EPIDEMIOLOGY

*Campylobacters* are commensals of many wild and domesticated birds and mammals. These animals may become colonized at a very early age, with the organisms establishing themselves as part of their normal bowel flora [7,8]. Humans usually acquire infection by eating contaminated meat or poultry from animals colonized with the bacteria [9]. Diarrhea is by far the most common human illness, and *C. jejuni* is the dominant species associated with disease [2,10,11]. However, *C. jejuni*, as well as other members of the genus, are increasingly being identified as causes of bacteremia and a variety of systemic or localized infections in immunocompromised hosts [12–17]. *C. jejuni* is identified in association with diarrhea more frequently in developing countries [18–20]. Notable differences exist in the epidemiology of human *Campylobacteriosis* between developing and industrialized countries (Table 1) in regards to incidence, seasonality, age distribution, identified risk factors, clinical presentation/infection, and the subsequent public health impact.

#### A. *Campylobacter* as a Cause of Travelers' Diarrhea

In many studies *Campylobacter* spp. are second only to ETEC as a pathogen isolated in association with TD [19,21–31]. In most industrialized countries with temperate climates *Campylobacter* incidence peaks during summer, whereas in tropical regions no seasonality is observed [18–20]. *Campylobacter*-associated TD appears more severe than TD caused by other enteropathogens [21,31,32].

The high percentage of *Campylobacter* infections associated with diarrhea among U.S. military personnel studied in Southeast Asia does not appear to be related to doxycycline malaria prophylaxis, as it is also seen in troops taking mefloquine [27,33].

Antibiotic resistance to erythromycin, the newer macrolides, and the fluoroquinolones exacerbates the threat of *Campylobacter*-associated diarrhea [34–41]. The trend of increasing fluoroquinolone resistance reinforces the rationale to develop a vaccine against this agent [34,39–41].

#### B. *Campylobacter* as a Cause of Endemic Diarrhea

*C. jejuni* is now believed to be the most common bacterial cause of diarrheal disease in the United States [18,42,43]. Rarely, large community outbreaks occur from consumption of food, particularly raw milk, or contaminated water [10,44,45]. In contrast, sporadic cases and household epidemics are extremely common, resulting from eating contaminated poultry or other meat. Person-to-person transmission is rare. A Center for Disease Control and Prevention multi-hospital study found that *Campylobacter* sp. were isolated from diarrhea stools twice as frequently as *Salmonella* sp. and over four times as often as *Shigella* sp. [3]. Similar data were obtained in two studies by a Seattle health maintenance organization that found the incidence of laboratory-confirmed *Campylobacter*-associated diarrhea to be 50–71 cases per 100,000 population per year, or about twice as frequent as *Salmonella* and *Shigella* combined [46,47]. Because these

**Table 1** *Campylobacter jejuni*-Associated Diarrheal Disease: Lesser Developed Vs. Industrialized Countries

Factors	Lesser developed countries	Industrialized countries	Reference(s)
Incidence	40,000/100,000 annual 0.4–0.6 episodes/child-year (≤3 years old)	14–22/100,000 annual (United States) 50–150/100,000 annual (in other industrialized countries)	[18–20,56]
Seasonality	Not evident	Summer peak (in temperate climates)	[18–20]
Age distribution	Typically limited to first 2 years of life (peak at 6–12 months old)	Highest <1 year old (53/100,000 in the United States) Second peak noted in young adulthood (particularly males)	[18–20,56]
Risk factors	Primarily sporadic disease Complex, multiple sources of exposure; identified risks include poor hygienic conditions and presence of animals in household	Primarily sporadic disease Identified risks: poultry consumption, transmission from pets, contaminated drinking water, raw milk consumption, and foreign travel	[18,19,56]
Clinical syndrome	Childhood watery diarrhea Less severe disease observed in developing countries	Spectrum of illness: watery diarrhea to dysentery; frequent fevers and abdominal cramps (less severe in children)	[10,19,20,32]
Infection	Frequent asymptomatic infection in early childhood	Infrequent asymptomatic infection	[19,20,56,122]
Disease impact	Duration of excretion ≤1 week Estimated 400 million cases/year  Associated with severe dehydration (13%) Contributor to overall infant morbidity/mortality from diarrheal disease  Chronic sequelae (not quantified)	Duration of excretion 2–3 weeks Estimated 2.4 million cases/year in the United States  Case fatality rate low (0.08%)  Significant economic burden  Chronic sequelae (Guillain–Barré syndrome—estimated as 1 GBS case/1–3000 <i>Campylobacter</i> infections)	[18–20,54,56,74]

studies included only patients who sought medical attention and had a stool culture done they likely underestimate the true disease incidence. Tauxe has estimated the total incidence of *Campylobacter*-associated illness in the United States by extrapolating from data obtained during investigation of a U.S. waterborne outbreak in which 1 of 18 who became ill consulted a physician [18,48]. Applying the same ratio of ill-to-treated patients to published estimates for the number of laboratory confirmed clinical cases and case-fatality rates, he estimates that the total number of *Campylobacter*-associated diarrhea cases in the United States is as high as 2.4 million per year (1% of the total population), resulting in about 200 to 700 deaths [49].

The major impact of *Campylobacter* diarrheal disease in industrialized countries stems from short-term morbidity and economic burden. Mortality typically is limited to populations at the extremes of age, particularly the elderly, and immunocompromised individuals [50]. Mead et al. estimated

13,000 hospitalizations due to *Campylobacter* spp. occur annually in the United States with approximately 125 deaths [50]. *Campylobacter* is also the leading foodborne pathogen observed in European surveillance systems [18].

In developing countries, where hygiene and sanitation are often suboptimal, the incidence of *Campylobacter* enteritis in children under 5 years of age is as high as 40,000/100,000, or 0.4 episodes per child per year [52,53]. One estimate suggests that as many as 400 million cases of *Campylobacter* diarrhea may occur annually worldwide [54]. Isolation rates of *Campylobacter* in children with diarrheal disease (typically ≤2 years old) range between 5% and 18% [20], but, in contrast to industrialized countries, asymptomatic infections are commonly observed, with prevalence rates as high as 15% [55]. Given the prevalence of this infection in healthy children it is challenging to discriminate the impact of campylobacter on child health in developing countries [56].

### III. CLINICAL SPECTRUM OF DISEASE

*Campylobacter* enteritis can present with a range of symptoms from watery diarrhea to dysentery [32]. Most frequently, there are moderate volumes of watery diarrhea that contain leukocytes and mucus. Frank blood is found in about 20–50% of cases. There is usually an accompanying fever and abdominal cramps which can be severe. Untreated acute infection usually runs its course in 3 to 5 days, followed by shedding of the organism for several days to weeks.

Two strains of *C. jejuni* (81–176 and A2349) fed to healthy adult North American volunteers both caused disease, but strain 81–176 (utilized by our group in a killed whole-cell vaccine) was much more virulent. Clinical illness included diarrhea, fever, dysentery, malaise, and abdominal cramps [1].

Like *Salmonella*, *Shigella*, and *Yersinia*, *Campylobacter* enteritis has been associated with development of a reactive arthritis/arthropathy (RA) [57–64]. Studies of outbreaks [59,63] and case series [60,65] have found an incidence of rheumatic complaints ranging from about 1% to 14% in subjects with evidence of *C. jejuni* infection. However, these studies did not use a consistent definition of reactive arthritis and included patients with joint symptoms that, in some cases, lasted only 3 to 7 days [60]. In the majority of reported cases, symptoms resolved completely. A genetic predisposition to acquiring a seronegative spondyloarthropathy after a bacterial enteric infection (approximate risk gradient: *Yersinia* spp. > *Shigella* spp. (*S. flexneri*) > nontyphoidal *Salmonella* > *C. jejuni*) has been observed in individuals with the human leukocyte antigen HLA-B27 [66]. An overall estimated 18-fold increased risk of reactive arthritis exists for HLA-B27 positive as compared to negative individuals following one of these infections [66].

A more devastating complication of *Campylobacter* infection is Guillain–Barré syndrome (GBS) [9,67–76]. Based on epidemiological studies involving both serology and culture results, approximately 30–40% of patients with GBS have had a *C. jejuni* infection in the preceding 10–21 days [66,70,75]. *C. jejuni*-associated GBS appears to be associated with a more severe clinical presentation [76]. Published data from a large case-control study of *Campylobacter*-associated GBS by Rees and coworkers showed evidence of *C. jejuni* infection in 26% of the 103 GBS and Miller–Fisher syndrome patients, compared to 2% of household controls, and 1% of hospital controls. *Campylobacter*-associated GBS more commonly presented with weakness as a first symptom had less severe sensory deficits at the peak of illness but had significantly greater disability at a 1-year follow-up than non-*Campylobacter*-associated GBS cases [77]. The pathogenesis of *Campylobacter*-associated GBS is unclear but may involve “molecular mimicry” wherein peripheral nerves share epitopes with some *C. jejuni* antigens. Thus an immune response, which is initially mounted against the infection, may be misdirected to the peripheral nerve in some convalescing patients. An association between GBS and infection with *C. jejuni* strains of the heat stable (HS) Penner serotype HS19 has been noted by several groups [67,71,78–81] as well as an association with HS41 serotype, particularly in South Africa [82,83]. The antigenic determinant of the

heat stable serotyping scheme was felt to be lipooligosaccharide (LOS), and structural analyses of *C. jejuni* LOS identified structures that resemble gangliosides (such as GM1, GD1a, and GQ1b) present on human nerves. But the antigenic determinant of the Penner serotyping scheme has recently been shown to be a phase-variable capsule in many strains. Karlyshev et al. found that capsular mutants in five out of six strains had lost the ability to be serotyped in the Penner scheme [84] and Bacon et al. showed that capsule mutants of *C. jejuni* 81–176 lost the HS23 and HS36 serotypes and showed reduced virulence [85]. But a capsule mutant of *C. jejuni* 81–116, which was serotyped as HS6,7, was serotyped as HS6 only, suggesting that the HS serodeterminant in most strains is capsule, but that the situation is complex [84]. The molecular structure of the capsule and any role in the pathogenesis of GBS remain unknown. Genetic predisposition of the host may also play a role [73,86].

### IV. ANIMAL MODELS OF CAMPYLOBACTER

*Campylobacters* naturally colonize numerous domestic and laboratory animal species, but usually without clinical signs of disease. This lack of disease has made the development of an animal model to be used in *Campylobacter* vaccine development challenging. This has led to the development of models using very young or surgically manipulated models that are cumbersome or not well suited to the study of vaccine efficacy [87–92]. Susceptibility to *C. jejuni*-induced diarrhea decreases rapidly with age, making these models more useful for pathogenesis studies than vaccine development [87,93]. As it has not been established that the mechanism(s) of diarrhea in nonprimate mammalian newborns or manipulated nonprimate animals is the same as that in humans, the relevance for humans of findings made in nonprimate mammals remains unanswered. *Campylobacteriosis* models investigated include nonhuman primates, piglets, rabbits, ferrets, mice, and chickens.

Experimental infection of very young rhesus monkeys with *C. jejuni* closely mimics human disease and *Campylobacter* enteritis appears to be an important cause of diarrhea in primate colonies [1,87]. After experimental infection, the onset and duration of the disease, infection-associated pathology and development of acquired immunity appear to make nonhuman primates an attractive model for human campylobacteriosis. However, these studies have not been duplicated in older animals. Attempts are underway to develop a *Campylobacter* disease model using adult rhesus and New World monkeys. Rhesus monkeys have been used to test the safety and immunogenicity of an adjuvanted *Campylobacter* whole-cell vaccine [94].

Gnotobiotic and newborn, colostrum-deprived piglets have both been shown to develop diarrhea when challenged orally with *C. jejuni* [95,96]. The disease affects mainly the colon and is similar histopathologically to that seen in humans. However, the requirement for newborn animals makes this a logically difficult and expensive model for most laboratories and limits its application to vaccine development.

Overt diarrheal disease can be induced when young ( $\leq 1$  kg) rabbits are challenged with strains of *Campylobacter*,

using the removable intestinal tie adult rabbit diarrhea (RITARD) procedure. In the RITARD surgical model, the cecum is ligated to prevent reabsorption of fluid and a reversible tie is placed below the bacterial inoculum to impede normal bowel motility and improve bacterial attachment and colonization. When young rabbits are challenged in this manner with live motile *C. jejuni*, most animals become bacteremic and develop diarrhea characterized by loose, mucus containing stools [97]. Older rabbits challenged by the RITARD procedure become colonized but fail to develop diarrhea. Therefore it cannot be used to measure protection against disease offered by vaccine candidates. But young rabbits can be orally immunized with either live strains or vaccines and then, approximately 30 days later, challenged via the RITARD procedure with either the same strain or a heterologous organism to measure protection against colonization. Protection against colonization in this model seems to be Lior serotype-specific. Thus immunization with one strain of *Campylobacter* protects against other strains of the same Lior serogroup, but not strains of other Lior serogroups [98,99].

In search of a suitable small animal model, different strains of mice and rats, bacterial isolates and routes of infection have been explored [91–93,100–110]. Mice can be used in a nondiarrheal disease model using oral, intranasal, or intraperitoneal routes of challenge [101,102,109]. An oral/intranasal immunization-intranasal challenge murine model has been adapted from its original use in studies of *Shigella* immunity [102,110]. Naive mice infected intranasally with virulent strains of *Campylobacter* develop pulmonary disease, accompanied by weight loss and other signs of illness including ruffled fur hunched back, dehydration, lethargy, and sometimes death [102]. Following intranasal infection, most strains colonize the intestine and some strains disseminate to the liver, spleen, and other organs. This model of oral/intranasal immunization followed by intranasal challenge appears to be useful in measuring the immune response to candidate vaccine antigens, and protective efficacy as measured by protection against pulmonary disease, intestinal colonization, and disseminated disease.

Young ferrets develop diarrhea when naturally or experimentally infected with *C. jejuni* via the oro-gastric route. Adult ferrets that have been intragastrically inoculated with some strains of live *Campylobacter* (e.g., *C. jejuni* 81–176) develop enteric symptoms lasting up to 3 days and remain colonized for up to 8 days [111]. Ferrets, which have been “immunized” in this manner, do not develop disease when rechallenged with the same strain. However, colonization resistance does not develop until after several additional exposures. This is similar to human volunteers studies where protection against disease develops before colonization resistance. However, difficulty in obtaining *Campylobacter*-free ferrets and the lack of ferret-specific immunologic reagents limit the utility of this model for studying acquired immunity.

An avian model of campylobacteriosis has been employed for studies of pathogenesis and immunity [90,112], and the immunoreactive complication, Guillain–Barré syndrome [113]. Whether results obtained with various animal

models can be extrapolated to the human-*C. jejuni* parasitism remains to be seen.

## V. IMMUNE RESPONSES TO CAMPYLOBACTER

Although infection with *Campylobacter* has been shown to provide protective immunity, relatively little is known about the nature of acquired immunity, correlates of protection, or the mechanism(s) of protection against this infection. Evidence for acquired immunity to *C. jejuni* comes mostly from epidemiological studies of residents of developing countries. Children living in endemic areas have frequent symptomatic infections in the first one to three years of life, but with increasing age and acquired immunity, the frequency of symptomatic disease decreases compared to asymptomatic infection [53,114–122]. Moreover, the number of *C. jejuni* excreted per gram of stool of infected individuals also declines with increasing age [122], as does the duration of excretion of the organism [53].

Direct evidence of acquired immunity to *C. jejuni* in man comes from the study of infection in volunteers. To evaluate the protective immunity induced by prior disease, volunteers who became ill after an initial challenge were rechallenged 28 days later [1]. The rechallenged volunteers were completely protected from illness, and some were protected against colonization after rechallenge with a homologous strain.

During the acute phase of infection IgA or IgM antibodies are elevated followed by induction of IgG in serum [30,123]. In challenge studies, volunteers with the highest prechallenge levels of anti-*Campylobacter* serum IgA were the least likely to develop disease [1]. In a field study, individuals with higher preexposure levels of *Campylobacter*-specific IgA in circulation were less likely to get *Campylobacter* disease in an endemic area [30]. Naturally acquired *C. jejuni* infection elicits antibodies which recognize *C. jejuni* antigens, and the titers of these antibodies increase with age [114,116,117,120–122]. The antigen preparations used in these studies contain outer membrane and flagellar proteins that appear to be antigenic [124,125]. In a recent *Campylobacter* case report, infecting strain-specific ~32 and 34 kDa proteins were detected early in infection (IgA first detected at day 3 after onset) and peaked at 10 (IgA) or 34 (IgG) days. IgA wanes, but IgG persists for at least 4 months [126]. Others have reported similar patterns of *Campylobacter*-specific antibodies of various isotypes [123]. The durability of these antibodies may be dependent on the endemicity of the agent. In endemic areas the level of acquired immunity may be maintained by repeated asymptomatic exposure to the same or cross-reactive *Campylobacter* serotypes. The level of mucosal antibody is probably more important than serum antibody levels in the protection against *Campylobacter* infection. Anti-flagellar IgA has been identified in human breast milk and has been shown to protect children from *C. jejuni* diarrhea [127,128]. A vaccine challenge study conducted at the Naval Medical Research Center also suggests a protective role of *Campylobacter*-specific fecal IgA.

Little information is available on cellular immune responses to *C. jejuni*, and the limited data available are on the role of T cell subset recognition in GBS patients [129,130]. Cellular responses might play important roles as helpers in antibody formation, in the clearance of *C. jejuni* as well as recall of memory response upon reexposure. A vigorous and sustained antigen-specific, IFN- $\gamma$ -dependent lymphocyte proliferative response was seen in a naturally acquired *C. jejuni* infection [126]. Our unpublished data also support the role of Th-1-type IFN- $\gamma$ -dependent cell-mediated immune response in protecting volunteers from a homologous rechallenge with *C. jejuni*. Given the complex and highly regulated cytokine network, it is difficult to determine the precise role of a given cytokine in *Campylobacter* infection and immunity. We have recently shown that the high levels of pro-inflammatory cytokines such as IL-1 and IL-8 in stool and, to a lesser magnitude, in serum and CRP in circulation are present during the acute phase of the infection. In contrast, IFN- $\gamma$  and IL-6 appear in circulation at 4–8 days of onset, suggesting the regulatory roles of these cytokines in immunity [126]. Heretofore, it has not been possible to demonstrate a definitive association between any specific antigen and protection.

## VI. PATHOGENESIS/PROTECTIVE EPITOPES

Although *C. jejuni* is a leading cause of diarrheal disease worldwide [4,5,11,18–20,22], little is understood about the mechanisms by which it causes disease. Moreover, compared to other diarrheal agents (e.g., *Shigella* and ETEC), there is a paucity of information available on the development of rational vaccines against *C. jejuni*. Studies aimed at deciphering the virulence mechanisms of *C. jejuni* have been hampered by a number of unique aspects of this pathogen, including limitations in systems of experimental genetics and in nonprimate models of diarrheal disease.

Flagella and motility are clearly virulence determinants in all strains of *C. jejuni* [1,131,132]. Moreover, flagellin is the immunodominant antigen recognized during infection, including human volunteer feeding studies, and has been suggested to be a protective antigen [120]. *C. jejuni* flagellin is a glycoprotein that contains conserved and hypervariable protein domains [133–135]. The carbohydrates are surface exposed in the filament and variations in the structure of the pseudaminic acids found on the filament appear to contribute to the antigenicity of flagellin.

Other putative virulence factors include the PEB proteins and cytolethal distending toxin [136–140]. The PEB proteins may act as adhesins. Cytolethal distending toxin is a multisubunit toxin that causes cell cycle arrest, cytoplasm distention, and, eventually, chromatin fragmentation and cell death [137]. One of the subunits of this toxin, CdtB, was shown to exhibit features of type 1 deoxyribonucleases [141]. The toxin is membrane bound and highly conserved among strains [142].

To better understand *Campylobacter* pathogenesis, the Sanger Institute has sequenced the genome of one strain of *C. jejuni*, NCTC 11168, which was a clinical isolate from the

United Kingdom [143]. Analysis of the sequence has revealed a number of interesting features such as the presence of capsule genes [84,85], and hypervariable regions upstream of capsule, LOS, and protein glycosylation genes. Although the sequence provided numerous insights into the ultrastructure, biology, and physiology of *C. jejuni*, it offered few clues into the pathogenesis of the organism. Other than the known cytolethal distending toxin, no cytotoxins or enterotoxins were identified. In addition, there were no genes encoding proteins with homology to known invasins or other known virulence determinants; neither was there evidence of a type III secretion system found in other enteric pathogens.

Current data suggest that comparative genomic studies may yield additional data on pathogenesis that will impact vaccine development efforts. *Campylobacter* infections can present with a variety of symptoms from watery diarrhea to dysentery and there may be multiple mechanisms of pathogenesis, similar to diarrheagenic *E. coli*. There is a range in the ability with which *C. jejuni* can be internalized into intestinal epithelial cells. Strain 81–176, which has been shown to cause disease in volunteer studies, invades at exceptionally high levels (2–5% of the input inoculum) compared to other strains [144–148]. Most other strains invade INT407 cells at levels below that of an *E. coli* K-12 negative control, and this includes NCTC 11168. We have also observed a gradation of symptoms in the ferret model among different strains. In this model the animals are fed different doses of *C. jejuni* and within 24 hr the animals develop diarrhea. Strain 81–176 is the most virulent strain tested in this model and causes a mucus diarrhea, often with occult or frank blood. Mutants of 81–176 defective in invasion show attenuation in the ferret model [85,132,149]. Other, less invasive strains cause a markedly milder diarrhea, and others (e.g., NCTC 11168, as mentioned above) cause no diarrhea [149].

Consistent with the above observations, there are differences in virulence genes among strains of *C. jejuni*. *C. jejuni* 81–176 contains two plasmids not present in NCTC 11168 which encode a number of proteins with significant homology to proteins in type IV secretion systems of other pathogens. Type IV secretion systems are specialized systems of protein transport in bacteria. Additionally, there appear to be differences in the chromosomal genes of different strains of *C. jejuni*. A recent microarray study indicated that as much as 21% of the genome of NCTC 11168 is missing in 11 other strains of *C. jejuni* [150]. This study indicated that 3.9% of the NCTC 11168 genes were missing in 81–176. These data and ongoing comparative studies will be useful in elucidating campylobacter pathogenesis and in identifying widely conserved antigens as vaccine targets.

## VII. CAMPYLOBACTER VACCINE STRATEGIES

### A. Killed Whole Cell Vaccines

Inactivated microorganisms offer several advantages as potential vaccines for mucosal immunization. Physically, they are naturally occurring microparticles, which should enhance interactions between their surface and mucosal lymphoid tissues. As vaccines they are relatively inexpensive to

produce and contain multiple antigens that may be important for protection. Presentation of multiple antigens may be particularly important for *Campylobacter*, for which protective antigens are not known. Although not suitable for parenteral administration, whole-cell preparations are safe for mucosal immunization.

Killed whole-cell vaccines have been developed for enterotoxigenic *E. coli* and *V. cholerae* O1, and the cholera vaccine is now marketed in Europe. This vaccine contains heat and formalin-killed *Vibrio cholerae* whole cells (WC), of different biotypes and serotypes, plus the nontoxic B subunit (BS) of cholera toxin. A randomized, double blind, placebo-controlled field trial involving 63,000 individuals in rural Bangladesh established the safety, immunogenicity, and efficacy of an early formulation of the WC/BS cholera vaccine. Three doses of the WC/BS vaccine conferred 85% protection against cholera for the first 6 months in all age groups tested, and 51% overall protection after 3 years [151–154]. No adverse effects attributable to the vaccine were reported. The same WC/rBS vaccine provided 86% protection against ETEC diarrhea in Finnish travelers [158]. More recently, a new formulation of the WC/BS cholera vaccine, containing a recombinant cholera toxin B-subunit (WC/rBS), was also found to be safe and give high levels of protection against symptomatic cholera in Peruvian military recruits [155,156]. Larger-scale studies in civilian populations in Peru have not shown any efficacy for a two-dose regimen but administering a third (booster) dose after 1 year was followed by ~60% protection observed over the ensuing 12 months of follow-up [157]. Although not as immunogenic as live attenuated *V. cholerae* strains [159,160], these vaccines have proven the concept that an orally administered, whole-cell vaccine can be safe and provide reasonable protection against an enteric pathogen.

Because of the success with other killed whole-cell vaccines, the NMRC has studied the hypothesis that a killed whole-cell vaccine against *Campylobacter* could be safe, immunogenic, and protect against disease. But in contrast to *V. cholerae*, campylobacters are invasive, and protection may be more difficult to achieve, so combining the vaccine with a mucosal adjuvant such as *E. coli* heat-labile toxin (LT) or one of its less toxin derivatives was felt to be important [161,162]. Initial studies using *C. coli* VC167 showed that when sonicated cells were combined with 25 µg of LT and given orally to mice, the mucosal immune response was equal to live infection with the same strain [163]. The duration of intestinal colonization after live challenge could also be significantly shortened in mice or rabbits immunized with sonicates plus LT, but not by immunization with sonicates alone. Studies using a mixture of heat and formalin-killed *C. jejuni* 81–176 in mice have shown that LT enhances the mucosal immune response over a wide range of vaccine doses [101]. Mice were orally immunized with three doses of  $10^5$ ,  $10^7$ , or  $10^9$  vaccine particles alone, or in combination with 25 µg of LT. Significant *Campylobacter*-specific IgA and low levels of IgG were detected in intestinal lavage fluid only after immunization with adjuvanted vaccine. In contrast, whole cells with or without LT stimulated similar levels of *Campylobacter*-specific serum antibody levels. The optimal secretory immune response was induced

following vaccination with  $10^7$  CWC-LT formulation suggesting that the ratio of adjuvant to inactivated cells may be important. When challenged orally with live *C. jejuni* 81–176, mice immunized with any dose of whole cells plus LT showed colonization resistance, whereas only the highest dose of CWC alone ( $10^9$  cells) gave comparable protection. Both vaccine formulations provided similar levels of protection against the systemic spread of challenge organisms [101].

In follow-on experiments, the relative protective efficacy and duration of immunity induced by CWC or CWC-LT vaccines were compared in an oral immunization-intranasal challenge model [102]. Both CWC and CWC-LT formulations provided varying degrees of protection against illness and intestinal colonization for up to 4 months after completing the two-dose primary immunization series (14-day intervals). However, the adjuvanted preparation appeared superior to formalin-inactivated whole cells alone in that immunity in this vaccination group was still evident in mice at 8 months post-immunization (S. Baqar, personal communication). In vitro T-cell proliferative responses to *C. jejuni* antigens were also measurably enhanced by the addition of LT. Two doses of orally administered CWC vaccine with or without LT were well tolerated in rhesus monkeys [101]. Elevated *Campylobacter*-specific IgA and IgG antibody-secreting cells (ASCs) were detected in the peripheral blood of most animals after vaccination, but the IgA ASC response was significantly enhanced by the co-administration of LT in a dose-dependent manner. Heat-labile toxin also significantly enhanced the serum *Campylobacter*-specific IgA and IgG responses. These results suggested that both killed whole-cells alone, and LT-adjuvanted preparations, are promising oral *Campylobacter* vaccine candidates. In various animal models, the addition of LT enhances the mucosal and serum immune response to *Campylobacter* antigens, increases the protective efficacy of the CWC at lower vaccine doses, and prolongs the duration of immunity compared to CWC alone. Given these data, clinical evaluation of a CWC vaccine was undertaken in human volunteers.

Currently, we are studying a monovalent, formalin-inactivated, whole-cell vaccine (CWC) made from *C. jejuni* 81–176 (Penner serotype 23/36; Lior serogroup 5). This strain is invasive in cell culture [148,164] and was originally isolated from the feces of a 9-year-old girl with diarrhea who became ill during a milk-borne outbreak in Minnesota [165]. In 1984, the strain was used in a human volunteer study at the Center for Vaccine Development, University of Maryland, described above [1]. The organism used to make the vaccine was recovered from a challenged volunteer with diarrhea. The vaccine is grown under conditions that maximize motility/flagella expression and ability to invade eukaryotic cells in vitro, and then inactivated using 0.2% formalin. The final preparation was shown to have intact flagella by electron microscopy and to retain its ability to agglutinate in Lior 5 antisera.

Volunteer studies have shown the vaccine to be generally safe and moderately immunogenic. However, when given in a two-dose regimen such as that used for the whole-cell cholera vaccine, the vaccine did not protect in a volunteer

challenge study. Nevertheless, there was a trend toward less severe disease in volunteers receiving the vaccine. Recent studies have shown that the immune response to the vaccine can be improved using a four-dose, short-interval vaccination regimen such as that used for live oral typhoid vaccine Ty21a (D. Tribble, unpublished data). Specifically, while a two-dose, 14-day regimen induced no fecal IgA response, the four-dose regimen produced a mean 13-fold rise in fecal IgA. It is not yet known if the enhanced immune responses will be adequate to provide protection against disease.

### B. Subunit Vaccines

Another approach is a recombinant protein vaccine based on a conserved surface-exposed antigen that has been shown to induce an immune response after infection. Because such a vaccine would not contain LOS or capsule it would not have any ganglioside mimicry and would therefore, presumably, have no risk of inducing GBS. Several *Campylobacter* antigens have been suggested as subunit vaccine candidates for use either as purified recombinant proteins or expressed in carrier vaccine strains such as live attenuated *Salmonella* or *Shigella*. Purified proteins could be delivered to the mucosa by oral or intranasal administration, or given parenterally.

A general characteristic of *Campylobacter* species is its rapid, darting motility. Sustained motility contributes to pathogenesis of diarrheal disease. Studies have shown that nonmotile mutant *Campylobacter* strains fail to colonize experimental animals or volunteers, nor do they invade epithelial cells in vitro [1,98,131]. A single uni- or bipolar flagellum, composed of a major [1,98,131] flagellin subunit, FlaA, and a minor FlaB subunit, imparts motility. *Campylobacter* flagellin has long been recognized as an immunodominant antigen recognized during infection, and numerous studies have suggested a role in protection [115,120,166,167]. The overall structure of *Campylobacter* flagellins is similar to those of the *Enterobacteriaceae* in that the amino and carboxyl ends, which function in the transport and assembly of the monomers into the filament, are highly conserved among different *Campylobacter* strains, and the central region appears antigenically diverse [134]. Power et al. have studied the antigenicity of *C. coli* VC167 flagellin in detail and have shown that the major immune response seems to reside in the highly conserved amino and carboxy ends of the protein [134].

Epidemiologic studies in children from the developing world provide evidence of protective immunity through investigations of clinical presentation, stool microbiology, and *Campylobacter*-specific immunology. Direct evidence of the importance of flagellin as an immune correlate of clinical outcomes derives from studies of breast-fed Mexican infants (<6 months old) [127]. A lower incidence of *Campylobacter*-associated diarrhea occurred in infants whose mothers had colostral *Campylobacter*-specific secretory IgA antibodies detected in breast milk.

During the last few years, researchers at NMRC have developed a recombinant subunit vaccine composed of truncated FlaA flagellin of *C. coli* VC167 fused to maltose binding protein of *Escherichia coli* [168]. The region of flaA

encoding amino acids 5–337 was chosen because of its high conservation among different strains of *Campylobacter*, and because this region has been demonstrated to be immunogenic [134]. Additionally, native *Campylobacter* flagellin is heavily glycosylated, and the region of the protein between amino acids 5–337 contains only a single glycosylation site [135].

The recombinant truncated flagellin protein (rFla-MBP) has demonstrated cross-species protection in murine models of *C. jejuni* pathogenesis [168]. Intranasal rFla-MBP vaccination induces higher levels of specific intestinal IgA and serum IgA and IgG antibodies than oral administration. In addition, a ferret diarrhea model has been used to study the safety, immunogenicity, and efficacy of the rFla-MBP vaccine. Intranasal immunization with a three-dose regimen of rFla-MBP (100 µg) provided an approximately 60% protective efficacy from diarrheal illness following oral challenge with  $1 \times 10^{10}$  CFU *C. jejuni* strain 81–176.

Another protein which has been suggested as a potential subunit-based vaccine target is PEB1, a highly immunogenic protein conserved among *C. jejuni* strains, which has also been suggested to function as an adhesin to eukaryotic cells [139]. PEB1 has high sequence similarity to the binding component of several amino acid transport systems, an observation that remains to be reconciled with a putative role in virulence. A subunit of cytolethal distending toxin may also be a vaccine candidate. As more is understood about pathogenesis of *Campylobacter* sp., it is likely that additional subunit target proteins will be identified which are conserved among strains sharing the same mechanisms of pathogenesis.

### C. Live Attenuated Vaccines

Live attenuated oral vaccines also have the potential to deliver the full complement of protective antigens, even if they have not been identified, and to be effective after only a single dose. Several live attenuated oral vaccines have been shown to effectively stimulate mucosal immunity and provide excellent protection in field or volunteer challenge studies. These include vaccines attenuated by serial passage (oral polio), chemical mutagenesis (the Ty21A vaccine strain of *Salmonella* Typhi), or targeted deletion of genes encoding important virulence factors (e.g., attenuated cholera vaccine strain CVD 103-HgR which has a deletion of the gene encoding cholera toxin A subunit) [169–172]. Using genetic methods to engineer a living attenuated *Campylobacter* vaccine is an attractive approach. This would allow the inclusion of the full complement of antigens, but selecting the appropriate mutations is complicated by the paucity of information on pathogenesis. Recent advances in pathogenesis research and sequencing of the *Campylobacter* genome provide numerous targets, and inclusion of a recA mutation [164] would preclude reversion to wild type by this naturally transformable enteropathogen [173]. On the other hand, the fact that there is currently an incomplete understanding of the mechanisms by which wild-type *Campylobacter* induces Guillain–Barré syndrome argues against pursuing the strategy of developing live attenuated vaccine strains (or at least calls for exercising caution).

## Vaccines Against Uropathogenic *Escherichia coli*

Solomon Langermann and W. Ripley Ballou, Jr.

MedImmune, Inc., Gaithersburg, Maryland, U.S.A.

Acute urinary tract infections (UTIs) are among the most common disorders prompting medical evaluation. A recent retrospective analysis demonstrated that 40% of adult women in the United States experience at least one UTI sometime during their lifetime [1], with a per year incidence rate between 0.5% and 0.7% in young adult females [2]. This results in approximately seven million office visits each year with an estimated annual health care cost exceeding \$1 billion [3]. *Escherichia coli* are the main causative agents of UTIs [4,5] and account for about 80–85% of cases of acute cystitis and pyelonephritis. *E. coli* also causes 60% of recurrent cystitis cases and at least 35% of recurrent pyelonephritis infections. In children an *E. coli* etiology is still more frequent [6,7]. Childhood pyelonephritis, which is almost exclusively caused by *E. coli*, has been a leading cause of end-stage renal disease [8]. One method of eliminating acute UTIs as well as preventing recurrent UTIs and ascending infections is the use of regular or intermittent antimicrobial prophylaxis [9]. Concern about the emergence of antibiotic-resistant bacterial strains limits the long-term feasibility of this approach. Given the high incidence of both primary and recurrent UTIs, along with the associated morbidity and significant cost of treatment, a prophylactic vaccine to block infection of the urinary tract by *E. coli* would be desirable.

In order for UTIs to occur, *E. coli* that originate in the bowel and ascend into the bladder must first attach to the uroepithelial cells lining the bladder mucosa. Numerous studies have shown that a bacterial ligand or adhesin known as FimH mediates attachment to the bladder epithelium and that the FimH adhesin is critical for cystitis to occur [10,11,12,13,14]. The FimH adhesin protein is located at the distal tip of proteinaceous, filamentous polymeric organelles, known as type 1 pili or fimbriae, expressed on the surface of the bacteria [15]. FimH interacts specifically with mannosylated glycoproteins known as uroplakin 1a and 1b that line the bladder mucosa [16] leading to bacterial colo-

nization and replication. These cellular receptors contain a single N-linked carbohydrate of the high-mannose type [17], common to most glycoproteins recognized by FimH.

Aside from its role in colonization, FimH is also involved in subsequent stages of pathogenesis. FimH-mediated binding to the bladder mucosa induces the expression of proinflammatory cytokines and chemokines by uroepithelial cells, resulting in neutrophil recruitment and the massive inflammatory response characteristic of cystitis. FimH has also been shown to induce exfoliation of uroepithelial cells by an apoptosis-like mechanism upon attachment to the epithelium followed by rapid reconstitution of the urothelium through differentiation of underlying basal and intermediate cells [18]. Furthermore, FimH mediates invasion of *E. coli* into the bladder epithelium, a mechanism that allows for survival and persistence of *E. coli* in the bladder [19].

Given the essential role of type 1 pili and in particular FimH in the initial stages of bladder colonization, antibodies targeting FimH should prevent UTIs. In addition to blocking attachment at the site of entry and colonization of mucosal surfaces at the earliest stage of the disease process, antibodies against FimH might also promote opsonization of bacteria that have invaded beyond the superficial epithelium for clearance by the systemic immune system. Furthermore, antibodies against the FimH adhesin might also be expected to protect against subsequent bacterial invasion or ascending infection into the kidney.

We have developed FimH as a vaccine candidate against UTI and have tested it in various animal models and surrogate in vitro assays. Our efforts have been focused on the development of a recombinant subunit vaccine that contains the FimH adhesin complexed with its cognate chaperone FimC, which is critical for proper folding and stabilization of the full-length adhesin [20]. The FimCH complex (FimC + FimH) forms the basis of a pilus vaccine candidate against *E. coli* UTI. Preclinical data with FimCH indicate that it induces high levels of serum IgG directed against functional

domains on the FimH adhesin. Anti-FimH IgG transudates into urogenital secretions and confers protection against colonization of bladder epithelium in several challenge models. The preclinical data suggest that the FimCH vaccine may have utility in preventing UTIs in humans.

### I. CHOICE OF THE FIMCH COMPLEX AS A VACCINE VERSUS FIMH SUBUNIT ALONE OR WHOLE PILI

Type 1 pili are composed of single or multiple protein subunits, called pilins or fimbriins, which are typically arranged in a helical fashion. They are expressed peritrichously around individual bacteria and range from a few fractions of a micrometer to greater than 20  $\mu\text{m}$  in length and vary from less than 2 nm up to 11 nm in diameter. The primary function of the type 1 pilus is to act as scaffolding for the presentation of the associated 29.1-kDa FimH adhesin protein. High-resolution electron microscopy of type 1 pili of *E. coli* has revealed that these structures are composite fibers, consisting of a thick pilus rod attached to a thin, short distally located tip fibrillum with the adhesin located at the distal end of the tip fibrillum [15,21,22]. Its location at the distal tip of the pilus allows the FimH adhesin to mediate interactions of bacteria with each other, with inanimate surfaces, and with tissues and cells in susceptible host organisms. Such interactions facilitate the formation of bacterial communities such as biofilms and are often critical to the successful colonization of the host by both commensal and pathogenic bacteria [23].

Early studies using purified whole type 1 pili as immunogens demonstrated that these vaccines induced some protection against *E. coli* infections in animals and man [24,25], although these vaccines were not tested in the context of UTIs. A major disadvantage to pilus-based vaccines has been the fact that the major immunodominant components of pilus fibers are often highly variable antigenically and therefore afford protection against only a limited number of bacterial strains. In contrast, pilus-associated adhesins, such as FimH, are highly conserved proteins among different species and strains of bacteria. However, adhesin-based vaccines have been difficult to develop given the inherent instability of these proteins. Recombinant technology has been used to produce adhesin proteins in pure form but as such are often rapidly proteolytically degraded when the corresponding periplasmic chaperone protein is absent. Adhesins can, however, be readily stabilized by the presence of periplasmic chaperone molecules, which are important in the synthesis of adhesins and assembly of pili, but are not incorporated into the structure.

FimC is the periplasmic chaperone protein that mediates assembly of type 1 pili in bacteria. The FimC chaperone stabilizes the type 1 pilus subunits in the periplasm through formation of distinct periplasmic complexes. FimC binds to and caps interactive surfaces on the pilus subunits, preventing aggregation and allowing for correct folding and assembly. The chaperone–subunit complexes are targeted to a large channel protein in the bacterial outer membrane called the usher where the chaperone is released, exposing interac-

tive surfaces on the subunits that facilitate their assembly into the pilus [26,27]. Each of the pilus subunits are then incorporated into the pilus depending, in part, upon the kinetics with which they are partitioned to the usher in complex with the chaperone [28] (Figure 1).

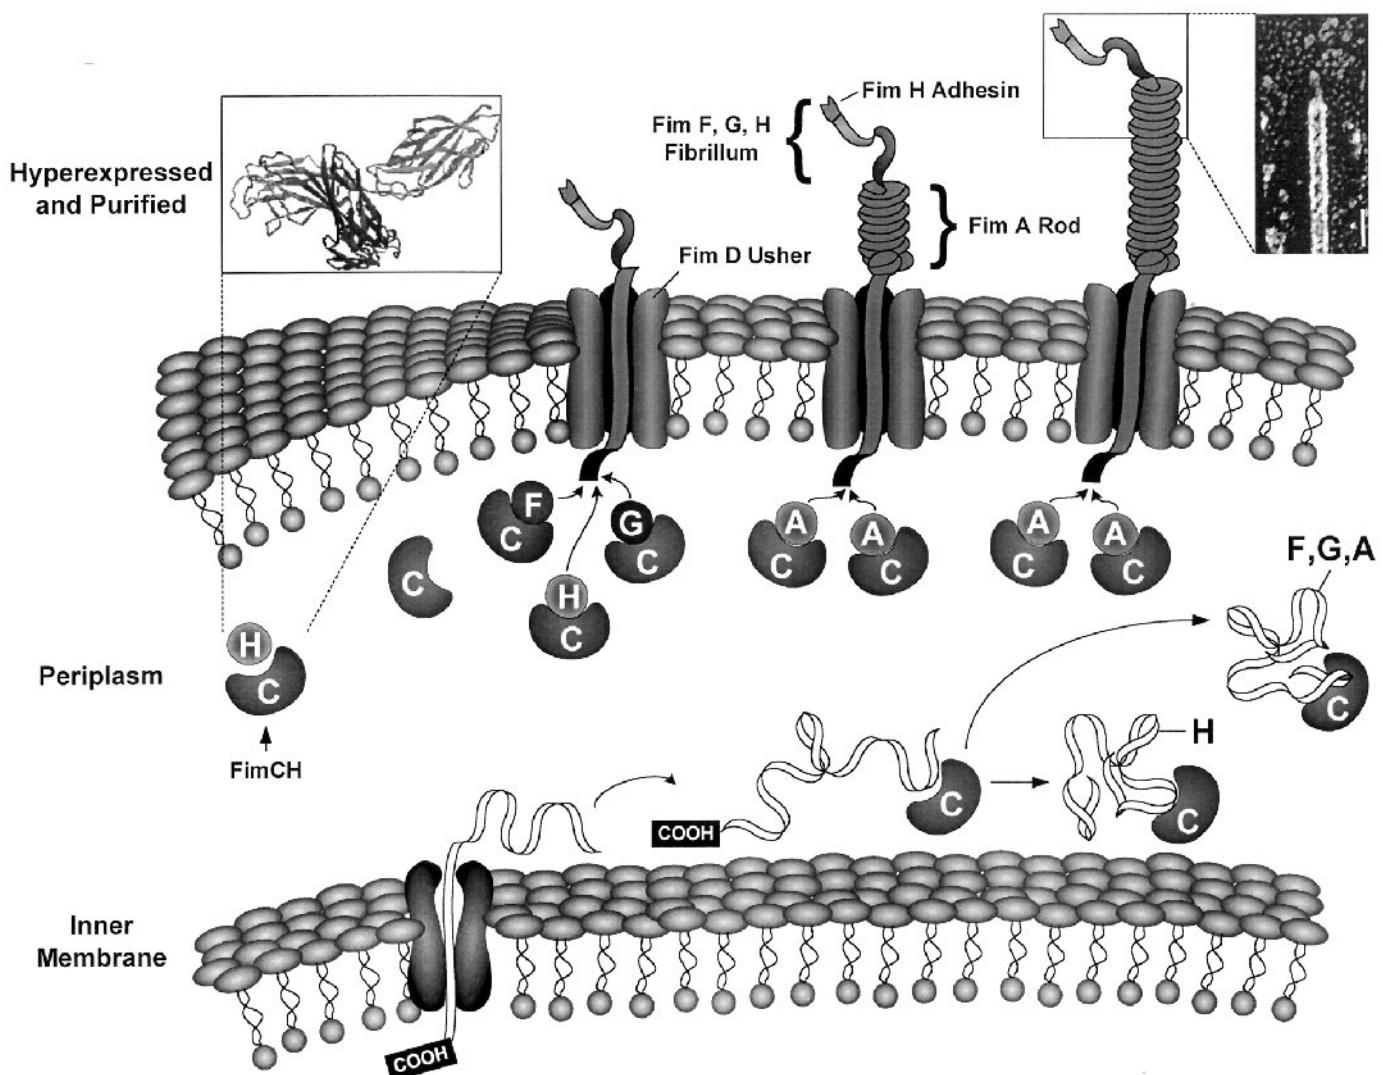

X-ray diffraction studies of the FimH adhesin in a complex with its chaperone FimC have shed new light on the nature of the chaperone subunit interaction [20]. With regard to the 52.0-kDa FimCH complex, the following was noted. The FimH adhesin has two domains; one interacts with the FimC chaperone (the pilin domain) while the other interacts with mannose (the lectin-binding domain) (Figure 2). The pilin domain that interacts with FimC, as well as FimC itself, has an immunoglobulin-like fold made up of antiparallel  $\beta$  strands. However, the seventh strand is missing from the FimH immunoglobulin fold, exposing a hydrophobic groove on the surface of the pilin domain. This groove would render the FimH unstable were it not for the fact that the FimC chaperone temporarily shares its seventh strand with the FimH subunit without parting with the shared strand, in a process called donor strand complementation. This complementation during formation of the FimCH complex stabilizes the FimH adhesin.

These observations explain in part why initial attempts at developing a subunit adhesin vaccine based on only FimH without its cognate chaperone protein FimC were unsuccessful. The use of hyperexpression systems to produce and purify large amounts of adhesin most likely failed because FimH expressed as an independent moiety, with an exposed hydrophobic groove, enters a nonproductive pathway in the bacterium and is rapidly degraded [29,30]. In contrast, hyperexpression of recombinant FimH in combination with FimC as a FimCH complex allows for high-level expression of the full-length adhesin. Since the FimCH complex is a stable compound, and presents the lectin-binding domain of FimH in the proper conformation, the complex was selected as a vaccine candidate for eliciting functional adhesin-blocking antibodies to type 1 pilated uropathogenic *E. coli*.

### II. PRECLINICAL IMMUNOGENICITY AND PROTECTION STUDIES WITH FIMCH

Experiments were conducted in C3H/HeJ mice using purified FimCH complex at doses ranging from 0.3 to 30  $\mu\text{g}$  emulsified in complete Freund's adjuvant (CFA) to test for immunogenicity of FimCH. Booster doses were administered in incomplete Freund's adjuvant (IFA). Antibodies to the FimH adhesin were measured in an enzyme-linked immunosorbent assay (ELISA)-based format using a truncated form of FimH expressed as a histidine-tagged fusion protein (FimH T3) as the capture antigen. FimH T3 is truncated at its carboxy terminus and thus contains the amino-terminal lectin (mannose) binding domain of FimH.

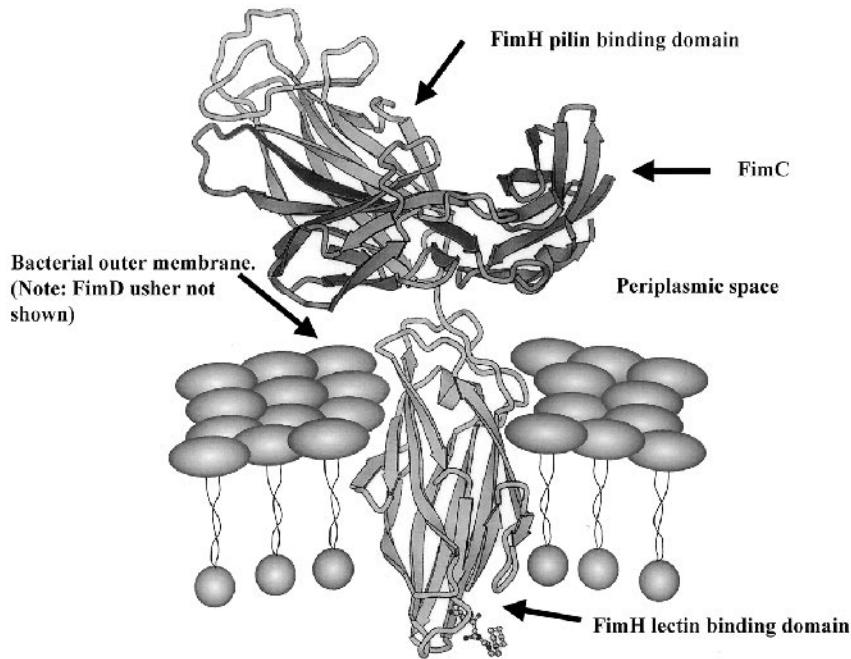

Mice immunized with FimCH developed strong, long-lasting immune responses to FimH T3 and to FimH associated with whole type 1 pilus rods [12]. Serum anti-FimH IgG was detected for more than 30 weeks. An additional dose of FimCH administered after the 30-week time point further boosted responses such that antibodies were detected more

**Figure 1** Type 1 pilus biogenesis. Schematic representation of type 1 pilus assembly via the chaperone–usher pathway. FimC chaperone-mediated extraction of subunits from the inner cytoplasmic membrane is coupled to their folding into an assembly-competent state. The G1  $\beta$  strand of the immunoglobulin-like chaperones, which may serve as a template in the subunit folding pathway, protects nascently folded subunits from premature oligomerization in the periplasmic space by directly capping the newly formed assembled surfaces. These interactive surfaces remain protected until delivery of the preassembly complex to the outer membrane assembly site. Such interactions with the chaperone also prevent the subunit from being proteolytically degraded in the periplasm. In the case of the FimH subunit, its carboxy-terminal domain has an immunoglobulin-like fold in which the seventh strand is missing, leaving part of the hydrophobic core exposed. The chaperone, FimC, donates a strand to complete the pilin domain 20.

than 1 year after immunization. Immunization studies in rabbits demonstrated immunogenicity profiles similar to those seen in mice. FimH-specific IgG was also detected in the urine and vaginal secretions of immunized mice. Antibodies to FimH generated in both mice and rabbits were shown to be biologically active by their ability to block attachment of uropathogenic *E. coli* to bladder cells in vitro; > 94% of primary *E. coli* clinical isolates induced to express type 1 pili were inhibited by FimH sera raised against a single FimH protein. Moreover, in a murine challenge model involving the uropathogenic *E. coli* strain NU14, more than

99% reduction in colonization of the bladder mucosa was observed *in vivo*. Similarly, immune serum from rabbits was used to passively immunize mice, which then underwent challenge using a panel of 10 diverse uropathogenic *E. coli* strains. Greater than 99% reduction in colonization of the bladder mucosa was observed, and highly significant protection was seen with 9 of 10 uropathogenic strains. Thus, preclinical studies involving active immunization of mice with FimCH in Freund's adjuvant confirmed that the vaccine was immunogenic and able to induce strong, long-lasting, antigen-specific, functional antibody responses that

**Figure 2** MOLSCRIPT ribbon diagram of the FimCH complex. The FimH pilin domain and the NH<sub>2</sub>-terminal domain of FimC form a closed superbarrel with a continuous core made from conserved residues in both proteins. A ball and stick model of a mannose-like compound (C-HEGA) molecule bound to the lectin domain indicates the position of the carbohydrate-binding site at the tip of the domain [20]. This portion of the molecule is also being depicted as it is extruded from the bacterial outer membrane, where it will form the distal tip-associated adhesin on the pilus rod.

were able to block attachment of uropathogenic *E. coli* to bladder cells and protected mice against challenge.

### III. DEVELOPING A VACCINE FORMULATION SUITABLE FOR HUMAN STUDIES

The initial preclinical studies involved formulations containing Freund's adjuvant, which is not suitable for use in humans. The data suggested that protection was dependent upon high-titer IgG responses, and therefore a potent formulation suitable for human use would be essential. Additional studies were thus conducted in mice to determine the relative potency of FimCH adsorbed to alum [Al(OH)<sub>3</sub>], the only adjuvant currently licensed as a component of a vaccine in the United States. As an alternative to alum, FimCH was adjuvanted with MF59C.1, an oil-in-water (squalene) emulsion developed by Chiron that has been extensively tested in humans and that is used in an influenza vaccine that has been licensed in Italy [31,32]. FimCH formulated with alum consistently gave titers to FimH in mice that were 5- to 10-fold lower than those seen with Freund's adjuvant. In contrast, FimCH formulated with MF59C.1 gave titers as high as those seen with Freund's adjuvant. Since there is a relationship between antibody titer to FimH and protection against infection *in vivo*, subsequent efforts focused on developing FimCH formulated with MF59C.1. At the same time new formulations with alum in combination with different buffers and pH conditions are being investigated in ongoing preclinical studies.

Additional studies were conducted to demonstrate the immunogenicity of different doses of FimCH formulated with MF59C.1. C3H/HeJ mice were immunized with doses ranging from 0.16 to 20 µg per injection. Some groups received two doses at 0 and 18 weeks, while others received three doses at 0, 4, and 18 weeks, either intramuscularly, intraperitoneally, or subcutaneously. The results confirmed the immunogenicity of FimCH formulated with MF59C.1 by all routes at doses as low as 0.8 µg and revealed the superiority of three doses over two. Moreover, IgG antibodies to FimH were detected in urine and vaginal secretions similar to those seen with formulations involving Freund's adjuvant, and active immunization ( $\times 3$  injections) protected mice against challenge with uropathogenic *E. coli*.

Having identified a highly immunogenic FimCH formulation that was potentially suitable for human use, adult female cynomolgus monkeys (*Macaca fascicularis*) received either 2 or 3 injections of 4, 20, or 100 µg of FimCH mixed 1:1 with MF59C.1. The formulation appeared to be well tolerated and was highly immunogenic, resulting in endpoint titers in excess of 50,000 in monkeys that received 2 doses of vaccine, whereas those that received 3 doses reached endpoint titers in excess of 200,000. Immunized animals underwent challenge studies to determine *in vivo* efficacy. Vaccination and challenge studies in the primate model corroborated the original murine studies [33]. Monkeys vaccinated with purified recombinant FimCH chaperone-adhesin complex with the MF59 adjuvant developed long-lasting serum IgG antibodies to FimH as well as functional inhibitory titers as measured by the ability of the antibodies

to block in vitro binding of type 1-piliated *E. coli* to mannose. The vaccine protected the monkeys from bladder infection by uropathogenic *E. coli* and from an inflammatory response typically associated with cystitis. Three out of four animals were completely protected from colonization by the NU14 *E. coli* strain. Furthermore, although the number of animals was small, there was a direct correlation between the presence of inhibitory antibodies in local (vaginal wash) secretions and protection against colonization and infection [33].

In a second challenge study in monkeys, 2 of 4 monkeys receiving a 100- $\mu$ g dose of FimCH vaccine ( $\times 3$  doses) were protected from colonization by a high dose of a highly virulent strain of *E. coli*, DS17 [34]. The two vaccinated monkeys that had *E. coli* in their urine following challenge were nonetheless protected from inflammatory responses and hematuria typically associated with cystitis. In contrast, all four MF59 control monkeys had high levels of *E. coli* in their urine for at least 9 days following challenge, and all had potent inflammatory responses and hematuria. The highly virulent DS17 strain used in the second primate study was originally isolated from a patient with pyelonephritis, and is capable of expressing multiple virulence determinants including P pili in addition to type 1 pili *in vivo*. Thus, these results further point to the potency of the FimCH vaccine and its ability to protect against uropathogenic *E. coli* strains expressing multiple adhesins.

One of the theoretical concerns with development of a FimCH vaccine is the potential to affect the normal *E. coli* flora of the gastrointestinal tract. To address this issue, we collected fecal samples from each monkey over the entire course of this first study to investigate whether vaccination with the FimCH vaccine would affect the normal gut flora. Overall coliform counts per milliliter of fecal suspension were determined at each time point and compared to three preimmune samples taken for each animal. No differences between immunized and control monkeys were observed. To examine whether the vaccine caused a shift in subpopulations within the coliform bacteria, a biochemical profile assay was used for biochemical characterization of the fecal isolates obtained during the immunization period. No differences in the coliform populations were observed. Thus, systemic vaccination with the FimCH adhesin vaccine does not appear to have an effect on the normal gut flora.

In summary, preclinical studies of FimCH formulated in MF59C.1 confirmed its immunogenicity in two animal species, including doses administered to nonhuman primates in the range intended for human studies, and revealed the superiority of three over two doses of vaccine. The vaccine does not appear to have adverse effects on the normal flora of the gastrointestinal tract and should be well tolerated in humans.

#### IV. CLINICAL EXPERIENCE WITH MEDI-516

A Phase I study of MEDI-516, an *E. coli* FimCH vaccine formulated with MF59C.1 adjuvant, Chiron's proprietary oil (squalene)-in-water adjuvant was conducted as a double-blind, randomized, adjuvant-controlled, dose-escalation study. The study protocol, all amendments to the protocol,

and volunteer informed consent documents were submitted for review to an Institutional Review Board (IRB). Written IRB approvals were obtained prior to implementation. Written informed consent was obtained from each participant prior to conduct of any protocol-specific activity or study entry. The study was conducted in accordance with the Declaration of Helsinki (amended 1989) and with the U.S. Code of Federal Regulations governing the protection of human volunteers (21 CFR 50), Institutional Review Boards (21 CFR 56), and the obligations of clinical investigators (21 CFR 312).

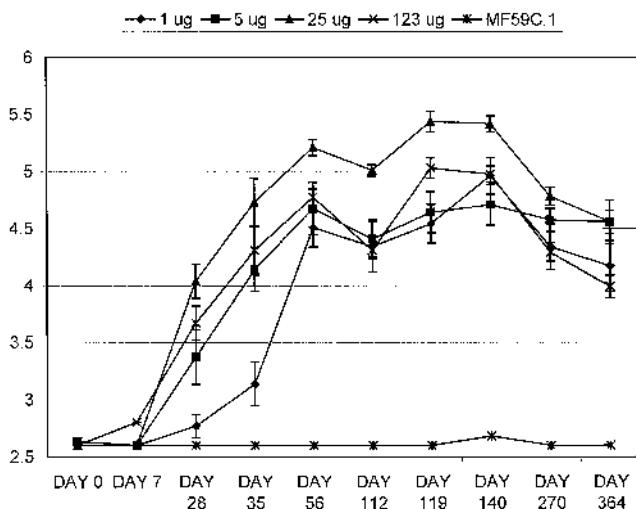

Forty-eight healthy adult women who were seronegative for antibody to FimH as measured by MedImmune's FimH T3 screening ELISA were sequentially randomized to four cohorts (1, 5, 25, or 123  $\mu$ g FimCH). Within each cohort, nine volunteers were randomized to receive injections of MEDI-516 with MF59C.1 adjuvant and three were randomized to receive adjuvant alone as a control. Injections were administered at 0, 1, and 4 months. Volunteers were followed for the occurrence and intensity of solicited adverse events for the 7-day period following each immunization and unsolicited adverse events for 28 days after each immunization. Volunteers were followed for the occurrence and intensity of serious adverse events occurring during the period starting from the administration of the first dose of vaccine and ending 28 days after administration of the last dose of vaccine. The occurrence of severe solicited and unsolicited adverse events and any serious adverse events after each dose were to be reported immediately and reviewed by the medical monitor.

Dose escalation was by cohort and did not proceed until all of the following had occurred: all volunteers at a given dose level had received an injection of study vaccine; at least 9 of the 12 volunteers had been followed for at least 7 days after immunization; and the Medical Monitor had reviewed the available safety data with the Safety Monitoring Committee (SMC) and the SMC had recommended to continue with dose escalation. Volunteers who received one or more immunizations were asked to provide samples of blood, urine, and cervical secretions for measures of immune responses. Antibody responses were determined by measuring FimH T3-specific immunoglobulin G (IgG) concentrations in serum and the functional activity (binding inhibition) of IgG in serum were measured using methods reported previously [33].

All 48 volunteers were female. The mean ages were similar among treatment groups (range of means: 31–37 years). Most of the volunteers (45, 94%) were White/non-Hispanic; the remaining 3 volunteers were Black (2 in the 25- $\mu$ g MEDI-516 group and 1 in the 123-mg MEDI-516 group). Of the 48 volunteers who entered the study, 44 completed through study day 364. Four volunteers were lost to follow-up after completing all protocol evaluations on study day 119.

#### V. SAFETY AND REACTOGENICITY

All volunteers, except 1 in the 5- $\mu$ g MEDI-516 group, had at least one solicited adverse event. The most common solicited adverse event in all groups was pain at the injection site, reported by 78% to 100% of the volunteers in each group. No redness or swelling at the injection site within 7 days of

**Figure 3** Serum antibody responses to FimH T3 (ELISA titers).

immunization was observed in any volunteer. The most common general reactions among volunteers who received MEDI-516 were headache in 18 (50%), fever in 16 (44%), and fatigue in 13 (36%) volunteers. In the MF59C.1 control group, the most common general reactions were headache in 6 (50%) and fatigue in 3 (25%) volunteers, while fever occurred in only 2 (17%) volunteers. With the exception of fever, each solicited adverse event was reported by similar proportions ( $\leq 15$  percentage points difference) of MEDI-516 and MF59C.1 volunteers. There were no intensity grade 3 (severe) solicited adverse events and the frequency and intensity grade of solicited adverse events did not increase with increasing vaccine dose or number of injections. Local (site of injection) solicited adverse events were considered to be related to study injections. Systemic adverse events judged to be related to study injections, with the exception of fever, were reported by similar proportions ( $\leq 15$  percentage points difference) of MEDI-516 and MF59C.1 control volunteers. Fever was more common among MEDI-516 recipients and was reported by 14 (39%) of these volunteers as compared to 1 (8%) in the MF59C.1 control group. Fevers greater than  $100.0^{\circ}\text{F}$  were uncommon. The highest temperature recorded

during the study was  $102.0^{\circ}\text{F}$  (intensity grade 2 fever) on day 3 following the second injection in a volunteer who received 5  $\mu\text{g}$  MEDI-516. Fever in this volunteer was associated with headache, fatigue, and myalgia, and was attributed to the study vaccine. The incidence of unsolicited adverse events was similar between the MEDI-516 and MF59C.1 control groups (29, 81% and 9, 75%, respectively). There were no deaths or other serious adverse events through study day 140. No clinically meaningful changes were noted in vital signs (temperature, pulse, respiration rate, systolic and diastolic blood pressure) in any volunteer in any group from preinjection to 30 min after injection. No volunteers were permanently discontinued from study vaccine due to adverse events. There were no clinically meaningful changes in any of the laboratory parameters followed to assess vaccine safety (complete blood count, liver enzymes, renal function studies, or urinalysis) that were judged to be related to administration of study vaccine.

#### A. Immunogenicity

All anti-FimH T3 titers were  $\leq 1:800$  at baseline (study day 0). All volunteers who received the MF59C.1 control had titers of  $< 1:800$  at all time points tested except for one volunteer whose titer was 1:3200 at study day 140. All volunteers who received MEDI-516 seroconverted by study day 56. For each MEDI-516 group, geometric mean antibody titers rose rapidly after the second injection of MEDI-516 was administered, peaked at study day 56, and decreased by approximately 50% of peak values before the administration of the third injection of vaccine. After the third injection, geometric mean antibody titers increased further, exceeding the peak levels achieved after the second injection. For each MEDI-516 group, geometric mean antibody titers decreased between study days 140 and 364. Anti-FimH T3 ELISA data are summarized in Figure 3.

Sera were assayed for the ability to inhibit the in vitro binding of *E. coli* to J82 bladder cells as reported previously [12,33]. The results were reported as  $\text{IC}_{50}$ , the greatest dilution giving at least 50% reduction in mean channel fluorescence over baseline. For these assays, baseline sera for each group were pooled. Baseline pools were run in the same assay as the test sera, and calculations were made using the results of the baseline pool run on the same day as that assay.

No volunteer had inhibitory serum activity at baseline (Table 1). After three doses of the vaccine (study day 140)

**Table 1** Number (%) of Volunteers with Binding Inhibition Activity in Sera ( $\text{IC}_{50}$  Value  $\geq 50$ )

Study day	MEDI-516				MF59C.1 Adjuvant (N=12)
	1 µg (N=9)	5 µg (N=9)	25 µg (N=9)	123 µg (N=9)	
0	0 (0%)	0 (0%)	0 (0%)	0 (0%)	0 (0%)
140	6 (67%)	9 (100%)	9 (100%)	8 (89%)	0 (0%) <sup>a</sup>
270	7 (78%)	9 (100%)	8 (100%) <sup>b</sup>	6 (75%) <sup>b</sup>	0 (0%) <sup>a</sup>
364	6 (67%)	7 (78%)	7 (88%) <sup>b</sup>	5 (63%) <sup>b</sup>	0 (0%) <sup>c</sup>

<sup>a</sup> N=11.

<sup>b</sup> N=8.

<sup>c</sup> N=10.

substantial inhibitory activity ( $IC_{50} \geq 50$ ) was seen in 6 (67%), 9 (100%), 9 (100%), and 8 (89%) of the volunteers in the 1-, 5-, 25-, and 123- $\mu$ g MEDI-516 groups, respectively. In approximately half of these volunteers, significant inhibitory activity was not detectable until after the third injection had been administered.

Urine and cervical secretions were collected at baseline and on study day 140 and IgG responses against FimH T3 were determined by ELISA. Paired urine specimens were available from baseline and study day 140 for all volunteers except 1 in each of the 5- $\mu$ g MEDI-516 and MF59C.1 control groups. A twofold (or greater) increase over baseline optical density was seen in urine samples from 5 of 9 (56%), 4 of 8 (50%), 9 of 9 (100%), and 3 of 9 (33%) volunteers from the 1-, 5-, 25-, and 123- $\mu$ g MEDI-516 groups, respectively, and in 1 of 11 (9%) volunteers from the MF59C.1 control group. The highest group mean urine anti-FimH T3 ELISA response was seen in the 25- $\mu$ g MEDI-516 group. Paired cervical secretion specimens were available from baseline and study day 140 for all volunteers except 1 in the MF59C.1 control group. The optical density readings at baseline varied considerably from volunteer to volunteer. At least a twofold increase over baseline optical density was seen in cervical secretions from 7 of 9 (78%), 8 of 9 (89%), 8 of 9 (89%), and 8 of 9 (89%) volunteers from the 1-, 5-, 25-, and 123- $\mu$ g MEDI-516 groups, respectively, and in 3 of 11 (27%) volunteers from the MF59C.1 control group. Substantial group mean anti-FimH T3 ELISA response was seen in all MEDI-516 groups.

To confirm the specificity of the antibody responses in urogenital secretions, Western blot analysis was performed using the same specimens that were assayed by ELISA. Western blot analysis using highly purified recombinant FimCH as the antigen and electrophoretic separation of the FimH and FimC proteins permitted assessment of responses to each antigen individually. This analysis confirmed the presence of antibodies reactive with both FimH and FimC in samples from volunteers who had received MEDI-516. In volunteers for whom both urine and cervical samples were analyzed, reactivity against FimH by Western blot was detected in baseline urine and/or cervical secretions in 46% (16/35) of the MEDI-516 group and 55% (6/11) of the MF59C.1 control group, suggesting that these individuals had previous exposure to FimH, presumably through colonization or previous UTIs with bacteria expressing FimH.

In summary, this Phase I study indicated that MEDI-516 appears to be safe and well tolerated. Mild to moderate pain at the injection site was commonly reported following all injections and appeared to be indistinguishable from pain following immunization with MF59C.1 alone. Low-grade fever occurred more frequently after immunization with MEDI-516 than MF59C.1 control. Administration of MEDI-516 resulted in the production of binding-inhibitory antibodies directed against FimH, with optimum results observed at the 25- $\mu$ g dose. Antibody responses against FimH in urogenital secretions increased significantly after immunization with MEDI-516. On the basis of these results, MedImmune plans to conduct Phase II studies in adult women with and without a history of recurrent UTI to further assess the safety, tolerability and immunogenicity

of the vaccine. These studies will also provide important data on the incidence of *E. coli* UTI in these populations and potentially provide preliminary evidence of vaccine efficacy.

### I. RATIONALE FOR A *HELICOBACTER PYLORI* VACCINE

Nearly half of the world's population is infected with *H. pylori*, a bacterium that causes chronic gastritis and peptic ulcer and has been strongly incriminated in the etiology of gastric cancer, the second most common fatal malignancy. Although antibiotics can cure infection, multidrug regimens are required which are expensive, have side effects, and may induce resistance. These drugs are not amenable to widespread use for primary prevention, or even for treatment, of infection in some areas of the world. For these reasons, vaccines are being developed.

Because most *H. pylori* infections are acquired during the first years of life, vaccination strategies that target infants are being considered. A series of economic analyses predicted that the cost/benefit ratio of a prophylactic *H. pylori* vaccine for infants would be favorable in the United States [1], even if efficacy were as low as 55% [2]. An infant vaccination campaign lasting only 10 years has the potential to reduce the prevalence of *H. pylori* by 99% by the end of the twenty-first century, and virtually eliminate transmission [3]. A different situation is found in many developing countries, where persistently high rates of transmission would require a continuous vaccination program, a highly efficacious vaccine, and broad population coverage [3]. The large investment of resources needed to implement such a program would be a serious consideration for countries with limited health care budgets.

### II. FEASIBILITY OF DEVELOPING A *H. PYLORI* VACCINE

Several factors must be addressed in assessing the feasibility of developing an effective *H. pylori* vaccine. One issue is the remarkable genetic diversity of *H. pylori*. Each patient carries a unique pool of strains [4] and these strains undergo genetic variation over time, presumably as a result of mutation and host-mediated selective pressure [5]. It remains to be determined whether this has implications for the ability to identify shared antigens for inclusion in a vaccine.

There is no clear evidence for infection-derived immunity that could serve as a paradigm for vaccine development. Even in the face of strong humoral and cellular immune responses, *H. pylori* colonization persists for life. The ineffectiveness of the host response to natural infection is further illustrated by studies which demonstrate that reinfection rates in patients who receive successful eradication therapy are similar to those seen in previously uninfected individuals [6]. Nonetheless, reports that transient infections are common in childhood suggest that effective immune surveillance may exist [7,8]. Furthermore, immunomodulation by concurrent enteric helminth infection can ameliorate gastric pathology in *H. pylori*-infected mice despite persistent colonization [9]. Thus even if a *H. pylori* vaccine does not achieve the so-called sterile immunity, it might still protect against adverse clinical outcomes.

It is difficult to rationally select vaccine candidates that appear promising in clinical trial when the desired immune

responses are uncertain. In such circumstances, human challenge studies have been used to assess vaccine efficacy. The feasibility of experimentally infecting humans was proven by two investigators, who inoculated themselves with *H. pylori* in an attempt to fulfill Koch's postulates of pathogenicity [10,11]. More recently, investigators have attempted to develop a *H. pylori* challenge model in volunteers using a *cagA*-negative strain [12]. They successfully infected the subjects, and were able to observe clinical symptoms and gastric inflammatory changes. However, the role of volunteer challenge trials in *H. pylori* vaccine development is controversial, and animal studies remain an essential source of information on the mechanisms of vaccine-mediated immunity. These models have illustrated that vaccines can prevent *H. pylori* infection even when infection-derived immunity cannot be demonstrated.

A point of debate is whether the elimination of *H. pylori* infection using prophylactic vaccination would increase the risk of proximal esophageal diseases, such as gastroesophageal reflux, Barrett's esophagus, and esophageal adenocarcinoma [13]. The hypothesis is that *H. pylori* infection inhibits gastric acid secretion and thereby protects the esophagus from injury. Proponents of this theory contend that the natural decline in *H. pylori* infection that has followed industrialization is causally related to the concomitant increase in the incidence of proximal esophageal disease that has been observed in Western countries during the past century. In this scenario, the benefits of preventing peptic ulcer and gastric carcinoma with a *H. pylori* vaccine would have to be weighed against a potential increase in the risk of proximal esophageal disease.

A final consideration is that certain *H. pylori* antigens serologically cross-react with host moieties, such as Lewis b antigens on the surface of gastric epithelial cells, and that this so-called antigenic mimicry could elicit autoimmune sequela. Antibodies recognizing gastric epithelium have been observed in *H. pylori*-infected individuals but are of uncertain clinical significance [14].

### III. *H. PYLORI* VIRULENCE FACTORS AND PATHOGENIC MECHANISMS

*H. pylori* has evolved diverse mechanisms which foster its survival in the harsh environment of the human stomach. Specialized secretory machinery exports macromolecular messengers to subvert the host cell for bacterial needs. The bacterium can endure an acidic milieu, penetrate the viscous mucus layer, and adhere intimately to gastric cells. It effectively eludes the host immune system while silently colonizing the stomach for many years.

Production of a unique urease that is highly active at low pH is thought to be essential for colonization [15]. *H. pylori* urease is encoded by two structural (*ureA* and *ureB*) and seven accessory genes in a single chromosomal cluster. This 550-kDa nickel metalloenzyme catalyzes the hydrolysis of urea to yield ammonia and carbamate, which in turn form ammonium hydroxide and increase the pH of the microenvironment [16]. Although primarily intracellular [17], after autolysis urease can be found on the bacterial surface by

immunogold labeling using monoclonal antibodies [18]. Whether urease has a role in infection-derived immunity is not clear; most chronically infected individuals do not have specific antibodies [19,20] and only a minority of CD4<sup>+</sup> T-cell clones from gastric biopsies of infected individuals recognize this antigen [21].

Flagellate-mediated burrowing motility enables this spiral-shaped organism to penetrate the mucus layer and reach the neutral environment of the epithelial surface [22]. Adhesion to gastric cells induces an attaching and effacing epithelial lesion similar to that caused by enteropathogenic *Escherichia coli* [23]. Several outer membrane proteins are candidate adherence factors, including BabA [24], which binds to the Lewis b blood group antigen, and the flagella sheath protein HpaA [25] that binds sialic acid-containing macromolecules.

The dominant virulence factor is a 40-kb DNA sequence within the chromosome, called the *cag* pathogenicity island (PAI). This genetic cassette contains 31 genes, including the gene encoding CagA, a 126- to 145-kDa protein [26]. CagA is one of the most immunogenic proteins of *H. pylori*, stimulating production of both serum antibodies [27] and specific CD4<sup>+</sup> T lymphocytes at the level of the gastric mucosa [21]. The PAI genes encode for a type IV secretory machinery that translocates CagA into the host cell cytosol to be tyrosine phosphorylated, leading to actin polymerization with cellular elongation ("hummingbird" phenotype) and formation of adherence pedestals [28–30]. Furthermore, some PAI genes, such as *cagE*, regulate epithelial cell production of the inflammatory mediator IL-8 [31] and activation of nuclear factor (NF)- $\kappa\beta$  [32].

Many investigators have tried to correlate human infection with CagA-positive organisms with the occurrence of peptic ulcers and gastric cancer. These studies have yielded discrepant results [33–37], probably because the principal determinant of virulence is a functional PAI. Mutagenesis studies suggest that other PAI genes, such as *cagE*, play a more direct role in the pathogenesis of severe gastric pathology [32]. This organism's genetic metamorphosis further complicates the relationship between the PAI and clinical outcome. *H. pylori* infecting the human stomach contain isogenic populations of *cag*-positive and negative strains in which the PAI presumably has been excised [38]. A dynamic state is postulated in which chronically infected patients have periods of *cag*-positive predominance which lead to disease expression [34].

Another protein with an important (albeit incompletely understood) role in gastric injury is the vacuolating cytoxin A (VacA). *vacA* is a pleomorphic gene present in all *H. pylori* strains and expressed in most strains [39,40]. It encodes VacA, a secreted protein composed of individual ~90-kDa monomers, each formed by two distinct domains (p37 and p58) [41]. When orally administered to mice, VacA induces gastric epithelial erosion similar to that seen in humans with peptic ulcer [42]. It is postulated that after binding to the host cell, VacA becomes internalized via endocytosis [43] and triggers formation of anion-selective channels in the endosomal membrane [44], producing vacuoles [41,45], and ultimately cell death by apoptosis [46]. VacA also enhances permeability of polarized epithelial

cells by altering the tight junctions [41,47], a phenomenon that could favor *H. pylori* survival by providing an efflux of nutrients from the gastric submucosa.

The presence of VacA in the late endosomes and the formation of vacuoles alters the capacity of antigen-presenting cells to appropriately process antigens and present them in a Ii-dependent pathway [48]. This may explain the paucity of VacA-specific CD4<sup>+</sup> cells in biopsies of infected individuals [21], as well as the reduced ability of *H. pylori*-infected animals to mount CD8<sup>+</sup> cell responses specific for a virus concomitantly infecting the mice [49]. However, it remains unclear whether this inhibitory activity of VacA significantly influences *in vivo* immune responses.

A *H. pylori* protein with chemotactic and proinflammatory properties is the neutrophil-activating protein (NAP) [50], a 170-kDa iron-binding protein [51] that is highly conserved among isolates. After binding to a specific receptor, NAP stimulates leukocytes to produce reactive oxygen intermediates [52] and triggers mast cells to degranulate and release inflammatory mediators such as IL-6 [53]. NAP also enhances the expression of tissue factor and depresses fibrinolysis, thus impeding the physiological mechanisms leading to tissue repair [54].

#### IV. MECHANISMS OF PROTECTIVE IMMUNITY

The operating assumption when the first successful vaccination studies were performed in mouse models was that vaccine-mediated protection against *Helicobacter* infection was a result of the induction of mucosal antibodies while avoiding proinflammatory, ineffective immune responses associated with active *H. pylori* infection. We have since come to realize that antibodies have little or no role in effector mechanisms that lead to protection, and that vaccine-induced bacterial clearance involves the action of MHC class-II restricted CD4<sup>+</sup> T cells. While these mechanisms are not well elucidated, several lines of experimentation have contributed to the current understanding of this rather complex problem.

A role for antibodies in protective immunity was suggested by the finding that passive immunization with *H. pylori*-specific IgA protected mice against *Helicobacter felis* challenge [55]. This notion was further supported by the strong correlation observed between mucosal antibodies and protection in immunized mice [56]. Initial indication that mucosal antibodies were not as important for protection as originally believed was provided by Weltzin and coworkers [57], who showed that a nasal immunization regimen administered without mucosal adjuvants induced high levels of mucosal antibodies against urease but did not protect against challenge. This was defined more clearly in later experiments, in which genetic knock-out agammaglobulinemic mice vaccinated with various regimens were equally protected against *H. pylori* or *H. felis* challenge compared with wild-type mice [58,59]. Furthermore, IgA-deficient humans do not exhibit more severe pathology due to *H. pylori* [60]. Taken together, these findings suggest that antibodies play little or no role in protection against *Helicobacter*. Although mucosal antibody induction is a marker for

successful adjuvant effect of cholera toxin (CT) or *E. coli* heat-labile enterotoxin (LT), protection is mediated by mechanisms coinduced with mucosal antibodies.

A series of experiments in defined knock-out mice attempted to identify the immune mechanisms required for protection. CD8<sup>+</sup> T cells were found to play no role in preventing bacterial colonization because MHC Class I-deficient mice were protected from *H. pylori* challenge by using various immunization regimens [58,61]. However, MHC Class II knock-out mice were not able to generate vaccine-related protection [58,61], suggesting that CD4<sup>+</sup> T-cell-mediated mechanisms in the gastric mucosa are required. This hypothesis is also supported by studies using adoptive transfer techniques, in which CD4<sup>+</sup> T cells from mice immunized by various methods protected syngeneic recipients against challenge with *H. felis* and *H. pylori* [62–64]. To define the effector mechanisms, studies were performed in which cytokine deficient mice were either vaccinated or were used as syngeneic recipients in adoptive transfer experiments. These studies demonstrated that neither IL-4, IL-10 [63], nor IFN- $\gamma$  [65] are required for protection.

The above studies defined protection microbiologically as lack of colonization with *H. pylori* or *H. felis*; resolution of gastritis, and thus disease, was seldom assessed. Eaton and coworkers [66] further explored the role of IFN- $\gamma$  and IL-10 in protective immunity by examining their effect on gastric histopathology. When SCID mice were infected with *H. pylori* and then reconstituted with splenocytes from uninfected, immunocompetent syngeneic mice, severe gastritis developed within 2–4 weeks and then gradually resolved [66], accompanied by bacterial clearance. Adoptive transfer of splenocytes from IL-10-deficient mice resulted in more severe gastritis than seen in wild-type mice suggesting that IL-10 modulates gastritis [66]. On the other hand, adoptive transfer of splenocytes from IFN- $\gamma$  deficient donors resulted in milder gastritis than seen in immunocompetent mice, suggesting that IFN- $\gamma$  may exacerbate gastric pathology [66]. This last finding was further supported by experiments showing that IFN- $\gamma$  depletion by specific antibodies inhibited the delayed-type hypersensitivity response in the stomach that occurs with *H. felis* infection or oral immunization with antigen and CT [67].

In sum, vaccine-induced protection against *H. pylori* colonization is not mediated by antibodies or CD8<sup>+</sup> T-cell mechanisms but requires CD4<sup>+</sup> T cells. IL-4, IL-10, and IFN- $\gamma$  are not involved in the vaccine-induced protection against colonization. Nevertheless, IL-10 and IFN- $\gamma$  appear to play a role in disease modulation, and should be considered in the design of vaccines. IL-10 stimulation may be a desirable goal as it ameliorates gastritis, while IFN- $\gamma$  induction may be undesirable as it exacerbates gastritis.

#### V. ROUTES, ADJUVANTS, AND DELIVERY SYSTEMS

Most preclinical studies have used mucosal routes of vaccine delivery, usually orogastric. Antigens (either whole-cell lysates, or purified recombinant, or native molecules) have invariably required concomitant mucosal adjuvants for both

prophylactic and therapeutic efficacy (reviewed in Ref. [68]). These have included wild-type LT and CT, and various mutants of LT retaining little or no enzymatic activity.

Inspired by successful parenteral vaccination against other mucosal pathogens, such as poliovirus and *Bordetella pertussis*, more recent experiments have utilized the parenteral delivery of *H. pylori* vaccine antigens. Intramuscular immunization with both whole-cell lysate and purified antigens effectively protected animals against *H. pylori* infection prophylactically and therapeutically, although results varied in different models. Adjuvants known to enhance immune responses to parenterally administered antigens were used in these experiments, such as Freund's adjuvant in mice [64] and in gnotobiotic piglets [69], aluminum hydroxide in mice [64], in dogs (G. del Giudice, unpublished), and in gnotobiotic piglets [69], QS21 in mice [70,71], Bay adjuvant in mice [70,71] and in monkeys [72,73], as well as the cationic lipid adjuvant DC Chol in mice [74] and in monkeys [75]. Interestingly, wild-type LT enhanced protective immunity engendered by urease when both were subcutaneously administered [76]. A combined delivery approach in which a mucosal prime is followed by parenteral boosts has been shown to be more efficacious than parenteral immunization alone in a rhesus monkey model [77]. The challenge in human studies involving parenteral immunization will be to understand whether the immune response that no doubt will be vigorous will elicit effector mechanisms leading to protection.

Little work has been reported on the use of DNA vaccines [78,79]. The predilection of DNA vaccination to enhance Th1-type responses may make this an inappropriate method for immunization against *H. pylori*. Th1-type responses may exacerbate *H. pylori* induced inflammation and CD8<sup>+</sup> cell responses do not appear to play a major role in vaccine-mediated protection against this organism.

## VI. LESSONS FROM ANIMAL MODELS

### A. Murine *H. felis* Models

The mouse model provided the first proof-of-principle that a vaccine could be developed to prevent and treat *Helicobacter* infection. Initial studies were performed by inoculating mice with a feline *Helicobacter* isolate designated *H. felis*. Infection caused acute inflammation which progressed to chronic gastritis typified by formation of microabscesses involving neutrophils and lymphocytes [80,81]. Successful mucosal immunization with *H. felis* sonicate antigens [55,82] or purified *H. pylori* antigens conserved between species [56,83–85] required coadministration of CT or LT adjuvant. Therapeutic immunization was often effective in reducing bacterial burden to a nondetectable level [86,87]. However, the agar-swarming nature of *H. felis* prevented the evaluation of bacterial colonization status by culture, and required that histopathology and gastric urease activity be used instead. Initially, urease assays (the least sensitive methods for detecting colonization) suggested that mice protected by vaccination were free of *H. felis* [55,82,85]. This notion was dispelled when gastric histopathology revealed residual bacteria, albeit at levels much lower than those seen in unim-

munized animals [56,84,88]. These residual bacteria were shown to be responsible for a phenomenon termed “post-immunization gastritis,” whereby gastric inflammation was observed in immunized mice when they encountered *H. felis* challenge [67]. The inflammation subsides upon antimicrobial treatment to eradicate residual *H. felis* [89].

### B. Murine *H. pylori* Models

An early study showing that *H. pylori* can transiently colonize the stomachs of conventional mice [90] led to subsequent studies in which persistent infection was achieved [91]. Marchetti and coworkers inoculated mice with a VacA/CagA-producing *H. pylori* clinical isolate, SPM326, evoking extensive gastric pathology including gastritis and ulcer formation [91]. More fulminate infections with *H. pylori* were achieved when stomach tissues from mice infected with other clinical strains were harvested and used to infect additional mice [92,93]. Initially, a cat *H. pylori* isolate, termed X47-2AL [94], was used [93,95]. Lee and coworkers [92] serially adapted a human isolate, designated as SS1, to colonize mice and offered this strain as a standardized model for vaccination and other studies. SS1 produced chronic gastritis with infiltration of inflammatory cells and mucosal atrophy [92]. Other *H. pylori* strains have been reported to infect mice [65,95], but none achieved the bacterial colonization levels of SS1 and X47-2AL [92,96,97].

The ability to determine colony-forming units (CFU) of *H. pylori* confirmed the histological finding in the *H. felis* model that vaccination does not achieve sterile immunity. Thus the “postimmunization gastritis” phenomenon reported in the *H. felis* model was not observed when mice were infected with *H. pylori*. Using the X47-2AL strain, it was determined that vaccination, at best, resulted in a 100-fold reduction in bacterial burden compared to unimmunized controls [58,98]. Although resolution of gastritis was not apparent in the short-term experiments, it is unknown whether this residual level of bacteria would eventually become an asymptomatic infection.

### C. Ferret Models

Ferrets purchased from a commercial vendor were found to be infected with a *Helicobacter* species, *H. mustelae*. Colonization resulted in superficial gastritis consisting of glandular atrophy and a mononuclear leukocytic infiltration [99]. Spontaneous occurrence of adenocarcinoma has also been described in aged infected animals [100]. When naturally infected ferrets were orally immunized with *H. pylori* urease, an antigen that shares a 70% homology with *H. mustelae* urease, plus CT adjuvant, there was eradication or reduction in bacterial colonization in 30% of animals, and gastric inflammation was diminished [101]. This was the first proof-of-principle showing vaccine efficacy in a nonmurine model and one that becomes naturally colonized with a native *Helicobacter* species. The 30% vaccine efficacy was encouraging, considering that a heterologous antigen was used for immunization. This model also suggested that infection does not elicit protective immunity, because the animals whose *H. mustelae* infection was eradicated with antibiotics

remained susceptible to reinfection with a homologous strain [102].

#### D. Feline Models

Cats develop persistent *H. pylori* infections characterized by multifocal gastritis with lymphoid aggregates and occasional neutrophil infiltration [103]. Uninfected cats orally vaccinated with recombinant *H. pylori* urease admixed with LT adjuvant and then challenged with a human isolate of *H. pylori* had a 20-fold lower gastric burden of *H. pylori* and diminished gastric inflammation compared to cats receiving adjuvant alone [104].

#### E. Primate Models

The rhesus monkey is the only nonhuman primate shown to be useful for evaluating *H. pylori* vaccines [72,73,105]. Rhesus monkeys raised in captivity are ubiquitously infected with *H. pylori* [106]. Infection results in chronic gastritis with intense mononuclear cell infiltrates, but in contrast to humans, neutrophils are rare and gastric ulcers have not been seen [106]. The inability of *H. pylori* infection (that was eradicated with antimicrobials) to confer protection against reinfection with the homologous strain was clearly demonstrated in this model [72]. Nonetheless, prophylactic vaccines have been efficacious. In one study, seronegative juvenile monkeys were orally immunized with *H. pylori* urease admixed with LT and then housed in social groups where they were exposed to *H. pylori* [105]. Ten months later, 93% of unvaccinated monkeys were infected with *H. pylori* compared with only 69% of vaccinated monkeys. In contrast, the same formulation appeared ineffective when administered to specific pathogen-free rhesus monkeys either orally or parenterally [73]. Similarly, therapeutic vaccination of older chronically infected monkeys with oral rUrease plus LT failed to reduce the gastric *H. pylori* burden [72]. However, when the infection was eradicated with antimicrobials and the monkeys rechallenged with *H. pylori*, bacterial colonization was significantly reduced in vaccinated monkeys compared to unvaccinated monkeys [72]. In a follow-up study, antimicrobial-treated monkeys were immunized with different regimens of rUrease. Those primed with oral vaccine and boosted with an intramuscular formulation had a more than 10-fold lower bacterial burden following *H. pylori* challenge compared with placebo recipients [77].

#### F. Swine Models

The earliest success at developing a *H. pylori* animal model was achieved by Krakowka and coworkers [107,108] using gnotobiotic piglets. Histopathological changes consisted of diffuse and follicular infiltration of mononuclear leukocytes into the gastric mucosa and submucosa with few neutrophils. Infection persisted for at least 90 days even if the piglets were transferred to conventional housing [109]. Two vaccination studies have been performed using this model. Killed bacteria were administered orally with and without LT, or parenterally with incomplete Freund's adjuvant [69,110]. Oral vaccination yielded disappointing results as

LT adjuvant induced diarrhea and the piglets were not protected against challenge [69]. Parenteral immunization provided partial protection but evoked gastritis in both protected and unprotected pigs [69,110].

#### G. Canine Models

Conventional beagle dogs can be experimentally infected with a *H. pylori* strain previously adapted to the mouse [111]. Infected dogs exhibit inflammatory cell changes in the gastric mucosa that mimic the response in humans. Interestingly, the lymphoid follicles in the gastric mucosa of infected dogs consist of peripheral CD4<sup>+</sup> lymphocytes surrounding a germinal center-like structure particularly rich in B(CD21<sup>+</sup>) lymphocytes [112]. Studies of vaccine efficacy have been carried out in this model (G. Del Giudice, unpublished).

#### H. Mongolian Gerbils

The mongolian gerbil is not only susceptible to infection with *H. pylori*, but infection results in a high incidence of gastric ulcers (80%) [113] and adenocarcinoma of the stomach (37%) by 62 weeks postinfection [114,115]. The induction of these severe gastric pathologies was strictly associated with presence of the *cag* PAI [32]. This small animal model is useful for testing the efficacy of vaccination in preventing long-term effects of *H. pylori* infection and provides a valuable addition to data gathered in other animal models that mainly focus on bacterial burden.

### VII. APPROACHES TO VACCINATION

#### A. Subunit Vaccines

##### 1. Urease

Recombinant *H. pylori* urease apoenzyme (rUrease) expressed in *E. coli* from the *ureA* and *ureB* structural genes is devoid of enzymatic activity because additional *H. pylori* genes are required for insertion of nickel ion [116]. However, the recombinant protein is fully assembled into the 13-nm diameter, disk-shaped particles that are characteristic of the native protein [56,56,117]. The genes encoding urease are well conserved among *Helicobacter* species and provided an easy antigen to test in the animal models available in the early days of vaccine research.

Subunit vaccines consisting of native *H. pylori* urease [85], recombinant urease subunits expressed as fusion proteins [84,85], or, most commonly, rUrease apoenzyme [56] have been tested in animals. All had comparable efficacy in the *H. felis* challenge model. Subsequent studies in mice [58,98], cats [104], and monkeys [77] used *H. pylori* as the challenge strain. All showed that prophylactic vaccination diminished bacterial colonization (10- to 100-fold), and in many instances ameliorated gastritis and/or other epithelial abnormalities [72,77,104,105]. More recently, mouse studies have shown that parenteral immunization induces levels of protection similar to that achieved with mucosal immunization alone [74], and that mucosal prime followed by parenteral boost may be even more efficacious [58,77].

Promising preclinical data indicating that mucosal immunization with urease induces protective immunity led to a series of clinical trials in which urease was delivered by various mucosal routes. In an initial trial, 12 adults with asymptomatic *H. pylori* infection were randomized to receive either 60 mg rUrease or placebo orally once weekly for 4 weeks. Vaccination was well tolerated but minimally immunogenic, and did not eliminate infection or reduce gastritis [118]. As a next step toward developing a therapeutic vaccine, rUrease was combined with native LT as a mucosal adjuvant. In a double-blind design, 26 volunteers with asymptomatic *H. pylori* infection were randomly assigned to receive four weekly oral doses of either rUrease (20, 60, or 180 mg) plus LT (5–10 µg), LT alone, or placebo [119]. Native LT plus rUrease vaccine induced serum and antibody-secreting cell (ASC) IgA responses, but not local (salivary or gastric) responses to the vaccine antigen [119]. Most subjects (67%) receiving LT developed diarrhea [119]. Although none of the subjects were cured of their *H. pylori* infection, a significant decrease in gastric *H. pylori* density (but not inflammation) was observed in biopsy tissue. It remains to be determined whether sterilizing immunity can be achieved by a *H. pylori* vaccine and, if not, whether suppression alone can prevent the pathological consequences of infection.

Banerjee and coworkers [120] attempted to confirm that LT possesses adjuvanticity for rUrease in humans, and to identify the lowest dose that would be safe and immunogenic. They immunized 42 *H. pylori* uninfected adults with 60 mg rUrease in soluble or encapsulated form, given in four spaced doses (days 1, 8, 29, and 57) with LT at doses ranging from 0 to 2.5 µg. Preliminary results indicate that mild diarrhea (1–4 loose stools) occurred after the first dose in 50% of subjects receiving 2.5 µg LT but not in subjects receiving lower LT doses. A serologic response to urease was seen in 67% of subjects who received 2.5 µg of LT, and in 17–33% of those given lower doses of LT (0.5 and 0.1 µg). These data support the notion that coadministered LT enhances the immune response to oral rUrease vaccine and indicate that at the minimal effective dose of LT (2.5 µg), mild diarrhea occurs.

Rectal delivery of rUrease was evaluated in a clinical trial as a means to achieve an alternative mucosal route of immunization. Eighteen *H. pylori* uninfected volunteers were randomized to receive either 60 mg rUrease alone, or 60 mg rUrease plus native LT (5 or 25 µg). Three doses were given on days 0, 14, and 28. The rectally delivered vaccine was well tolerated. Although most subjects mounted excellent IgG and IgA serum antibody (60–80%) and IgA ASC responses (100%) to LT, few (8–25%) had responses to urease [121]. Interestingly, salivary and fecal antibody responses were not detected.

## 2. Other *H. pylori* Vaccine Antigens

Although urease has received the most attention for vaccine development, antigens such as VacA, CagA, and NAP, selected because of their contribution to *H. pylori* virulence, have generated promising preclinical results. Both native and recombinant VacA confer prophylactic and therapeutic protection against *H. pylori* infection after oral immuniza-

tion of mice when given with either native LT or with the nontoxic mutant LTK63 [91,122–124]. The full-length molecule was required to achieve high levels of protection, because the mice immunized with recombinant fragments corresponding to the 37- and 58-kDa subunits of VacA did not resist infection [122]. Interestingly, recombinant VacA generates protective immunity although it retains neither its native conformation nor its toxic activity *in vitro* [123]. The mechanism of immunity is strictly antigen-specific, because VacA does not protect against challenge with an isogenic strain lacking the *vacA* gene [122]. Moreover, therapeutic vaccination with recombinant VacA plus LTK63 prevents reinfection with the same *H. pylori* strain, providing further proof that this regimen induces antigen-specific immunological memory *in vivo* [124]. Notably, all these studies used the infecting strain to rechallenge, and protection was defined as failure to cultivate *H. pylori* from the excised stomachs of the mice. While the ability of VacA to induce sterilizing immunity is encouraging, it will be important to confirm these findings using heterologous *H. pylori* challenge strains.

Prophylactic and therapeutic protection has also been observed in mice after oral [122,124] and intranasal (G. Del Giudice, unpublished) immunization with CagA plus LTK63. As in the case of VacA, the full-length CagA molecule achieves high levels of protection, whereas neither the A17/12 fragment (known to contain immunodominant epitopes in humans) [122] nor a fusion protein containing a 65-kDa fragment of CagA [95] protects mice against challenge.

Oral immunization of mice with *H. pylori* NAP, along with LTK63 as adjuvant, also provided excellent prophylactic efficacy [52]. It is possible that neutralization of the chemotactic and proinflammatory properties of this protein interferes with the colonization and/or survival of *H. pylori*.

Several other *H. pylori* antigens have been reported as potential vaccine candidates. The bacterial heat shock proteins, for example, were used to immunize mice as recombinant proteins [83,125], as synthetic peptides [126], and as DNA plasmids [78,79]. Other antigens reported as protective in mice following prophylactic immunization are enzymes such as catalase given mucosally [127] or parenterally [74], and a serine protease given parenterally [74], bacterial adhesins such as AlpA and BabB given parenterally [74], heparan sulphate-binding protein covalently linked with the B subunit of the CT given orally [128], outer membrane proteins such as the Lpp20 [129,130], several Hop proteins [131], and a protein of 26 kDa [132], the L7/L12 ribosomal protein [130], and other proteins that are yet to be characterized [130,133].

For some bacterial infections, such as pertussis, optimal protection is achieved by combining multiple antigens in a vaccine formulation [134]. Given the difficulty in identifying protective *H. pylori* antigens in humans, and the likelihood that broader immunity could be achieved by stimulating immune responses against multiple targets, a multivalent approach has been considered for *H. pylori*. Preclinical assessment of this strategy is limited by the fact that optimum protection is often achieved with a single antigen. Nonetheless, improved protection was reported in mice orally immunized with heat shock proteins plus urease B

subunit [83] or with VacA plus urease [122], and with combinations of various antigens plus urease given parenterally [74]. More recently, intramuscular immunization of beagles with VacA, CagA, and NAP (formulated together with aluminum hydroxide) was shown to confer significant protection against *H. pylori* challenge (G. Del Giudice, unpublished). This formulation has now been tested in volunteers [135]. A total of 57 *H. pylori*-negative subjects were immunized intramuscularly, with three doses of each antigen ranging from 10 to 25 µg. The vaccine was very well tolerated and induced strong antigen-specific antibody and lymphocyte proliferation responses.

### B. Live Vectors

The experience with subunit vaccines illustrates that, although efficacious mucosal immunizations were achieved in animal models, in which the reactogenic doses of CT or LT adjuvants exceeded the level required for successful adjuvant effect, this has not been the case for humans who are exquisitely sensitive to these bacterial toxins [119,120]. Thus the use of live vectors for mucosal delivery was investigated, first in mouse models and then in volunteers.

Attenuated *Salmonella enterica* strains expressing *H. pylori* antigens have shown promise in murine challenge models. Mice immunized with attenuated *ΔphoP<sup>c</sup>* or *ΔaroA* *S. enterica* serovar Typhimurium strains expressing *H. pylori* urease [136,137] or catalase [138] were protected against challenge with *Helicobacter*. These studies formed the basis for several exploratory clinical trials using *S. enterica* vectors. Disappointing results were obtained from a study using a serovar Typhi vector strain deleted for the virulence regulon *phoP/phoQ* (Ty800) and engineered to constitutively express the urease A and B subunit genes from a stabilized multicopy plasmid. Vaccination of eight volunteers with a single oral dose of  $\geq 10^{10}$  CFU of this Ty1033 strain was mildly reactogenic and failed to elicit immune responses to urease, although the mucosal and serum antibody to *Salmonella* antigens were detected [139]. Possible reasons for this lack of immunogenicity include the cell-associated presentation of urease or insufficient antigen production by the vector. A similarly meager immune response was observed in nine volunteers orally inoculated with *S. enterica* serovar Typhi Ty21a expressing *H. pylori* rUrease A and B [140].

A more successful outcome was obtained with a similarly constructed *ΔphoP/phoQ* serovar Typhimurium strain LH1160 derived from the wild-type mouse virulent strain ATCC 14028 and engineered to express urease [141]. Six subjects received a single oral dose of vaccine containing  $5-8 \times 10^7$  CFU. Two subjects experienced unacceptable fever and constitutional symptoms, but none had diarrhea. Three subjects mounted urease-specific IgA ASC responses (measured either by ELISPOT or by soluble immunoglobulin release from PBMC grown in tissue culture to high density), and one subject had an increase in serum antiurease IgG antibody. These results suggest that, despite the same attenuating mutation, plasmid expression system, and expressed antigen, even at a 3-log lower dose, serovar Typhimurium appeared to be a superior vector for engendering immune responses to urease compared with serovar Typhi. Enhanced

plasmid stability and more vigorous intestinal colonization were postulated to explain these differences [141]. Nonetheless, issues that must be considered if LH1160 were to be developed further include tolerability, potential transmission to immunodeficient individuals, and the risk for post-infectious reactive arthritis (that may follow wild-type nontyphoidal *Salmonella* infections).

An alternative strategy was studied by McKenzie and coworkers [142], in which two attenuated strains of *S. Typhi* Ty2, CVD 908 (*ΔaroC*, *ΔaroD*) [143], and CVD 908-*htrA* (*ΔaroC*, *ΔaroD*, *ΔhtrA*) [144], were engineered to express *H. pylori* urease. In an ascending-dose design, volunteers received two oral inoculations 4 weeks apart. Preliminary reports indicate that the less-attenuated strain (*ΔaroC*, *ΔaroD*), at doses of  $5 \times 10^7$  or  $2 \times 10^8$ , caused adverse reactions in several volunteers. The more attenuated *ΔaroC*, *ΔaroD*, *ΔhtrA* strain at doses of  $5 \times 10^8$  or  $5 \times 10^9$  was well tolerated. The stool shedding pattern of the two strains was similar but, most interestingly, the more attenuated strain elicited a better immune response to urease. The high dose of the triple mutant stimulated urease-specific IgG ASCs in 10 of the 12 subjects and fecal IgA in 5 subjects. These trials provide encouraging results that mucosal immunization against *H. pylori* can be achieved in humans, but whether or not these immune responses could lead to protection against disease or infection is not known.

### C. Inactivated Whole-Cell Vaccines

Administration of inactivated whole cell preparations (as sonicates, lysates, or formalin-treated cells) is an empiric approach to vaccine development that has the potential to elicit immunity to multiple *H. pylori* antigens. Numerous preclinical studies have shown that both mucosal and parenteral vaccination with whole cell preparations of *H. pylori* or *H. felis*, together with appropriate adjuvant confers protection against challenge with the homologous organism [55,56,82,83,91,122]. Similar formulations were also shown to be an effective therapeutic strategy in mice [87,145] and piglets [69] when given mucosally, but not parenterally [69,145].

Formalin-inactivated whole cell *H. pylori* vaccine coadministered with mutant LT<sub>R192G</sub> adjuvant was evaluated in Phase 1 studies involving subjects with and without *H. pylori* infection [146]. In a double-blind, randomized fashion, 18 *H. pylori*-infected subjects ingested either  $2.5 \times 10^{10}$  vaccine cells or placebo, plus 25 µg LT<sub>R192G</sub> or placebo. Diarrhea, low-grade fever, and/or vomiting were observed in ~30% of subjects, usually after the first dose. The diarrhea appeared to be related to receipt of mutant LT, but was augmented by increasing doses of vaccine. Whereas serum antibody responses to the whole-cell antigen were marginal and seen only in *H. pylori*-infected subjects, mucosal (fecal and salivary) IgA responses were stronger and occurred among *H. pylori*-infected and uninfected subjects, but only following inoculation with vaccine plus LT<sub>R192G</sub>. Some *H. pylori*-negative volunteers developed lymphoproliferative and IFN-γ responses. No subjects were cured of their *H. pylori* infection. These results suggest that it is possible to stimulate mucosal and systemic immune responses in humans to *H.*

*H. pylori* antigens using a whole-cell vaccine, but more immunogenic, better-tolerated formulations are required.

### VIII. FUTURE DIRECTIONS

To date, the design of most *H. pylori* vaccine candidates submitted to preclinical or clinical evaluation has been based on empirical approaches, as in the case of whole cell preparations, outer membrane vesicles, or antigens representing virulence factors. More recently, the genome sequence of *H. pylori* has been explored. Several hundred genes have been cloned and their products tested in the mouse challenge model, some of which elicited protective immunity when given parenterally with adjuvant [74]. However, the lack of immunological correlates of protection against *H. pylori* limits the possibility to exploit the genomics information fully without having to test each antigen empirically. Much interest has thus turned to analyzing the gene products of the bacterium (proteomics) because of considerable progress in protein separation and biochemical analysis. These bacterial extracts can be reacted with a source of specific antibodies, mainly serum samples from infected patients, to select new potential targets for use in vaccines [147–151]. It is likely that the next generation of vaccines will combine multiple *H. pylori* antigens to produce a multivalent vaccine formulation.

We have reached a critical juncture in which animal systems and molecular techniques have identified numerous protective antigens, but available clinical models cannot effectively discern which of these holds promise. Clearly, formulation and delivery systems must be optimized to overcome the meager immunogenicity elicited by most mucosally delivered candidates subjected to clinical trial thus far. Additional data are needed about the requirements for induction of antigen-specific cell populations, homing of these cells to the gastric mucosa, and the mechanisms involved in effector responses that mediate protection against *H. pylori* following immunization. However, even if immunogenic vaccines were constructed, the appropriate clinical endpoints for evaluating these candidates remain undefined. It is unclear whether a therapeutic vaccine should be required to eradicate infection, reduce bacterial burden, or merely ameliorate gastritis. Even if the latter two choices were deemed acceptable, noninvasive means to measure these outcomes are not available for use in larger Phase 2 and 3 trials. Furthermore, gastric injury is patchy, so it is difficult to accurately quantify bacterial load and inflammatory changes. Strategies for selecting promising prophylactic vaccines are also problematic. One approach is to seek vaccines that demonstrate therapeutic efficacy and assume that similar effector mechanisms are operative in prevention. Alternatively, one could develop constructs that appear immunogenic in Phase 1 and 2 trials. Ultimately, prophylactic efficacy must be evaluated, either in an experimental challenge model, which remains controversial, or in field trial. Again, this would require clarification of reasonable endpoints.

In conclusion, remarkable gains have been made in understanding *H. pylori* infection during the two decades

since it was discovered. Nonetheless, further progress in *H. pylori* vaccine development will depend on the discovery of innovative approaches to vaccine design, host immunity, and clinical evaluation.

## Vaccines for *Staphylococcus aureus* Infections

Ali I. Fattom, Gary Horwith, and Robert Naso

W. W. Karakawa Microbial Pathogenesis Laboratory, Nabi Biopharmaceuticals, Rockville, Maryland, U.S.A.

### I. INTRODUCTION

Staphylococci are commensal bacteria of the anterior nares, skin, and the gastrointestinal tract of humans that rarely cause systemic infections in otherwise healthy individuals, and therefore are considered opportunistic pathogens. Through various mechanisms, adult humans and animals attain an innate but incomplete natural protection from staphylococcal infections. Partial protection is afforded by mucosal and epidermal barriers, in addition to possible immunological mechanisms that impart resistance. Interruption of these natural barriers as a result of immunosuppressive diseases or therapies, or injuries such as burns, traumas, or surgical procedures involving indwelling medical devices, increases the risk for staphylococcal infections [1,2]. Nasal carriage of *Staphylococcus aureus* is reportedly one of the major risk factors for surgical wound infections after surgery, and for infections of the vascular access site in hemodialysis patients [3–5]. It is estimated that staphylococcal infections account for >50% of all hospital-acquired infections. *S. aureus* alone is responsible for 15–25% of such infections and is surpassed only by *S. epidermidis*, which reportedly accounts for as many as 35% of these infections [6–12]. Staphylococcal infections, especially those caused by *S. aureus*, are associated with high morbidity and mortality [13,14].

### II. PATHOGENESIS

*S. aureus* produces a wide range of extracellular enzymes and toxins that play a significant role in pathogenesis. Enzymes such as hyaluronidase, coagulase, and fibrinolysin, among others, facilitate the establishment of *S. aureus* infections and dissemination of the microorganisms. Toxins produced by *S. aureus* isolates have a wide range of activities that compromise the host's resistance. *S. aureus* include enterotoxins that are responsible for food poisoning; exfoliative exotoxin causes intraepidermal splitting of tissues and necrosis; hemolysins alpha through delta, and toxic shock syndrome toxin-1 cause rash, fever, and, in extreme cases, shock

[15–18]. In addition, *S. aureus* produces extracellular proteins responsible for destroying human polymorphonuclear leukocytes (PMNs), thus, compromising opsonophagocytosis, the mechanism that is believed to play a major role in clearance of staphylococci from infected tissues [19]. *S. aureus* is also a major cause of infections associated with indwelling medical devices such as catheters and orthopedic devices [20]. Multiple surface proteins that play an important role as receptors for plasma proteins, glycoproteins, and tissue matrices, enhance the adherence of *S. aureus* to medical devices and facilitate the initiation of infection [21]. *S. aureus* also produces extracellular and cell-associated enzymes, such as coagulase and clumping factor, that enhance survival of the microorganism and establishment of infection [22]. In addition, *S. aureus* possesses other surface antigens that facilitate its survival in the bloodstream by helping the bacteria evade phagocytic killing by host leukocytes. These surface antigens include cell wall components such as teichoic acid, protein A, and capsular polysaccharides (CPs) [6,7,23–25]. Due in part to the versatility of these bacteria and their ability to produce extracellular products that enhance infectivity and pathogenesis, staphylococcal bacteremia (and its complications such as endocarditis, septic arthritis, and osteomyelitis) continue to be serious and frequently observed nosocomial infections [26,27]. While neutralizing staphylococcal extracellular toxins or blocking adherence of *S. aureus* to medical devices by antibodies may reduce virulence and confer protection against the specific indication [21,28], clearance of the bacteria from the body and elimination of the infectious locus remain the underlining mechanisms of protection against *S. aureus* infections [20,29,30].

The introduction, in the 1940s, of penicillin G temporarily solved the problem of staphylococcal infections. However, by 1948, the prevalence of penicillin-resistant strains had seriously reduced the value of this antibiotic in treating serious staphylococcal infections [31]. By the late 1950s, *S. aureus* clinical isolates had acquired resistance to virtually all the systemic antibiotics then in use, including penicillin, erythromycin, streptomycin, and the tetracyclines. These

resistant strains, especially phage type 80/81, caused a global pandemic and were isolated from nosocomial infections in hospitals around the world. The introduction of the semi-synthetic penicillins, methicillin and oxacillin, was considered a giant step toward controlling multiresistant *S. aureus* infections, and again temporarily brought *S. aureus* infections back under control [32]. Shortly after the introduction of these semisynthetic agents, however, strains of methicillin-resistant *S. aureus* (MRSA) were isolated in England (in 1961) and, by 1965, these isolates were common in Europe. In 1968, the first outbreak of MRSA in the United States was reported in Boston, MA [33]. Currently, methicillin resistance among staphylococci isolates from nosocomial infections continues to increase in frequency, and resistant *S. aureus* strains continue to cause epidemics in hospitals in spite of developed preventive procedures and extensive research into bacterial epidemiology and antibiotic development [34,35].

While the initial efficiency and efficacy of these antibiotic agents in treating and curing staphylococcal infections has drawn attention away from the development of immunological approaches for dealing with these infections, the emergence of multiple-antibiotic-resistant strains of *S. aureus* has now reduced the options for treatment to virtually one antibiotic, vancomycin. This, in combination with the emergence of vancomycin-resistant enterococci (that in laboratory experiments can transfer vancomycin resistance to *S. aureus*), and of *S. aureus* with reduced sensitivity to vancomycin, has renewed the interest in alternative strategies to prevent and treat *S. aureus* infections [36–39].

### III. PREVIOUS EXPERIENCE WITH *S. AUREUS* VIRULENCE AND VACCINES

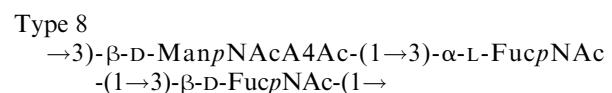

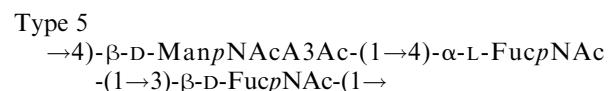

The late 1950s and early 1960s witnessed vigorous research activities into *S. aureus* virulence, pathogenesis, and the development of vaccines for treatment and prevention of staphylococcal infections. Two experimental vaccines were produced and tested in human trials. The first was comprised of a phage lysate of virulent *S. aureus* isolates belonging to phage groups I and III. This vaccine was evaluated in treatment and cure of severe staphylococcal skin infections in humans. Of 607 patients immunized with this vaccine, 80% reportedly recovered from their infections, which included furunculosis, pustular acne, and eczema, among others [40]. However, this trial was neither randomized nor placebo controlled. A subsequent placebo-controlled study with a similar phage lysate vaccine, comprised of phage group I and Cowan 1 strain *S. aureus*, showed no significant improvement in the number, size, or frequency of furunculosis lesions [41]. Another vaccine containing polyvalent somatic antigens, produced by enzymatic treatment of *S. aureus* clinical isolates representing the four major phage groups, protected immunized animals against intradermal challenge with a variety of clinical *S. aureus* isolates [42,43]. In a clinical trial to treat and prevent impetigo in Native Americans, the vaccine showed a significant curative efficacy for 4 months following two injections of the vaccine [44]. These data appeared to confirm protection results obtained in a previous study with this vaccine [45]. Examination of the

vaccine phage types used in these vaccines as listed by these authors, using data published by Sompolinsky et al. [46] on phage types and the corresponding capsular types, revealed that the polyvalent lysate or the somatic antigens vaccine used in these studies were basically comprised of *S. aureus* strains representative of CP type 5 (phage group III), type 8 (phage group I), and so-called nontypeables (other groups). Observations from these studies testify to a possible role of capsular polysaccharides in the protective activities: (1) the only failed vaccine was that comprised of Group I (CP 8) and the noncapsulated strain Cowan 1 [41], (2) a group-specific protection was observed in the potency test for the release of the polyvalent somatic antigen vaccine, and (3) protection was achieved following one or more rounds of immunization, and was associated with rise of agglutinins in immunized animals [42,43], indicating that the observed protection was mediated by antibodies generated in response to vaccination with these antigens. These preliminary encouraging data were not enough to counter the prevailing opinion among staphylococcal researchers that protective immunity against staphylococcal infections was not a valid approach and led to the conclusion that the immune-based approach to combat staphylococcal infections “has gone as far as it can go” [47].

### IV. CAPSULAR POLYSACCHARIDES OF *S. AUREUS* CLINICAL ISOLATES

A renewed interest in staphylococcal immunology was generated by the work of Karakawa and colleagues in the early 1980s, who showed that *S. aureus* isolates associated with bacteremia and other systemic infections possessed CP [48–50]. To date, at least 13 serologically different *S. aureus* capsular types have been found among human and animal infection isolates [51–53]. Surveillance of *S. aureus* infection isolates from the United States and Europe by various laboratories, using Karakawa’s serological typing scheme, showed that of the 13 known capsular types, types 5 and 8 comprised >80% of the isolates [50]. Data from several surveillance studies over the last few years have shown that these two types and their variants comprise >90% of all clinical isolates in certain patient populations.

The chemical composition of CP types 5 and 8 is nearly identical. Both are polymers composed of *N*-acetyl-amino-uronic acid and *N*-acetyl-fucosamine in a 1:2 ratio but differ in the glycosidic linkages and the site of O-acetylation [23, 54,55]. Despite the similarities, however, no demonstrable immunological cross-reactivity between the two capsular types is found. The subunit structure of these CP molecules is shown below:

In vitro studies show that polyclonal and monoclonal antibodies elicited against these CP are biologically active

and mediate opsonophagocytic killing of the type-specific bacteria by human PMNs [56]; in this respect, the CP of *S. aureus* are no different from the capsules of other bacterial pathogens [57–60] and, as such, *S. aureus* CP may play a role in protective immunity and serve as vaccine candidates.

## V. CONJUGATE VACCINES

### A. Rationale and Evaluation in Animals

Bacterial CPs are generally poor immunogens, and their immunogenicity in humans is known to be related to their molecular size and the age of the vaccinee. Infants and toddlers below the age of 2 years, the elderly, and immunocompromised patients are poor responders to CP vaccines [61,62]. CP vaccines are T-cell independent and they induce humoral antibodies with no boost upon reinjection. Compared to other polysaccharides vaccines used in humans, types 5 and 8 CP are of low molecular size, ~50,000 Da, and as such, they are expected to be poor immunogens in humans, especially in immunocompromised populations with reduced resistance.

Since immunization with a *S. aureus* vaccine would be intended for certain at-risk patients, such as those on chemotherapy, hemodialysis patients, infants, shock-trauma patients, surgical patients, and others with reduced resistance or partially compromised immune systems, we embarked on the development of capsular polysaccharide-conjugate vaccines, a strategy already proven to enhance the immunogenicity of other CP-based vaccines. Conjugation of polysaccharides to protein carriers makes bacterial CP antigens T-cell-dependent immunogens, thus increasing their immunogenicity and potentiating their use in infants and immunocompromised patients [63–67]. The two clinically significant CP types, 5 and 8, were conjugated to a nontoxic, recombinant exoprotein A from *Pseudomonas aeruginosa* (rEPA). The immunogenicity of the two CP and their conjugates was evaluated in mice. While the nonconjugated CP were not immunogenic, the conjugates were highly immunogenic and acquired T-cell-dependent properties such as booster response and carrier priming. CP conjugate vaccines elicited antibodies shown to be biologically active in vitro and mediated the opsonophagocytosis and killing of bacteria of homologous serotype by human PMNs [68,69].

### B. Evaluation in Humans

*S. aureus* type 5 and 8 CP-conjugate vaccines have now been evaluated for their safety and immunogenicity in healthy adult volunteers [70]. In the initial studies, vaccinees received, via intramuscular injection, either type 5 or type 8 CP-rEPA conjugates at a nominal dose of 25 µg CP in 0.5 mL phosphate-buffered saline. A second dose of CP conjugates was administered 6 weeks following the first injection. No serious local or systemic reactions were recorded following the first or second injection. However, most of the volunteers experienced a slight tenderness and erythema after the second injection. These reactions were generally mild and disappeared within 48 hr of the injection. Two volunteers experienced a slight transient elevation in their liver

enzymes for 5 days following the initial injection, but there was no elevation in liver enzymes in any of the volunteers following the second injection.

During the clinical trials described above, it was noted that most volunteers had preimmunization antibodies to type 5 and type 8 CP; their geometric mean IgG antibody titers were in the 5–10 µg/mL range. All volunteers in both groups responded to immunization with greater than four-fold increase in IgG antibody levels. Maximum antibody levels were reached by 6 weeks after the first immunization with a geometric mean rise in antibody titer over preimmunization levels of 35-fold for type 5 and 10-fold for type 8. A significant rise in titer was observed for IgM class antibodies as well. As shown with other conjugate vaccines, the second injection did not stimulate a booster response. This was attributed to the fact that adult humans are already primed to these antigens. Therefore, the immune response following the first immunization is considered a booster [64,71]. The conjugate-induced antibodies were mostly of IgG1 and IgG2 subclasses and the antibodies mediated opsonophagocytic killing of the appropriate CP type *S. aureus* by human PMNs. A decrease in type 5 and type 8 antibody levels was observed in the immunized volunteers by 6 months post-immunization (14–20% and 9%, respectively).

Ultimately, bivalent formulations will be made to simplify immunization. A clinical trial was undertaken to evaluate the immunogenicity of the two monovalent conjugates when injected simultaneously into separate arms of volunteers. Results showed no difference in the anti-CP antibody levels, IgG subclasses, or longevity of the immune response for the two vaccines injected simultaneously compared to data obtained with the monovalent regimen in healthy volunteers [72]. A bivalent CP5-rEPA and CP8-rEPA conjugate was formulated in one vial (StaphVAX™), and evaluated in healthy volunteers. The bivalent formulation containing 25 µg of each CP conjugated to rEPA was well tolerated by the vaccines, with no serious local or systemic reactions being recorded in the vaccine group compared to the placebo control group. IgG antibody levels to type 5 and type 8 CP were comparable to those elicited by the previous monovalent vaccines, 173.4 and 70.8 µg/mL, respectively. Moreover, in a subsequent study, the immunogenicity of the two conjugates in the bivalent formulation was compared to their immunogenicity when administered concurrently as monovalent vaccine in separate arms. The IgG levels to CP5 and CP8 achieved by bivalent formulations were equivalent to those elicited by the double monovalent regimen, 178.2 µg/mL versus 139.3 µg/mL for CP5, and 62.7 µg/mL versus 74.6 µg/mL for CP8, respectively. These results show that the bivalent combination is safe and no immunogenic interference of one component against the other is observed. Furthermore, these data point out to feasibility for combining the two conjugates into one single injection that may simplify the future immunization regimen (unpublished data).

## VI. VACCINATION STRATEGIES

*S. aureus* vaccines are intended for specific populations at heightened risk and not for mass immunization. The target

populations for immunization may be divided into two major categories: (1) patients who are able to mount an immune response following active immunization and (2) patients who are unable to respond to a vaccine or who do not have time to respond to active immunization and require the passive administration of antibodies that were previously raised in other hosts.

### A. Active Immunization

Active immunization may be a feasible strategy for preventing staphylococcal infections in patients scheduled for cardiac or orthopedic surgery (especially hip replacement) and for patients undergoing implantation of medical devices, including renal failure patients on dialysis. Typically, these target populations are sufficiently immunocompetent to respond to a vaccine and have a sufficient time to mount an immune response.

The safety and immunogenicity of the type 5-rEPA conjugate vaccine was evaluated in hemodialysis patients at Walter Reed Army Medical Center [73]. Seventeen hemodialysis patients were immunized twice, 6 weeks apart, with 25 µg CP type 5-rEPA conjugate vaccine. The vaccine was well tolerated and serious local or systemic reactions were not observed. The type 5 CP specific IgG postimmunization levels were comparable to those achieved in normal volunteers immunized with the same lot of vaccine, 179.5 IgG and 317.8 µg/mL, respectively ( $P = 0.11$ ). A lower percentage of vaccinees responding with greater than fourfold increase in the specific antibody levels compared to preimmunization levels was observed in this hemodialysis patient population compared to the study in normal, healthy volunteers described above, 81% and 100%, respectively [73]. A second immunization at 6 weeks failed to boost immune response beyond levels achieved with the first injection. A significantly larger decrease in antibody levels, 39% versus 14%, respectively, was observed 6 months postimmunization in the hemodialysis patients than was observed in healthy volunteers immunized with the same lot of the conjugate vaccine. These data suggest that active immunization with *S. aureus* conjugate–polysaccharide vaccine may be feasible even in an immunocompromised target population, although immunogenicity remains an issue. Strategies to improve active vaccination, such as reimmunization when titers fall to low levels, optimizing the dose for each target population, the use of adjuvants, and alternate delivery systems, are under evaluation.

### B. Passive Immunization

Populations at high risk for *S. aureus* infections, where active immunization is unlikely to be helpful, include neonates, especially premature newborns [74]; other more completely immunocompromised individuals (e.g., certain cancer patients on immunosuppressive therapy); and populations where the risk for infection is both high and immediate (e.g., shock-trauma patients). Passive protection may be useful for such high-risk subjects. To accomplish this, vaccines would be used to actively immunize healthy adult plasma donors, whose plasma would then be collected and fraction-

ated to produce specific hyperimmune gamma immunoglobulin (IGIV) for intravenous passive immunization. To this end, plasma donors were immunized with a bivalent type 5 and type 8 CP-rEPA conjugate (StaphVAX, Nabi, Boca Raton, FL) and plasmapheresis was performed. Plasma units collected from this donor stimulation program were pooled and fractionated using licensed fractionation techniques. When compared to the commercially available standard intravenous immunoglobulin (IGIV), the specific hyperimmune IGIV (Altastaph™, aka StaphGAM™, Nabi) contained 30- to 40-fold more *S. aureus* types 5 and 8 CP-specific IgG. This antibody preparation was opsonic in an in vitro opsonophagocytosis assay and was protective in animal model studies (see below). This vaccine-induced antibody product might have an advantage over screened and/or standard IGIV by having a higher specific IgG content. Moreover, preliminary results showed that vaccine-induced IgG had greater than fourfold higher affinity for *S. aureus* CP than did commercial IgG (unpublished data). Studies are ongoing to optimize the donor vaccination regimen and vaccine dose, and to evaluate the effect of plasmapheresis frequency on the specific antibody levels in plasma donors.

In a study performed in collaboration with the Shock-Trauma Center (STC) at the University of Maryland School of Medicine, Baltimore [75], *S. aureus* infections in patients admitted to the STC over an 18-month period in 1993–1994 were evaluated. A high *S. aureus* infection rate was observed (7.54%) with bacteremia and pneumonia as the two major infections; infection rates for bacteremia and pneumonia were 4.9% and 2.64%, respectively. Nearly all of these infections occurred within 2–5 days following the initial day of hospitalization. Since a robust immune response to vaccination with a polysaccharide-conjugate vaccine such as StaphVAX usually takes more than two weeks to develop, the immediate-risk status of shock trauma patients makes active immunization impractical. Studies are therefore planned to passively immunize patients such as these with Altastaph. Based on previous experience with the pharmacokinetics of standard IGIV and other specific polyclonal antibodies, passive immunization is expected to provide protective levels of circulating antibody and possibly protection for at least 3 weeks, more than enough time to protect the shock-trauma patient and potentially emergency surgery patients during the period of highest risk.

It should be noted that for some patients, for example, those receiving prosthetic devices such as hip replacements, it may be necessary to provide both passive and active immunization to protect the individual from infection immediately after surgery and for the longer term. Studies are in progress in animals to evaluate combined passive and active immunization against *S. aureus*.

## VII. IN VIVO AND IN VITRO VIRULENCE AND PROTECTION DATA

### A. Early Human and Animal Data

Two clinical trials using a vaccine composed of a whole-cell lysate combined with *S. aureus* toxoids (Staphypan Berna)

were performed in an attempt to prevent *S. aureus* infections in end-stage renal dialysis (ESRD) patients on chronic ambulatory peritoneal dialysis (CAPD). Although conclusions could not be drawn from the results of the first study, the authors expressed optimism about the possible future usefulness of this vaccine in controlling *S. aureus* infections in these patients [76]. This vaccine was subsequently evaluated in a multicenter, placebo controlled, double-blinded trial. Data published from the subsequent trial showed no significant advantage of the vaccine over the placebo [77].

It has been well established since the 1960s that capsules belonging to *S. aureus* strains Smith (capsular type 2) and M (capsular type 1) are virulence factors and protective antigens [78–83]. Subsequent work by Lee et al. [84] showed that mutants that lost their capsules are less virulent than their parent strains and that these capsules, when used as vaccines, induced protective activity against bacterial challenge [85]. In contrast, the role of the clinically significant capsules, types 5 and 8, in virulence and possible protection continues to be controversial. While some authors have reported these capsules to be antiphagocytic (requiring type-specific antibodies to mediate opsonophagocytosis) [48,56,68–70], others have reported that *S. aureus* CP types 5 and 8 are not virulence factors [86]. One study reports that encapsulated isolates are equally phagocytosed in the presence of homologous or heterologous sera as well as sera raised against noncapsulated strains[87]. In fact, it has been reported that capsular polysaccharides actually attenuate the virulence of these clinical strains [88]. In other related studies, immunization of animals with type 5 whole cell vaccine failed to protect against bacterial challenge in rabbit as well as rat endocarditis models [89,90].

## B. Current Animal Data

To further evaluate the role of capsule and antibodies to capsular polysaccharides in *S. aureus* infections, we have used a lethal, challenge mouse model to evaluate CP-conjugate vaccines and hyperimmune IgIV. Our data showed that either intraperitoneal or subcutaneous administration of hyperimmune human IgIV (Altastaph, aka StaphGAM) directed to *S. aureus* CP protected mice against lethal intraperitoneal challenge with a clinical *S. aureus* isolate (CP type 5); we observed >90% survival in mice passively immunized with specific polyclonal antibody compared to a 22% survival rate in animals receiving standard IgIV ( $P < 0.001$ ) [91]. Studies in this mouse model have also shown that active immunization with CP-rEPA conjugate vaccine conferred significant protection compared to saline immunized animals. In these studies, survival of immunized animals after challenge with type 5 *S. aureus* was >73% versus <7% survival rate in nonimmunized animals ( $P < 0.001$ ).

Rabbit IgG preparations from animals immunized with a type 5 CP-conjugate vaccine were evaluated in a modified catheter-induced model of staphylococcal endocarditis rat model [92]. Data generated in this model showed that hyperimmune rabbit IgG significantly protected rats against intraperitoneal bacterial challenge of type 5 *S. aureus*. Animals receiving the hyperimmune IgG preparation developed fewer endocarditis episodes compared to those immunized

with nonimmune rabbit IgG (25% and 87.5%, respectively;  $P < 0.05$ ). Furthermore, these animals had reduced bacterial counts in blood, in vegetation on the catheter-damaged heart valve, and in kidneys compared to rats receiving the same amount of nonimmune rabbit IgG ( $P < 0.05$  for all three indications) [92].

## VIII. STAPHVAX—RECENT CLINICAL RESULTS AND FUTURE PROSPECTIVES

*S. aureus* is a major cause of infections associated with indwelling medical devices such as catheters and orthopedic devices [93]. Peritonitis, exit-site infections, and bacteremia due to staphylococci are the major cause of morbidity and mortality in patients with ESRD [94–100]. ESRD patients are, therefore, considered to be appropriate targets for evaluation of active vaccination. StaphVAX containing 25 µg of each polysaccharide conjugated to rEPA was evaluated for its safety and immunogenicity in ESRD patients on hemodialysis. Although this dose of vaccine was determined to be safe and immunogenic, specific antibody levels achieved were lower in this population than seen previously in normal, healthy volunteers. In addition, although antibody levels declined over time faster in the ESRD patients than in normal, healthy volunteers, one year after vaccination, CP-specific antibody levels remained significantly elevated over preimmunizaton levels (not shown).

A Phase 2 multicenter, double-blinded efficacy trial of StaphVAX in 237 ESRD patients undergoing chronic ambulatory peritoneal dialysis also demonstrated that a single dose of 25 µg of StaphVAX was safe and well tolerated. However, this dose of vaccine did not decrease the incidence of *S. aureus* peritonitis (unpublished results). Importantly, the results suggested that the vaccine dose selected was suboptimal, since lower antibody levels were achieved than previously observed in normal, healthy volunteers administered that dose.

In an attempt to optimize the performance of StaphVAX in ESRD patients, a dose-escalating clinical study in ESRD patients on hemodialysis was performed using 50 and 100 µg/mL of each polysaccharide conjugated to rEPA in the bivalent formulation. Data in Table 1 show a dose response to the vaccine in both antibody levels achieved and the percent responders. As shown in Table 1, the antibody levels at 42 days postimmunization at the 100-µg dose in ESRD patients approximated the levels seen in normal healthy volunteers at the 50-µg dose (not shown). However, the antibody levels declined more rapidly in ESRD patients than previously observed in normal, healthy volunteers at all vaccine doses tested (not shown).

In 1998, a single dose of bivalent vaccine containing 100 µg of each polysaccharide conjugated to rEPA was evaluated for safety, immunogenicity, and efficacy in a double-blinded, randomized, placebo-controlled study in ESRD patients (ages 18–91) on hemodialysis [101]. A total of 1804 adult patients at 73 hemodialysis centers received a single intramuscular injection of either vaccine ( $n = 894$ ) or saline ( $n = 910$ ). IgG antibodies to types 5 and 8 CP were measured at intervals for up to 2 years, and episodes of *S. aureus* bac-

**Table 1** Dose Response to StaphVAX Immunization in ESRD Patients

Nominal dose ( $\mu\text{g}$ )	N	Type 5 IgG antibodies ( $\mu\text{g/mL}$ )			Type 8 IgG antibodies ( $\mu\text{g/mL}$ )		
		Day 0	Day 42	Responders (%)	Day 0	Day 42	Responders (%)
25/25	15	6	62	80	10	31	47
75/75	16	4	82	75	3	50	75
100/100	17	4	172	88	6	143	88

teremia were recorded. The primary endpoint of the trial was efficacy through 1 year of follow-up postvaccination. Efficacy was estimated by comparing the attack rate of *S. aureus* bacteremia in the vaccine group to that of the controls. Vaccine reactions were generally mild to moderate and most resolved within 2 days. The vaccine elicited a significant CP-specific antibody response in 86% of the patients. Through 54 weeks of follow-up postvaccination, the incidence of *S. aureus* bacteremia was 27/892 in the vaccine group and 37/906 in controls, for a person-time estimate of efficacy of 26%, a value that did not differ significantly from zero ( $P$  value = 0.2, 95% confidence interval, 24.5–56.8%). A post hoc analysis of results through 40 weeks postvaccination, however, showed that the incidence of *S. aureus* bacteremia was 11/892 in the vaccine group, and 26/906 in controls for a person-time estimate of efficacy of 57% (nominal  $P$  value = 0.02; 95% confidence interval, 10–81%). Analysis of efficacy versus antibody concentrations through 40 weeks postvaccination demonstrated that there was a strong correlation between the falloff of efficacy after approximately 40 weeks postvaccination and the falloff of mean antibody concentrations below 107  $\mu\text{g/mL}$  type 5 antibody ( $P < 0.0001$ ) and 111  $\mu\text{g/mL}$  type 8 ( $P < 0.0001$ ) antibody in the vaccinated population. Although this population-based correlation between efficacy and antibody titer appeared evident in this trial, it was clear from the results of the trial that relatively high levels of antibody to CP were insufficient to protect some ESRD patients. The failure to establish a correlation between efficacy and antibody titer in individual ESRD patients may reflect the immunological heterogeneity of the ESRD population and the variable general health of individuals in the population. Factors such as underlying disease, age, variable complement levels and phagocytic competency of leukocytes, and other complicating factors that characterize this population may make it impossible to predict a threshold protective antibody level for any individual ESRD patient.

Another interesting outcome of the ESRD trial with StaphVAX was the results observed in a subset of subjects. It is generally recognized that nasal carriage of *S. aureus* is associated with an increased risk of *S. aureus* bacteremia among hemodialysis patients and other at-risk individuals [96–100]. Although the numbers are small, it appears that nasal carriage put controls but not vaccinees at higher risk of bacteremia ( $P$  value = 0.057). This suggests that vaccination may have provided protection against *S. aureus* infection associated with nasal carriage.

Also of note from this large trial was the CP type distribution of *S. aureus* isolates from bacteremic patients. As

predicted from earlier typing studies, approximately 80% of clinical isolates of *S. aureus* received for typing were either type 5 or type 8 [46,48–53]. The remainder of isolates were so-called type 336, a new subtype of *S. aureus* characterized by a specific surface polysaccharide (Fattom et al., manuscript in preparation). In this trial, there was also a similar distribution of methicillin resistance among isolates from both the vaccine and placebo groups. These results are consistent with in vitro data showing that both antibiotic-resistant and -sensitive *S. aureus* are killed by vaccine-induced antibody-mediated opsonophagocytosis.

Patients participating in this study, in addition to being on hemodialysis, were elderly (mean age 58.3 + 14.8 years), and many suffer from type 1 or 2 diabetes (51.9%). It is well established that uremia and hyperglycemia have a major debilitating impact on host defense mechanisms, in particular, complement activity and opsonophagocytosis, the two main mechanisms for clearance of gram-positive pathogens [102–105].

In summary, this large, double-blinded, placebo-controlled clinical trial showed that StaphVAX, a bivalent *S. aureus* CP-conjugate vaccine, was able to reduce *S. aureus* bacteremia in an immunocompromised, at-risk, adult patient population. This is the first time that a vaccine against *S. aureus* has shown efficacy in humans in a well-controlled trial. Because of their reduced immune competency, hemodialysis patients are among the patient populations least likely to be protected by immunoprophylaxis. An efficacy of 57% through 10 months postvaccination is a remarkable achievement for StaphVAX in this patient population. It is reasonable to expect that the efficacy of this vaccine might be higher in other more immunocompetent patient populations such as scheduled orthopedic, cardiac, and general surgery patients. Additional clinical trials of StaphVAX are planned in ESRD and other at-risk patient populations.

## ACKNOWLEDGMENT

We are grateful to Kimberly L. Taylor and Phyllis Link for reviewing the manuscript.

### **I. INTRODUCTION**

Successful bacterial vaccines are composed of either killed or attenuated whole bacteria, detoxified exotoxins, or polysaccharides (and polysaccharide–protein conjugates). A newer vaccine development approach uses bacterial surface proteins as purified subunits, albeit in combination with a detoxified exotoxin. Acellular pertussis vaccines, the first example of this strategy of exploiting surface protein subunits, may contain, in addition to pertussis toxin (PT), the *Bordetella pertussis* pertactin (PRN), filamentous hemagglutinin (FHA), and fimbriae (FIM). Other nonencapsulated pathogenic bacteria such as nontypable *Haemophilus influenzae* (NTHi) and *Moraxella catarrhalis* (*M. cat*) are potential targets for using surface components other than capsular polysaccharides as vaccine components. However, in terms of immune evasion, there is a major difference between *B. pertussis* and NTHi/*M. cat*. *Bordetella* exhibits rather limited antigenic variability in its various surface components and exotoxins such as PRN, FHA, FIM and pertussis toxin (PT), and adenylate cyclase (AC). *B. pertussis* may evade host immune responses by the immunomodulating effects of PT and AC. Both NTHi and *M. cat* use the antigenic variability of surface and secreted components to evade the human immune response. This hampers the identification of candidate antigens and complicates vaccine development. Although oral immunization with killed NTHi of adults with a history of chronic recurrences of respiratory NTHi infectious diseases has shown an impact on NTHi carriage and subsequent diseases [1–3], the duration of this effect is not known. However, these findings have demonstrated the feasibility of immunization for protecting against NTHi infection. With respect to the potential of immune escape, it can be postulated that a multicomponent vaccine targeting a few components associated with essential biological functions would be

needed for successful immunization. Such a multicomponent product can be either killed or live attenuated bacteria, or a multicomponent subunit. In the case of whole bacteria, it would be beneficial to genetically delete highly variable and nonprotective antigens and to up-regulate (minor) conserved, biologically essential, and protective components. Another option could be the use of outer membrane vesicles extracted from such manipulated bacteria.

How can we identify biologically essential, conserved, and protective NTHi/*M. cat* antigens? Various steps in the host–bacterial interaction are being delineated [4,5]. Both NTHi and *M. cat* exploit mechanisms to adhere to or to colonize various host cells [5–16]. Invasion and survival within epithelial cells allow NTHi/*M. cat* to survive/evasive immunity [17]. The removal of iron from host proteins such as lactoferrin, transferrin, haptoglobin, and hemoglobin is essential for NTHi/*M. cat* survival within the human host, and various bacterial iron uptake mechanisms have been identified [18–24]. Specific immune evasion processes exist, such as the activity of bacterial immunoglobulin (Ig) A proteases as well as complement binding and degradation or serum resistance [13,25,26]. Animal models that have been developed to study the immunizing potential of various NTHi/*M. cat* components mimic the major clinical infections caused by NTHi/*M. cat* such as otitis media (OM), pneumonia, and other respiratory diseases [27–33].

Although many potential NTHi/*M. cat* candidate antigens have been identified such as adhesins/invasins, iron uptake systems, porins, secretins, etc., many more potentially exist. Nontypable *H. influenzae*/*M. cat* each possesses a single chromosome of ~1.8 and 1.9 Mb, respectively; full sequence information should reveal the identity of new candidates. A similar genomic approach has been applied to the pneumococcus and meningococcus. In the case of the pneumococcus, the genomic approach has identified several

new candidate antigens [34]. In the case of the meningococcus, a relatively large number of candidate antigens have been identified via nongenomic approaches, making it more difficult to find new bona fide antigens. New antigens were discovered from the genome sequence of one meningococcal strain, and early studies suggested at least one promising conserved candidate that induces bactericidal antibodies [35]. However, in subsequent studies, this antigen did not prove useful [36]. These examples illustrate that the genomic antigen discovery approach can be valuable, although caveats still exist.

Nontypable *H. influenzae*/*M. cat* cause clinically important infections such as otitis, pneumonia, and other respiratory diseases. Vaccination, if successful, may allow better control of these diseases. A comprehensive approach that considers previously defined antigens as well as new candidates derived from genomics is needed. Aside from protein antigens, the surface lipopolysaccharides (LPS) must be considered because of their dominance at the bacterial surface, their role in host bacterial interactions, and the greater difficulty of bacteria to vary saccharide structures as compared to protein antigens [14,37–39]. However, NTHi/*M. cat* LPS do show antigenic variability, complicating the identification of conserved epitopes [40–45]. A summary of previously identified antigens and new antigens identified by genomic is presented in this chapter.

## II. *M. CAT*

*M. cat* is a gram-negative bacterium that has long been considered a harmless commensal colonizer of the nasopharynx. Only recently has *Moraxella* been associated as the causative agent of a variety of respiratory tract diseases of which the most important are otitis media in infants and children, and pneumonia in the elderly. *Moraxella* also causes sinusitis, nosocomial infections, and, much less frequently, invasive diseases.

In 1921, Gordon [46] described *M. cat* as a saprophyte of negligible virulence that could be isolated from the throat of healthy adults. This view decreased the scientific interest in *Moraxella* and explained why this bacterium was not well studied until the 1970s. Vaneechoutte et al. [47] critically examined 112 publications stating that *M. cat* is a common commensal and found that no studies provided experimental evidence supporting this view. They concluded that misidentification of *M. cat* and confusion with *Neisseria cinerea*, which is present in 90% of throats, were probably responsible for the original misconception that *M. cat* is only a harmless commensal. Other arguments demonstrating the pathogenic potential of *M. cat* were recently reviewed [48].

The immune response to *M. cat* is poorly characterized. The analysis of strains isolated sequentially from the nasopharynx of babies followed from birth to 2 years of age indicates that they frequently acquire and eliminate new strains. This could indicate that an efficacious immune response against this bacterium is developed by colonized children [49]. The antibody response to outer membrane proteins (OMPs) of *M. cat* in children with otitis media is raised mainly against four dominant targets corresponding

to UspA, TbpB, CopB (see below), and a 60-kDa protein [50]. An opsonizing activity has been observed in the sera of children recovering from otitis media. A very low or even undetectable IgG3 antibody response to *M. cat* in children under the age of 4 years having increased otitis media or sinusitis caused by this pathogen has been reported [51,52].

In most adults tested, bactericidal antibodies have been identified [53]. Strains of *M. cat* vary in their capacity to resist serum bactericidal activity; in general, isolates from ill individuals are more resistant than strains isolated from individuals who are simply colonized [25,54]. Serum resistance could therefore be considered as a virulence factor of the bacteria. A recent study indicates that complement-resistant strains represent a separate lineage in the species. The clonal nature of the complement-resistant strains offers an interpretation of the observations made in a previous study, which showed that strains isolated from the upper respiratory tract of healthy children are primarily sensitive to complement-mediated killing. Although several factors have been suggested to be involved in serum resistance (Cop B), no final demonstration has been reported.

*M. cat* produces outer membrane vesicles (blebs), which have been isolated by different methods [55,56]. The protective capacity of such bleb preparations has been tested in a murine model for pulmonary clearance; active immunization with a bleb vaccine or passive transfer of antibleb antibodies induces significant protection against homologous challenge [57].

Several proteins or bacterial compounds are potential antigens and putative virulence factors of *M. cat*, and can be categorized as factors involved in bacterial attachment to host surfaces, proteins induced by iron limitation, or other antigens.

### A. Factors Involved in Bacterial Attachment to Host Surface

#### 1. Pili (Fimbriae)

Type 4 pili on the surface of some *M. cat* strains [58] are expressed during infection. Their length varies between 50 and 80 nm [59]. Pili could be involved in bacterial attachment to bronchial cells. However, nonpiliated strains also adhere to these cells, although in smaller numbers [60]. The host-cell receptor for fimbriae has been identified on pharyngeal cells as ganglioside M2 [16]. It is not known if pili induce a protective immune response.

#### 2. UspA1/2

UspA is a surface protein first recognized by a protective monoclonal antibody. Convalescent-phase sera from patients with *M. cat* pneumonia or otitis media, but not acute-phase sera from these patients, contain anti-UspA antibodies [61,62]. In general, IgG and IgA serum levels are higher in adults than in children [63]. Two UspA genes that encode two distinct proteins bearing conserved epitopes have been identified [64]. UspA1 is involved in bacterial adhesion to human epithelial cells whereas UspA2 is involved in normal human serum resistance [65]. Both proteins have been purified and characterized. Purified UspA2 has an affinity for vitronectin; UspA1 binds Hep-2 cells and

fibronectin. Immunization of mice with both proteins induces bactericidal antibodies and protects against pulmonary challenge [66]. Some strains produce a third protein, UspA2H. Its N-terminal half is similar to the N-terminal half of UspA1, and its C-terminal sequence is nearly identical to the UspA2 C-terminal sequence. UspA2H may be an adhesin [67]. The expression of UspA1 is phase-variable, being affected by the length of a poly(G) tract located upstream of the *uspA1* ORF [68]. UspA1 and UspA2 may belong to the same family of proteins as YadA from *Yersinia* species. These surface proteins form a lollipop-shaped structure resulting in a tripartite organization, with the N-terminal head domain followed by a putative coiled-coil rod, the C-terminal part of the protein being a membrane anchor domain [69]. These proteins are promising vaccine candidates.

### 3. Omp106

Omp106, which has a molecular weight ranging from about 180 to 230 kDa, displays hemagglutination properties [70]. Antibodies to Omp106 are bactericidal and can block the adhesion of *M. cat* onto epithelial cells. Moreover, immunization with Omp106 enhances bacterial clearance in a pulmonary mouse model (unpublished data). The sequence of the 200-kDa OMP MID, which displays high affinity for IgD [71], is highly similar to Omp106.

## B. Proteins Induced by Iron Limitation

*M. cat* expresses specific iron-repressible proteins in response to iron-limited growth in vitro. Human transferrin and lactoferrin can be used as the sole source of iron in the absence of any detectable siderophore production [18]. *M. cat* was found to express transferrin-binding and lactoferrin-binding proteins. OmpB1 binds human transferrin [19]. OmpB1 and a 74-kDa protein are variants of the same protein, TbpB [72,73]. An 84-kDa OMP and a 95-kDa OMP have been isolated using immobilized human lactoferrin and were proposed to be the LbpA and LbpB proteins, respectively, constituting the lactoferrin receptor [74]. The LbpA and LbpB proteins have been expressed recombinantly and anti-LbpB mouse antibodies are bactericidal [75]. Although some variability between strains has been observed, LbpB remains a potential vaccine candidate. The same observations have been made using recombinant TbpA and TbpB proteins. The conservation of TbpB among strains is lower than that of TbpA. Children infected with *M. cat* show antibodies to OmpB1 in convalescent sera [19]. Recombinant TbpB binds human transferrin (recombinant TbpA does not) and elicits bactericidal antibodies in mice [76]. However, affinity-purified anti-TbpB human antibodies lack bactericidal activity although they react with all isolates tested [73].

### 1. CopB

CopB, an 81-kDa OMP similar to TonB-dependent OMP, is overexpressed in response to iron limitation. A *copB* mutant is severely impaired in its ability to utilize transferrin and lactoferrin as sole iron sources [77]. The sequence of this OMP is moderately conserved among strains. Most

of the variability is localized within three variable regions of the protein [78]. A monoclonal antibody against CopB-enhanced pulmonary bacterial clearance in an animal model exerts complement-dependent bactericidal activity against *M. cat*. This monoclonal antibody binds a 26-amino acid oligopeptide corresponding to a surface-exposed region of CopB [79].

## C. Other Protein Antigens

### 1. OmpCD

OmpCD is a 45- to 60-kDa heat-modifiable OMP that is highly conserved among *M. cat* strains. OmpCD might be analogous to OMP P5 of *H. influenzae* (see below) and OmpA from *Escherichia coli*. Moreover, the conservation of the protein sequence has been demonstrated among clinical isolates recovered at a 6-month interval from chronically infected patients [80]. Antibodies to the detergent-extracted and purified OmpCD elicited in mice and guinea pigs were shown to be bactericidal [81]. The protein contains at least two surface-exposed conserved epitopes and one of these epitopes is recognized by human convalescent sera [82]. Recombinant OmpCD induced strong protection in a rat pulmonary challenge model upon mucosal and parenteral immunization. Protection coincided with the presence of anti-OmpCD-specific antibodies in serum and bronchoalveolar lavages [83].

### 2. OmpE

OmpE is another heat-modifiable OMP. The gene encoding OmpE has been cloned and its sequence is already known. The predicted molecular mass of the matured OMP is 47 kDa. The *ompE* gene is conserved among strains [84]. Sequence analysis of the *ompE* gene from respiratory tract isolates from patients colonized with the same strain for at least 6 months indicated that the OmpE-encoding sequence remains stable during colonization [85]. Adults with chronic bronchitis have IgA antibodies to OmpE in their serum and sputum supernatants [86]. *M. cat* mutant strains lacking the *ompE* gene have been constructed. These mutant strains were more readily killed by human normal serum than the wild-type strains, suggesting that OmpE could be involved in serum resistance [87].

## D. Lipopolysaccharide

Lipopolysaccharides may be one of the virulence factors of *M. cat*. Serological typing of *M. cat* using rabbit sera shows that three serotypes account for 95% of the isolates: A (60%), B (30%), and C (5%). However, no correlation between the serotype and the severity of infection has been found [44]. The structural characteristics and antigenic properties of *M. cat* LPS have been reviewed [40]. Lipopolysaccharides and, in particular, an epitope of LPS have been shown to be an important factor in the resistance to normal serum bactericidal activity. Indeed, *galE* mutants have a reduced resistance to serum killing [88].

Detoxified LPS conjugated to tetanus toxoid (TT) or to NTHi high-molecular-weight (HMW) proteins induced a protective immune response in a mouse lung challenge

model. This protective immune response correlated with bactericidal antibody titers in the sera of animals [89]. These data suggest that LPS is a potential vaccine candidate.

### III. NONTYPABLE *H. INFLUENZAE*

Nontypable *H. influenzae*, a nonmotile fastidious gram-negative rod, is an important cause of localized respiratory tract diseases beginning with the colonization of the upper respiratory mucosa. Otitis media, sinusitis, bronchitis, and community-acquired pneumonia due to NTHi are major causes of morbidity and mortality in both developed and nonindustrialized nations [90,91].

#### A. Pathogenesis and Variability

Nontypable *H. influenzae* exist as commensals in the human nasopharynx, and 40–80% of healthy children and adults are colonized [92]. Carriage of a given strain may persist for months [93]. Pathogenesis involves a contiguous spread of the bacteria within the respiratory tract, resulting in local disease in the middle ear, sinuses, or lungs. Modifications of the host defenses and the bacterium can transform this natural commensal into an infectious agent. For example, disruption of the mucociliary clearance, mucosal integrity or neutrophil functions by a viral infection, cigarette smoke, or allergies can lead to infection with NTHi. On the other hand, the balance between host defenses and NTHi virulence mechanisms can also be disrupted by a rapid and efficient adaptation of the bacteria. One adaptive mechanism of NTHi is the exchange of genetic information within this naturally transformable population after spread of different subtypes. Another mechanism, called antigenic drift, involves an irreversible substitution of amino acids in immunodominant regions of proteins. Finally, NTHi variability can be enhanced by phase variation that is characterized by reversible loss or gain of a defined structure. This mechanism can occur by *rec*-dependent inversion of DNA fragments but more commonly by slipped-strand mispairing during DNA replication. This leads to variation in the number of nucleotides in a homopolymeric stretch or a number of oligonucleotide repeats in a tandem array within the relevant gene.

By these mechanisms, NTHi has demonstrated the ability to adapt the antigenic character of both proteins and LOS, which constitutes the major component of the outer membrane, in response to a preexisting or developing immune response. Indeed, the proteins P1, P2, and P5 are targets of antibody responses and reveal antigenic drift to avoid the host immune system during persistent infection [94–96]. In the same way, LOS phase variation due to four loci, *lic-1* to *lic-3* and *lgfC*, produce a heterogeneous range of polysaccharides and enhance NTHi-invasive capabilities [43,45,97,98]. Phase variation of protein antigens was also demonstrated with respect to HMW1 and HMW2 as well as hemagglutinating pili [99,100].

Although antibiotic treatment usually eradicates infections caused by NTHi, antimicrobial resistance is increasing worldwide [101]. Thus, there is a demand for NTHi vaccines.

However, the development of NTHi vaccines is hampered by difficulties in identifying protective antigens and the lack of an in vitro correlate of immunity against this pathogen.

#### B. Killed Whole Cell Vaccines

Oral vaccines containing killed nontypable *H. influenzae* were previously tested in double-blind, randomized, controlled studies for the prevention of acute bronchitis. In the first study on oral immunization with NTHi, Clancy et al. [1] observed a 10-fold reduction in the incidence of acute bronchitis in adults. Nevertheless, without further vaccination, no significant protection was observed during the next winter [1]. In the second trial conducted on adult patients with chronic bronchitis, the incidence rate of acute bronchitis was significantly reduced in the vaccine group as compared with the placebo group. No difference was observed with regards to more severe lower respiratory disease. Protection was maximal at times of peak incidence of acute exacerbation, persisted for the duration of the 12-month follow-up period, and was associated with a reduction in the number of viable *H. influenzae* in sputum samples [2]. A third reported study demonstrated protection against the occurrence of acute infection in elderly subjects with chronic bronchitis. This protection correlated with transient reduction in the level of colonization by *H. influenzae* and allowed a reduced use of antibiotics [3]. Despite promising results, follow-up studies have not been reported.

#### C. Subunit Vaccines

Recombinant DNA technology offers the possibility of developing subunit vaccines, a strategy that uses only part of the pathogen to raise a protective immune response. Several antigenic components have been identified for nontypable *H. influenzae*.

#### D. Potential Protein Vaccine Antigens

##### 1. Lipoprotein D

Lipoprotein D (LPD), encoded by the *hpd* gene, is a 42-kDa membrane-associated IgD-binding protein [102,103]. Lipoprotein D consists mainly of hydrophilic amino acids and contains a typical bacterial lipoprotein consensus sequence at its N-terminal region. The classification of LPD as a lipoprotein was further confirmed by the presence of covalently attached ester-linked and amine-linked fatty acids to the N-terminal cysteine residue [104]. Lipoprotein D is homologous to the periplasmic glycerophosphodiesterase GlpQ of *E. coli* and catalyzes the reaction of glycerophosphodiester to glycerol-3-phosphate [105]. Lipoprotein D is antigenically conserved and has been implicated in NTHi adhesion and invasion into host cells [105–107]. Akkoyunlu et al. [108] have demonstrated that in human donors, the levels of IgG antibodies to LPD start to increase after 1 year of age, and IgA after 2 years of age, whereas IgM levels start to increase as early as 6 months of age.

In rats, LPD was highly immunogenic and induced bactericidal antibodies [109]. Although immunization with LPD failed to protect rats from developing otitis media, it

might affect the course of otitis media by promoting faster recovery [109]. In a chinchilla model of otitis media, bacteria were cleared more rapidly from the middle ear fluids of LPD-immunized animals [110]. The same authors also demonstrated that the delivery of anti-LPD serum by passive transfer reduced the incidence of middle ear effusion [110]. In a rat model [111], immunization with LPD tended to clear NTHi from the middle ear and induced a significant reduction of bacterial counts in the lungs.

## 2. P5 (LB1)

The P5 protein is a heat-modifiable, antigenically variable, major outer membrane protein that has been shown to bind to nasopharyngeal mucin [112] or to RSV-infected respiratory epithelial cells [8]. Recently, P5 was described as a ligand for the carcinoembryonic antigen family of cell adhesion molecules (CEACAMs) [7,113]. Anti-P5-specific antibodies had no protective capacity in an infant rat bacteremic model [114]. However, it has been shown that purified mouse anti-P5 antibodies were bactericidal for the homologous NTHi strain and a few heterologous strains. P5 is predicted to adopt an eight-stranded  $\beta$ -barrel structure with four extracellular loop regions [115–117].

One synthetic peptide, called LB1 and corresponding to the sequence of the third loop in P5 fused to a T-cell epitope, was designed by Bakaletz et al. [27]. Based on sequence variability of this region, NTHi strains were clustered in three groups (LB1-1, LB1-2, and LB1-3) [115,118]. The LB1 peptide was able to inhibit the adherence of NTHi to chinchilla ciliated tracheal mucosal epithelium (65% reduction in adhering bacteria). In a chinchilla NTHi nasopharyngeal colonization model, significantly earlier clearance was observed in animals immunized with this peptide. In two other experiments, chinchillas immunized with P5 or LB1 with either Freund's adjuvant or alum had lower nasopharyngeal and middle ear NTHi colonization than control animals [110]. A passive transfer of anti-LB1 antibodies or antibodies generated against a fusion of LPD and three LB1 variant peptide sequences designated LPD-LB1(f)<sub>2,1,3</sub> to chinchillas prior to intranasal challenge with NTHi significantly reduced the severity of signs and incidence of otitis media development [110]. In recent passive transfer experiments, antisera directed against LB1 or LPD-LB1(f)<sub>2,1,3</sub> were found to be highly protective against the induction of otitis media following intranasal challenge with heterologous NTHi strains [119].

## 3. OMP26

The OMP26 protein was originally purified from NTHi by preparative electrophoresis (sodium dodecyl sulfate polyacrylamide gel electrophoresis, SDS-PAGE) of an outer membrane preparation. It contains 174 amino acids, has a molecular mass of 26 kDa, and displays no heat-modifiable characteristics. Analysis of the deduced sequence shows that this protein bears a cleavable signal sequence of 23 amino acids. The deduced amino acid sequence of OMP26 is 56% identical to that of the *Pasteurella multocida* Skp protein. In the Enterobacteriaceae, the highly conserved Skp protein is a periplasmic protein (chaperone) that might be involved in

the translocation of LPS or OMPs to the outer membrane [120]. Nevertheless, the role of OMP26 in NTHi strains has yet to be determined. Southern blot analysis of the genomic DNA of NTHi strains with an *OMP26* gene probe demonstrated the high conservation of OMP26 among NTHi strains.

Rats immunized with OMP26 purified from NTHi displayed a significantly enhanced bacterial lung clearance following intranasal challenge with NTHi. An experiment with a heterologous NTHi strain resulted in a similarly enhanced clearance. Lymphocytes from animals immunized with OMP26 proliferated in vitro upon restimulation with OMP26 or OMP extracts from NTHi strains. Like immunization with killed bacteria [121], immunization with OMP26 resulted in protection that correlated with a greater number of phagocytic cells in the lungs [120].

In further studies, two recombinant forms of OMP26, a full length 28-kDa protein and a 26-kDa protein lacking the 23-amino-acid leader peptide, were evaluated. The protein that included the leader peptide was described as more effective in enhancing pulmonary clearance, and it induced better cell-mediated responses and higher titers of systemic and mucosal antibody [122].

## 4. HMW1/HMW2

High-molecular-weight surface-exposed proteins of NTHi that are major targets of human serum antibody during NTHi infection were shown to be implicated in bacterial adherence to human epithelial cells [9,123]. The two high-molecular-weight proteins of prototypic strain 12 were characterized. The HMW1 protein is 125 kDa in size and is encoded by a 4.6-kb open reading frame (ORF). The HMW2 protein has an apparent molecular mass of 120 kDa and is encoded by a 4.4-kb open reading frame. Despite their overall sequence similarity of 80%, HMW1 and HMW2 proteins display distinct cellular specificities, suggesting the recognition of distinct receptors. Both proteins are antigenically related to filamentous hemagglutinin, a known adhesin and colonization factor of *B. pertussis*. Although absent from encapsulated strains of *H. influenzae*, approximately 75% of NTHi clinical isolates expressed proteins immunologically and antigenically related to HMW1 and HMW2 produced by *H. influenzae* strain 12 [124]. By Southern blot analysis, the presence of HMW1 and HMW2 structural genes (referred to as *hmw1A* and *hmw2A*, respectively) was identified in 80% of strains tested [125]. Both *hmw1A* and *hmw2A* are flanked downstream by two additional genes, designated B and C, respectively [126]. HMW1B/HMW1C and HMW2B/HMW2C proteins are interchangeable and required for the normal processing and secretion of HMW1 and HMW2 [127]. By generating complementary chimeric proteins, the binding domains of HMW1 and HMW2 were recently localized to an approximately 360-amino-acid region near the N-terminus of the mature protein [128].

In the chinchilla model of otitis media, immunization with a purified protein preparation containing primarily HMW1 or HMW2 provided partial protection against intrabullar challenge with NTHi strain 12 [129]. Interestingly,

among animals immunized with either HMW1 or HMW2 that developed otitis media, isolates from the middle ear uniformly expressed reduced amount of HMW1 or HMW2, respectively. This suggested a downmodulation of the expression of those proteins. More recently, it has been demonstrated that the expression of both HMW1 and HMW2 is subject to phase variation and varies based on the number of 7-bp tandem repeats in the *hmw1A* and *hmw2A* promoters [99].

### 5. Hia/Hsf

Hia (*H. influenzae* adhesin) is a high-molecular-weight adhesion protein that is highly immunogenic. Expression of the *hia* gene in nonadherent *E. coli* strains was associated with adherence to cultured Chang conjunctival cells [6]. Hia is an autotransporter protein that undergoes no processing between the internal and C-terminal domains, and thus remains full-length and completely cell-associated, allowing maximal adhesive activity [130]. This protein is expressed by only a subset of NTHi strains (20–25%) and is absent in HMW1-expressing and HMW2-expressing strains [6]. As 95% of NTHi strains contain either *hmw* or *hia* genes [125], several authors envisioned that a combination of those two major nonpilus adhesins could be an effective vaccine formulation.

### 6. Hemagglutinating Pili

Hemagglutinating pili are helical structures of approximately 5 nm in diameter and up to 450 nm in length that promote agglutination of human erythrocytes and attachment to some, but not all, cells derived from human respiratory tissues and to human mucins [10,12,131]. *H. influenzae* pili show strain-to-strain immunological diversity, and 14 different pilus serotypes have been described [132]. Pili are present on both typable and NTHi strains, but pili expression is phase-variable [133]. Phase variation could be required during the course of infection because pili are important for the initial colonization of the human nasopharynx, but their expression may hinder subsequent steps in infection [10,134–136]. Antibodies directed against *H. influenzae* type B pili were bactericidal for the homologous strains but not for strains expressing heterologous pili [137]. In the same way, immunization with purified pili from a NTHi strain induced protection against homologous, but not heterologous, strains in an NTHi chinchilla model of otitis media [138]. It is interesting to note that a gene cluster containing five genes (*hifA*–*hifE*) is required for pilus assembly and function [133,139]. HifA is the major pilin subunit, HifB is a periplasmic chaperone, HifC is an outer membrane usher, and HifD and HifE are minor tip proteins, localized at the end of the pili. HifE antiserum completely blocks pilus-mediated hemagglutination, suggesting that HifE contains the pilus-binding domain and mediates pilus adherence [140,141]. Recent data demonstrated that anti-HifA antibodies inhibited the adhesion of type B and NTHi strains on mucins [12].

The expression of pili and the carriage of the *hic* gene (no function identified yet) are mutually exclusive in NTHi strains [142]. Irreversible loss of *hif* genes may represent an

adaptative mechanism that profoundly influences the interactions of NTHi with its human host. This mechanism could be related to the reversible shutting off of *hif* genes by phase variation observed during Hib-persistent infection. An average of 18% of nonencapsulated *Haemophilus* strains has a fimbria gene cluster consisting of *hifA* to *hifE*, but differences in the frequency of fimbria cluster-positive strains were observed, depending on the source of isolates [143].

### 7. P1

This heat-modifiable surface-exposed protein accounts for ~10% of *H. influenzae* OMP content. Significant variability in the primary protein sequence and its ability to be heat-modified allowed it to be used as a form of subtyping for *H. influenzae* type B strains [94,144]. P1 has eight potentially surface-exposed loops [145]. Several distinct surface-exposed epitopes were identified in the antigenic domain of P1 but do not induce protective antibodies against a Hib infection in an animal challenge model [145,146]. Nevertheless, P1 extracted from NTHi enhanced homologous bacterial clearance from the lungs of rats after mucosal immunization [147]. More recently, chinchillas actively immunized with recombinant P1 protein were protected against otitis media due to homologous, but not heterologous, NTHi strains [148]. Strain-specific protective responses suggest that P1-based strategy will require the development of a polyvalent vaccine reflecting the P1 variability.

### 8. P2

This is the most prominent outer membrane protein. It self-associates as a homotrimer and acts as a porin, allowing the passage of molecules of 1.4 kDa or less through the outer membrane [149]. P2 protein is a target for bactericidal antibodies elicited during the antibody response against NTHi in humans [150]. Immunization with P2 protein induced enhanced pulmonary clearance of a homologous strain of NTHi in a rat model of infection [151]. Among the eight potential surface-exposed regions, loops 5, 6, and 8 were further studied [152–154]. For instance, antibodies directed against loop 6 of P2 induced complement-mediated bactericidal killing of several heterologous NTHi strains [155]. A potential drawback of using the P2 protein or a more conserved region thereof as vaccine molecules is that P2 porin exhibits marked diversity among strains of NTHi. Moreover, the horizontal transfer of P2 genes was demonstrated in four aboriginal infants persistently colonized with multiple strains of NTHi. The horizontal transfer of P2 genes encoding P2 with a highly heterogeneous surface-exposed region would function as a mechanism to evade a protective immune response [156].

### 9. P4

This 28-kDa surface-exposed lipoprotein is ubiquitous and conserved among *H. influenzae* strains [157]. P4 has a phosphomonoesterase activity and is involved in heme transport [23,158,159]. Despite some controversies, P4 appeared to induce bactericidal antibodies in mice and rabbits [157]. No bactericidal antibody production nor protection from infection was observed in chinchillas immunized with a

mixture of P4, P6 (see below), and PCP (see below), but effusion and inflammation were significantly reduced [160]. Further evaluation of the P4 vaccine potential remains to be done.

#### 10. P6

P6 is a 16-kDa peptidoglycan-associated lipoprotein (PAL), which is present in the outer membrane of all strains of NTHi and shows a high degree of sequence conservation [161–163]. P6 has been demonstrated as being immunogenic and able to induce bactericidal antibodies in rabbits, rats, and mice [30,160,162,164–166]. Moreover, clearance was observed after mucosal immunization with P6 in rat and mouse respiratory models as well as in an otitis media model [30,167,168]. In chinchillas, contradictory results were obtained probably because of differences in methods used. Green et al. [160] raised P6 antisera in chinchillas, but neither bactericidal activity nor protection against NTHi challenge was obtained. In subsequent studies, bactericidal antibodies and/or protection against otitis media in chinchillas were observed [169,170]. In humans, bactericidal antibodies directed against P6 were described [171]. In otitis-prone children, failure to recognize P6 as a specific immunogen may account for recurrent infections [172]. Moreover, antibodies directed against P6 in breast milk and nasopharyngeal secretions are associated with a decreased incidence of colonization with NTHi [173,174].

#### 11. D15

This ~80-kDa OMP is conserved in both typable and NTHi strains [175,176]. Antibodies directed against D15 were found in eight of nine convalescent-phase sera from children with invasive Hib infection, suggesting that it might be an important immunogen. Affinity-purified D15-specific antibodies induced protection against the development of bacteremia in a rat pup model [175]. Also, anti-rD15 antibodies protected infant rats from bacteremia caused by *H. influenzae* type B or type A [176]. In a recent study, rabbit antisera directed against a 20-kDa N-terminal fragment protected infant rats against Hia or Hib bacteremia, indicating that immunodominant protective B-cell epitopes are located within this D15 fragment [177].

#### 12. OapA

The opacity-associated protein A is a cell envelope protein responsible for the transparent colony phenotype of *H. influenzae* and required for efficient colonization of the nasopharynx in an infant rat model of *H. influenzae* carriage [178]. Further studies demonstrated that OapA contributes to binding to Chang epithelial cells and that its sequence appeared highly conserved among both encapsulated and nontypable *H. influenzae* strains [179].

#### 13. Hap

This *H. influenzae* surface protein is associated with the capacity for intimate interactions with cultured epithelial cells and formation of microcolonies [11,13]. This nonpilus adhesin is an autotransporter protein composed of three

domains: an N-terminal leader sequence, a serine protease domain (Hap<sub>s</sub>), and a C-terminal outer membrane domain (Hap<sub>c</sub>). The Hap<sub>s</sub> domain is extracellularly released by autoproteolysis. Interestingly, the inhibition of Hap autoproteolysis resulted in augmented Hap-mediated adherence to respiratory epithelial cells and bacterial aggregation [11,180]. Recently, the Hap autoproteolysis mechanism was more fully characterized [181].

#### 14. HtrA

This moiety (also called Hin 47) is a stress response protein of 46 kDa that functions as a serine protease and is highly conserved among encapsulated and NTHi strains [182]. Although predicted to be a periplasmic protein, surface expression under stress conditions may occur. The protective capacities of recombinant HtrA protein and two site-directed mutants (H91A and S197A) lacking the serine protease activity were evaluated. The three proteins were immunogenic and equally protective in a passive infant rat model of bacteremia. In a chinchilla model of otitis media, only the rHtrA and the H91A mutant induced protection [182]. Absence of protection with the S197A mutant may come from an improper folding observed by circular dichroism spectroscopy [183].

#### 15. PCP

This 16-kDa outer membrane lipoprotein is conserved in all *H. influenzae* tested, and antiserum directed against this protein showed high complement-mediated bactericidal activity [184]. When combined with P4 and P6 proteins, PCP did not induce protection in a chinchilla model of otitis media, but effusion and inflammation measured by tympanometry were significantly reduced [160].

### E. Iron and Heme Acquisition Proteins

Iron acquisition by *H. influenzae* occurs by a complex process involving several outer membrane or secreted proteins binding to hemoglobin or hemoglobin–haptoglobin (HhuA, HgpA, HgbA, HgbB, and HgbC) [185–187], haptoglobin (HxuA and HxuC) [188,189], transferrin (Tbp1 and Tbp2) [20,190,191], and lactoferrin [191]. Sera from healthy adults recognized Tbp1 and Tbp2, suggesting that both proteins are expressed in vivo [21]. More recently, the expression of *tbpA*, *tbpB*, and *hgpA* genes by *H. influenzae* during acute otitis media was confirmed by reverse transcription polymerase chain reaction (RT-PCR) [24]. Outer membrane localization and expression in *in vivo* conditions suggest a potential role for these iron transport proteins as vaccine immunogens.

### F. Lipopolysaccharide

The LPS of gram-negative bacteria is a complex amphiphatic molecule composed of lipids and sugars that represents the main component of the outer leaflet of the bacterial outer membrane. In contrast to the Enterobacteriaceae, the *H. influenzae* LPS lacks the O-antigen (repeating side chain) and

is therefore often called lipoooligosaccharide (LOS). The LOS of NTHi is antigenically heterogenous. This is mainly due to NTHi outer core region variability, the lipid A and inner core region being more conserved. Nontypable *H. influenzae* LOS is a major surface antigen that may be implicated in virulence and is described as a potential protective antigen. Human antibodies and mouse monoclonal antibodies directed against LOS are bactericidal for NTHi [123,192]. A mouse monoclonal antibody directed against NTHi LOS was opsonic and enhanced clearance in a murine pulmonary challenge model [193].

Using anhydrous hydrazine-detoxified NTHi strain 9274 LOS (type III) lacking the terminal lacto-*N*-neotetraose, Gu et al. [194,195] prepared two conjugates using tetanus toxoid or high-molecular-weight proteins HMW as carriers. Both conjugates were immunogenic in mice and rabbits. Conjugate-induced LOS antibodies elicited complement-mediated bactericidal activity against homologous and heterologous NTHi strains [194,195]. Moreover, vaccination with the two conjugates resulted in significant protection against experimental otitis media in chinchillas. This protection correlated with high anti-LOS titers in the chinchilla sera and middle ear fluids. Biological activities in the sera of the protected chinchillas sera were measured and 46% of the serum samples induced inhibition of NTHi adherence onto epithelial cells, 49% induced bactericidal activity, and 49% showed opsonophagocytic activity [196].

### G. In Silico Antigen Discovery

Whole genome sequencing opens the possibility of identifying "in silico" new surface-exposed or secreted proteins that can be tested as new potential vaccine candidates. We have followed such a strategy to identify new *M. cat* and NTHi vaccine candidates.

#### 1. *M. cat*

The genome from *M. cat* strain ATCC43617 was used for screening while the sequencing was still in progress. The genome was sequenced by Incyte Genomics, Palo Alto, CA. The last version of the genome screened was split into 41 DNA fragments (Patent WO0078968, Genbank accession

nos. AX067426–AX06766) of a total length of 1.91 Mb, where 1513 open reading frames were predicted.

To identify surface-exposed proteins, such as porins, fimbrial and nonfimbrial adhesins, lipoproteins, other outer membrane proteins, and periplasmic and secreted proteins, the strategy was based on screening by homology. Surface-exposed or antigenic proteins previously described in other bacteria were used as query for performing Blast searches. To increase the sensitivity, hidden Markov models (HMMs) derived from multiple alignments of protein domains were used to screen the ORFs [197,198]. Specific identification of porins or porinlike proteins and lipoproteins was used as second strategy. Porin detection was based on the identification of signal sequence within ORF, prediction of β-strand predominance, and presence of a C-terminal aromatic amino acid. Lipoprotein detection was based on identification of a type II secretion signal. The ORFs selected were annotated by homology and analyzed for detection of signal sequence, transmembrane regions, and specific features from Prosite, Pfam, Blocks, and Prints [199–204].

Among the *M. cat*-predicted ORFs, 71 ORFs were selected for further evaluation; 61 previously unknown ORFs included 6 predicted adhesins, 2 outer membrane enzymes, 3 proteins of unknown function, 2 outer membrane proteins involved in a type I secretion system, 6 porins, 4 additional porins involved in heme acquisition, 1 porinlike protein component of type IV pili, 31 lipoproteins of which eight were predicted to be anchored in the outer membrane, 3 periplasmic proteins, 2 potential hemolysins, and 1 potential collagenase (Table 1).

The protective potential of 27 proteins was assessed in vitro by anti-adhesion and bactericidal tests and in vivo in a mouse lung infection model. The 27 genes were cloned and expressed in *E. coli*; recombinant proteins were then purified and injected in rabbit and mice. The antiadhesion activity of induced antibodies was tested by measuring the inhibition of adhesion of *M. cat* onto epithelial cells in the presence of immune sera. The bactericidal activity of the antibodies was tested by measuring the complement-mediated cytotoxic activity of immune sera. The mouse lung infection model was based on the analysis of lung invasion by *M. cat* following a standard intranasal challenge to vaccinated

mice. Nine proteins yielded positive results with the mouse infection model; four of them were also positive in the bactericidal assay and one was positive in the antiadhesion assay. Furthermore, one protein was positive in the antiadhesion assay only, and one in the bactericidal assay only (data not shown).

## 2. Nontypable *H. influenzae*

The genome of nontypable *H. influenzae* strain 3224A was sequenced to 4× coverage by the University of Oklahoma. The shotgun sequence data were assembled into 535 DNA fragments for a total length of 1.67 Mb, covering 90% of the genome, and around 1800 ORFs were identified. The comparison of the NTHi genome with the HiRd genome [205] showed that the DNA sequences are very similar (around 95% identity) but that both genomes contained specific regions. NTHi-specific regions are, together, longer than 0.1 Mb and comprise more than 100 ORFs.

The strategy for identifying NTHi surface-exposed proteins was similar to that used to screen the *M. cat* genome. Because many NTHi ORFs were not complete, the ORFs of HiRd have been used as reference [205]. The corresponding sequence in NTHi was subsequently determined by sequencing. Furthermore, each ORF located within the NTHi-specific regions has been examined.

With respect to known antigens, 14 have been found, with Hmw1, Hmw2, and Hap being located in the NTHi-specific regions. Additional selected proteins comprise three adhesins VirG, YadA, and YadA-c, but none was in-frame (confirmed by sequencing). We also selected 16 lipoproteins of which 14 are potentially anchored in the outer membrane, 1 protein is involved in a type I secretion system, 8 porins are involved in iron acquisition, 5 porins or porinlike proteins, 5 other outer membranes, 2 periplasmic proteins, and 2 secreted proteins (Table 2). Furthermore, in an NTHi-specific region, there were four neighboring ORFs similar to one another (around 80% identity). They were predicted to have a signal sequence and were homologous to potentially antigenic surface exposed proteins.

In another NTHi-specific region, a set of genes similar to bacteriophage P1 was found. At the end of this phagelike genome, six hypothetical genes were predicted. They might encode proteins playing a role in virulence. Indeed, phage-associated virulence genes have been observed in other bacterial genomes such as *Streptococcus pyogenes* and *N. meningitidis*. Some of them encode proteins able to induce bactericidal antibodies against the organism from which they were derived [206,207]. Those six hypothetical proteins could thus be protein vaccine candidates.

The protective potential of five proteins has been assessed in vivo in a mouse infection lung model similar to the one used for *M. cat* proteins. Of those, three proteins yielded positive results. These proteins are well conserved among NTHi strains.

## IV. FUTURE CHALLENGES

Nontypable *H. influenzae* and *M. cat* cause a number of respiratory infectious diseases, particularly in the very

young and very old. Immune prophylaxis by way of active or passive immunization represents an important tool toward improved control of these diseases. It is very likely that such control programs will eventually result in improved public health and are to be welcomed, in addition to similar programs aimed to prevent infectious diseases due to influenza, pneumococci, and RSV, among others. A further clarification of the relative importance of each of these infectious agents in diseases such as otitis media warrants careful epidemiological studies. Pediatric pneumonia in developing countries has, to some extent, been investigated [208–210]. Further information from various regions of the world is needed. Pediatric otitis has been studied extensively. It appears that a wide variety of viral agents (RSV influenza, parainfluenza, adenoviruses, and rhinoviruses) and a limited number of bacteria (pneumococci, NTHi/*M. cat*) are the predominant causes. Quite often, it seems that a mild viral infection precedes a bacterial otitis [211]. It is remarkable that group A streptococci have gradually disappeared as a major otitis-causing agent as compared to 50–100 years ago [212]. Adult (particularly in the very old)-sustaining pneumonia, bronchitis, and chronic obstructive pulmonary disease (COPD) also are infections where population-based immunization programs are likely to become important tools to improve public health. Influenza and pneumococcal vaccines already play an important role in the elderly and the public acceptance is still growing. Further epidemiological data on the relative importance of infections agents causing adult pneumonia are highly needed to allow rational vaccine development and societal implementation to become a reality.

The identification of protective antigens from NTHi and *M. cat* is difficult. These bacteria are noncapsulated, the surface proteins and lipopolysaccharides demonstrate a high variability, and no major exotoxins have been identified. This suggests that the successful principles used in developing many bacterial vaccines such as targeting capsular polysaccharides (preferentially conjugated to protein), detoxified exotoxins, or single surface proteins cannot be applied.

On the other hand, some success has been achieved with oral killed whole cell NTHi, implying that a combination of a number of protective surface antigens can lead to effective vaccines. Over the years, a number of surface antigens that represent candidate antigens, such as the adhesins (HMW proteins, Hia, pili, Hap, P5), the iron uptake systems (Tbps, Lbps, hemoglobin/hemopexin uptake systems), and other candidates as described in this review have been identified. Similar candidates have been identified for *M. cat* (Omp106, UspAs, pili, Tbps, Lbps, etc.). Aside from surface proteins, the lipopolysaccharides of NTHi and *M. cat* represent attractive antigens because these are major surface components and these molecules play an important role in the pathogenesis of NTHi/*M. cat* infectious diseases. Unfortunately, LPS also reveals extensive antigenic and phase variability [40–45]. Nowadays, the unraveling of the sequence of a bacterial genome has become standard practice, although the first genome available in 1995 for *H. influenzae* strain Rd was a major scientific breakthrough [205]. However, strain Rd is not representative for the major NTHi clonal lineages responsible for infectious diseases [213].

We decided to sequence strain 3224A and discovered that approximately 100 additional open reading frames (absent in Rd) are present. In silico antigen discovery is a powerful tool that enables one to screen the genome systematically for homologues of known protective antigens from other bacterial species. It is also possible to look for specific sequence features associated with families of proteins such as porins, lipoproteins, proteins containing signal peptides, etc. In silico mining has been successful in finding conserved protective surface proteins in case of the pneumococcus [214]. A similar approach has been used for the meningococcus, but conserved candidates remain to be found from genome sequence, as opposed to antigens described previously. The availability of full genome sequences will likely disclose further possible candidates within many bacterial species.

The consolidation of an antigen as a robust vaccine candidate requires multiple preclinical evaluations using stringently validated animal models and other tests. An example of such a model is the pertussis mouse lung clearance assay that accurately mimics the clinical effectiveness of the different acellular pertussis vaccines, being composed of pertussis toxin filamentous hemagglutinin, pertactin, and/or fimbriae in various combinations [215]. It is hoped that similar lung clearance/pneumonia models are equally predictive for protection induced by candidate antigens in case of *Streptococcus pneumoniae*, NTHi, and *M. cat.* Aside from preclinical models, one can evaluate antigens by using human nasopharyngeal colonization as readout after challenge. Preclinical otitis models have been developed to be able to evaluate vaccine candidates from the pneumococcus and NTHi [27,216].

Carefully designed preclinical and human nasopharyngeal challenge studies are needed to investigate a number of preselected candidates before clinical studies in the target populations (infants and elderly). The preselection process is a critical step and depends upon high-throughput but still robust preclinical models. Finally, formulation, adjuvantication, and route of administration represent critical parameters for immunization efforts against NTHi and *M. cat* respiratory infectious diseases for which mucosal immunity likely plays an important role.

## Vaccines for *Chlamydia trachomatis* and *Chlamydia pneumoniae*

**Andrew D. Murdin**

Aventis Pasteur, Toronto, Ontario, Canada

**Robert C. Brunham**

University of British Columbia, Vancouver, British Columbia, Canada

The history of chlamydia vaccine research is characterized both by empirical approaches using whole inactivated organism and, more recently, by rational molecular vaccine design. Unfortunately, human trials with inactivated vaccines ended in the late 1960s, and no rational design approach has been successful enough to move to clinical testing. Although several chlamydia vaccines are at various stages of development by several vaccine manufacturers there is little information on these in the scientific literature. To provide an overview of the current status of chlamydia vaccine development this chapter focuses on *Chlamydia pneumoniae* and *Chlamydia trachomatis*, which are the two main chlamydial pathogens of humans, on our understanding of protective and pathologic immune responses to these pathogens, and on past and present attempts to develop human vaccines against these organisms. For another recent perspective on this subject, see Igietseme et al. [1]. It should be noted that although there are veterinary vaccines available or under development that may inform vaccine strategies for humans, veterinary vaccine development is beyond the scope of this chapter.

### I. THE PATHOGENS

*C. pneumoniae* and *C. trachomatis* are obligate intracellular parasites, which share a unique intracellular developmental cycle [2]. The extracellular stage or elementary body (EB) is infectious but metabolically inert, whereas the intracellular stage or reticulate body (RB) is noninfectious but metabolically active. Intracellular replication occurs within a membrane-bound inclusion, the development of which appears to be mediated by the multiple chlamydial proteins associated with the inclusion membrane. There is evidence for a cryptic or latent intracellular stage associated with persis-

tent infection, but this stage is not well characterized. Persistent infection may be an important cause of much of the long-term tissue damage secondary to chlamydial infection [3,4].

*C. pneumoniae* has been associated with a broad spectrum of diseases, including sinusitis, bronchitis, community-acquired pneumonia, chronic obstructive pulmonary disease, asthma, cardiovascular disease, multiple sclerosis, and Alzheimer's disease. The association with cardiovascular disease, which is of particular recent interest, is strong but not yet proven to be causal [5,6]. *C. trachomatis* infection is associated with trachoma, lymphogranuloma venereum, and sexually transmitted infections of the genital tract. It is the most common sexually transmitted disease in the United States with an estimated three million cases occurring in 1999 [7]. Up to 70% of infected women are asymptomatic, making the infection difficult to diagnose despite the availability of effective and accurate diagnostic tests. Serious sequelae of infection in women include endometritis and/or salpingitis, pelvic inflammatory disease, infertility, ectopic pregnancy, and possibly cervical cancer [8,9].

The genome sequences of several chlamydia isolates have been determined [10–13,13a]. These reveal organisms well adapted to their intracellular lifestyle, auxotrophic for many amino acids, ribonucleotides, and cofactors, and dependent on the host for energy. With respect to vaccine development, the available *C. pneumoniae* genome sequences reveal a highly clonal organism, which arguably occurs as a single strain with global distribution [10–13,13a]. There is the possibility that members of a family of 21 putative membrane proteins (pmmps) may carry antigenic determinants that vary to some extent among isolates, and that expression of these proteins may vary from cell to cell in a process analogous to phase variation [14], but this is not yet clear. The pathogen possesses an array of virulence determinants in-

cluding an apparently functional type III secretion system, three Hsp60 homologs, and an array of proteases, kinases, and other enzymes with homologies to known bacterial virulence factors [2]. The *C. trachomatis* genome sequences show both strong similarities to and important differences from *C. pneumoniae* [11,12]. In particular, both sequence and serological data reveal an organism with much greater antigenic variation than *C. pneumoniae*. There are 15 well-established serovars of *C. trachomatis*, with several more proposed [15,16]. Surprisingly, the genetic basis for specific disease association found among chlamydiae remains unknown even with genomic information in hand.

Both *C. pneumoniae* and *C. trachomatis* appear well adapted to evade the host immune response, possessing a sophisticated multilayered repertoire of immune evasion strategies. First, replication of the bacterium within a membrane-bound inclusion limits exposure of bacterial antigens to the host–cell antigen presentation machinery. Second, the bacterium is in any case able to moderate the effectiveness of host–cell antigen presentation by downregulating the expression of MHC I and MHC II by infected cells [17,18]. Third, the pathogen elaborates at least one protein able to inhibit host–cell apoptosis, rendering infected cells resistant to fas-mediated killing [19]. The organism's biphasic developmental cycle can also be viewed as an immune evasion mechanism, in that the extracellular EBs are susceptible only to antibody-mediated immunity, and the intracellular RBs are susceptible only to cell-mediated immunity. One of the developmental stages might be able to persist in the face of a relatively weak cellular or humoral response, and it is speculated that when the overall host response has declined active infection may recur.

## II. IMMUNITY TO CHLAMYDIAL INFECTIONS

Despite the ability of the pathogen to circumvent the host response, both innate and adaptive immune responses can confer protection. Innate immunity falls outside the scope of this chapter, but see Brunham [3] for a discussion of the protective effects of innate immune responses against chlamydial infection. Evidence that adaptive immune responses can be protective against infection and disease is provided by early human challenge studies and vaccine trials, by epidemiological studies, and by studies of animal models of infection. Numerous observations of chlamydial persistence in various tissues raise the possibility that complete elimination of an infection does not occur in many individuals, and that a common effect of a protective immune response is to hold the pathogen in a quiescent state in certain preferred sites within the body rather than to clear it completely. This leads to important questions about host–pathogen interaction, in particular regarding the nature of the interactions that occur among chlamydial antigens, antigen-presenting molecules, and antigen-specific lymphocytes that determine the heterogeneity in the clearance rate of chlamydial infection. We will briefly review what is known of immunity to *C. pneumoniae* and *C. trachomatis*, and highlight areas where differences are known to occur.

### A. Observations in Humans

Jawetz et al. [20] first demonstrated strain-specific immunity to ocular *C. trachomatis* infection in challenge studies using human subjects, and these observations were subsequently replicated in immunization and challenge studies in both humans and primates (see, e.g., Refs. 21,22). Epidemiological studies in human populations show similar evidence for the development of protective immune responses following infection [23,24]. In aggregate, the human data are strongly supportive of the notion that *C. trachomatis* infection or immunization induces strain-specific, but possibly short-lived, resistance to reinfection.

Several immunoepidemiological studies of host resistance and susceptibility to human ocular and genital *C. trachomatis* infection have demonstrated the importance of cell-mediated responses in protective immunity. Individuals spontaneously clearing an ocular chlamydial infection exhibited enhanced lymphoproliferative responses to chlamydia compared to individuals with persistent ocular disease, whereas individuals with conjunctival scarring in the advanced stages of trachoma had markedly depressed lymphoproliferative responses to chlamydia in comparison to controls without scarring [25]. Other studies have indicated that enhanced Th2 and depressed Th1 responses may be associated with the development of scarring trachoma [26,27]. Most data suggest that class II-restricted  $\alpha\beta$  CD4 $^+$  T cells are essential for immunity to chlamydial infection (e.g., Refs. 24,28). A protective role for CD8 $^+$  T cells is less clearly defined, and may differ between *C. trachomatis* and *C. pneumoniae*. Several studies have demonstrated CD8 $^+$  cytotoxic T-lymphocyte (CTL) responses specific for *C. trachomatis* major outer membrane protein (MOMP) and Hsp60 in the peripheral blood of infected individuals [29,30] and demonstrated their cytolytic function through specific lysis of *C. trachomatis*-infected epithelial cells *in vitro* [30]. Based on these findings, it seems probable that MHC I-restricted CD8 $^+$  T-cell responses to *Chlamydia* antigens can contribute to effective immunity against these pathogens.

### B. Observations in Mice

Cell-mediated responses play a key protective role in mice as well as in humans. In the case of *C. trachomatis*, *in vivo* depletion studies [31], studies using mice defective in CD8 $^+$  T-cell function [31], and adoptive transfer studies [32] all indicate a dominant protective role for CD4 $^+$  T cells and a lesser role for CD8 $^+$  T cells in host defense against primary *C. trachomatis* infection. The bulk of the animal data regarding protective immunity to *C. pneumoniae* infection suggest that the CD8 $^+$  T-cell subset plays a more prominent, although not exclusive, role in defense. *In vivo* depletion of CD8 $^+$  T cells resulted in an increase in the chlamydial burden in the lungs of infected animals and an extended duration of secondary infection [33]. Furthermore, various knockout mice lacking functional CD8 $^+$  T cells are all more susceptible to *C. pneumoniae* infection than normal mice [34,35].

The mechanisms through which both the CD4<sup>+</sup> T-cell and the CD8<sup>+</sup> T-cell populations contribute to protection include the release of IFNγ, a key cytokine in the resolution of both *C. pneumoniae* and *C. trachomatis* infections [34–40]. Studies of other cytokines and their receptors have demonstrated an important role for both IL-12 and IL-10 in antichlamydia responses. IL-12 is known to be a differentiating cytokine for IFNγ-production by sensitized Th1 cells, and can clearly drive antichlamydial responses toward that pathway [38,41,42]. By contrast, IL-10 has been shown to have a negative regulatory role, and can attenuate the Th1 type response [43–45]. In addition to the important role of these two molecules, TNF-α, IL-1β, and IL-8, have all been shown to be released from chlamydia-infected cells [46], and presumably serve to activate specific leukocytes and recruit them to sites of infection.

Although B cells appear not to be required for protection from chlamydial infection [47], recent evidence obtained from in vivo T-cell depletion studies in normal and B-cell-deficient mice indicate that B cells can play a key role during the resolution of secondary, but not primary, *C. trachomatis* vaginal infections [48,49]. Depletion of either CD4<sup>+</sup> T cells or CD8<sup>+</sup> T cells, or both, in previously infected wild-type C57BL/6 mice had a limited effect on resistance to reinfection, whereas depletion of CD4<sup>+</sup> T cells, but not CD8<sup>+</sup> T cells, in previously infected B-cell-deficient mice resulted in a chronic infection which did not resolve until anti-CD4 treatment was halted. That is, either CD4<sup>+</sup> T cells or B cells were sufficient to resolve a secondary chlamydial infection, indicating a previously unrecognized but significant role for B cells in resistance to chlamydial reinfection. The mechanism by which B cells contribute to immunity to *C. trachomatis* infections and how B cells and CD4<sup>+</sup> T cells interact during an intact immune response are unknown, but represent important goals for future research. It will also be important to determine whether B cells make a similar contribution to immunity to *C. pneumoniae* infections.

### C. Role of Antibody in Humans

In contrast with the clear role for T cells in immunity to *Chlamydia*, the evidence for a direct protective role of antibodies is less convincing. In many instances, high serum antibody responses often correlate with complications of chlamydial disease. Elevated anti-*C. pneumoniae* serum IgG titers in patients with atherosclerosis were the first indication of the association between *C. pneumoniae* and cardiovascular disease (CVD) [50]. Serum antibodies against *C. trachomatis* are produced at surprisingly high titers among women with acute salpingitis [51], the Fitz-Hugh-Curtis syndrome [52], and postsalpingitis tubal infertility [53]. As such, it appears that high-serum antibodies do not protect against the complications of chlamydial infection except, perhaps, in some special circumstances [54]. In contrast to serum antibodies, secretory immunoglobulin A (IgA) antibodies may play a more important role in protection, from both ocular [55,56] and genital infection [57,58]. Furthermore, the possibility that synergistic interactions between cellular and humoral immune responses are required for optimal protec-

tion from chlamydial infection should not be overlooked (see, e.g., *Francisella* [59]).

### D. Immunopathology

Many immunological findings seen with chlamydial disease are highly reminiscent of immune correlates in other infectious diseases that exhibit a spectrum of host immunological responses, such as leishmaniasis and leprosy [60]. In aggregate, the results suggest that MOMP-specific Th1-like CD4<sup>+</sup> T cells are important in immunity to and clearance of *C. trachomatis* infection and disease and that Hsp60-specific Th2-like CD4<sup>+</sup> T cells are associated with the pathological sequelae of persistent *C. trachomatis* infection. Similar responses may govern the outcome of *C. pneumoniae* infection, although the target antigens in this case are less easy to identify. Persistent infection is a common correlate of the more severe manifestations of chlamydial disease. Some hosts fail to clear chlamydial infection and remain persistently infected or susceptible to frequent reinfection [61–67]. These individuals appear to be at increased risk of developing the long-term sequelae of chlamydial disease [68], which arise as a result of inflammation and fibrosis. Cytokine synthesis by chronically infected cells together with persistent antigen synthesis in the face of an ineffective or partially effective immune response is thought to contribute to chronic inflammation, tissue damage, and immunopathology [69]. For a complete discussion of chlamydia-induced immunopathology, see Ward [9].

Much remains to be learned regarding the identity of the chlamydial antigens contributing to the development of immunopathology. Several antigens, including Hsp60, lipopolysaccharide (LPS), OmcB, and Cpn0483, have been implicated as potential virulence factors playing a role in these processes [70–72], but the inability to generate chlamydial mutants has inhibited more extensive studies of chlamydial virulence and pathogenesis. The availability of multiple chlamydial genome sequences offers new potential for defining chlamydial virulence factors and their role in the disease process, and it will be critical to take advantage of this information to ensure that chlamydia vaccines do not inadvertently elicit immunopathological responses in vaccinees.

## III. VACCINES FOR CHLAMYDIAL INFECTIONS

### A. Vaccine Antigens

Early efforts at developing a chlamydial vaccine were based on parenteral immunization with various partially purified preparations of live or inactivated chlamydial elementary bodies. A good overview of this early body of work is provided by Collier [73]. Although this approach met with some success in human trials, protection was short-lived and serovar-specific [74–79]. More significantly, these whole-organism vaccines sometimes exacerbated the incidence and/or severity of disease during subsequent infection episodes, possibly because of pathological reactions to certain chlamydial antigens [77–79]. Exacerbation was not seen in

all cases, and tended to be more obvious in monkeys than in humans [80, 81, 82; Grayston, personal communication cited in 83]. On reading these accounts one is left with a suspicion that the choice of adjuvant may have been a significant influence on this effect, but it is impossible to be sure because the various vaccine preparations were so diverse. Regardless, the potential for the induction of immunopathogenesis has deterred more recent investigators from considering live or inactivated whole organisms as vaccine candidates.

However, because chlamydial infection confers partial protection against reinfection, it has been suggested that an avirulent, nonimmunopathological strain of *Chlamydia* might have potential as a vaccine. A significant practical restriction in pursuing this idea has been the lack of a system for the genetic manipulation of *Chlamydia*; nevertheless, the idea of an attenuated vaccine still receives attention. In a study to evaluate the potential efficacy of a live attenuated vaccine, the effect of an attenuated chlamydia strain was simulated by treating mice with a subchlamydiacidal concentration of oxytetracycline following vaginal infection [84]. Antibiotic-treated mice generated levels of *Chlamydia*-specific antibody and cell-mediated immunity equivalent to those of infected but untreated control mice and were as immune as control mice when rechallenged vaginally. In particular, these mice produced a minimal inflammatory response in urogenital tissue and did not experience infection-related sequelae, suggesting that protective and immunopathological immune responses can be separated. This result is interesting, but further research into the molecular basis of chlamydial virulence and immunopathology will be required before an attenuated vaccine candidate can confidently be expected to be safe.

An alternative to the killed whole-organism approach has been described by Pal et al. [85] who investigated a sub-unit vaccine consisting of *C. trachomatis* outer membrane complexes (COMCs). Mice immunized with COMCs were challenged by inoculation of the mouse pneumonitis (MoPn) strain of *C. trachomatis* into the ovarian bursa, then assessed for vaginal shedding of chlamydia and for fertility. The mice developed significant humoral and lymphoproliferative immune responses, including vaginal IgA chlamydia-specific antibodies. COMC-immunized mice exhibited a significant decrease in the intensity and duration of vaginal shedding post challenge and were as fertile as normal control mice. This is a promising result, particularly in view of the relatively severe intrabursal challenge, but the potential of COMCs to induce immunopathology requires additional study. The reason for the enhanced immunogenicity of the COMCs also remains to be determined, because it is unclear which of the multiple antigens in the COMC are the targets for protective responses, or how these antigens are processed by the immune system.

Many recent attempts at *C. trachomatis* vaccine development have focused on MOMP, which is the dominant surface antigen and comprises over 60% of the total membrane protein [86]. It is recognized by sera from infected humans and is a principal target of neutralizing antibodies [87]. The extensive antigenic variation observed in *C. trachomatis* MOMP means that a cocktail of several MOMPs would be required to produce a vaccine. Candidate vaccines

have typically been based on a subunit design using whole MOMP protein, or fragments or peptides. These vaccines have had mixed success, perhaps because the immunogens do not reliably induce protective cellular and humoral immune responses recalled by native epitopes on the organism [88–93]. Some success was reported with whole recombinant MOMP in a mouse model of genital tract infection [94], but the result was heavily dependent on the route of immunization and challenge.

The most effective MOMP protein vaccines have been based on the intact native protein extracted from chlamydial EBs, although the results obtained have been dependent on the method of extraction and the adjuvant used. MOMP extracted using SDS is largely denatured and no more effective as an antigen than synthetic peptides, whereas MOMP extracted with the nonionic detergent n-octyl-beta-D-glucopyranoside has been found to elicit partial protection in mouse and primate models [91, 95, 96]. This is possibly because MOMP extracted in this way remains as multimers [96, 97], which may retain at least some elements of the native conformation, but the mechanism of protection in these studies is unclear. In one study, OGP-extracted MOMP formulated into immune stimulating complexes (ISCOMs) [98] raised a protective cell-mediated response in mice that could be adoptively transferred to naïve recipient animals [95]. It is not obvious that MOMP conformation would be important to raising this kind of cellular immune response, but recent data suggest that it may be. MOMP extracted with the detergent Zwittergent 3-14, and estimated to be >99% pure, was refolded by dialysis against glutathione-PBS [96]. Refolded MOMP was obtained as multimers, as shown by nonreducing SDS-PAGE, but could be converted to monomers by sonication. Refolded MOMP in complete Freund's adjuvant elicited strong humoral and lymphoproliferative responses in mice, and conferred partial protection from vaginal shedding and infertility following an intrabursal chlamydia challenge. In contrast, refolded and sonicated MOMP elicited only a humoral response, conferred only minimal protection from vaginal shedding, and had no effect on infertility following chlamydial challenge. The authors speculate that conformational differences between monomeric and multimeric MOMP influence the development of CD4<sup>+</sup> T-cell responses, citing the precedent of the *Leishmania major* surface antigen PSA-2 [99]. It will be important to determine the extent to which MOMP conformation actually influences the induction of cellular responses because despite the data for refolded MOMP, the successful use of DNA vaccines encoding MOMP [100–102] argues that the correct conformation is not an absolute requirement for eliciting a protective response.

Until recently few chlamydial antigens other than MOMP had been seriously evaluated as vaccine candidates. The most noteworthy of these is the secreted glycolipid GLXA, a soluble genus-specific glycolipid that is secreted into the extracellular environment during the chlamydial developmental cycle [103–105]. A guinea pig anti-idiotype antibody (anti-id) mimicking the immunogenicity of GLXA of *C. trachomatis* was reported to elicit antibodies in rabbits that could neutralize heterologous chlamydiae in vitro and in vivo [106]. Furthermore, mice immunized with a murine

monoclonal anti-id encapsulated in polylactide microspheres were significantly protected against ocular and genital challenge with human strains of *C. trachomatis* [107,108]. In contrast to the studies with MOMP, but consistent with the use of the anti-id as an immunogen, protection was apparently associated with induction of anti-GLXA antibody and antichlamydial neutralizing antibody. However, significant questions remain regarding the induction of a protective immune response to GLXA. For example, is neutralizing antibody the sole or dominant protective effector mechanism, or does the anti-id somehow elicit a protective cell-mediated response to a nonprotein antigen? It will be important to achieve a better understanding of the immunobiology of GLXA to properly interpret these findings.

Chlamydial LPS was found to be ineffective as a protective antigen against *C. trachomatis* ocular disease when administered orally to monkeys as a recombinant antigen expressed by an *E. coli* vector [109]. DNA vaccines encoding *C. pneumoniae* Hsp60 have been found to be protective in mice, with efficacy comparable to a similar vaccine encoding *C. pneumoniae* MOMP [35,102]. However, the extensive homology between human and chlamydial Hsp60s may prevent the use of chlamydial Hsp60 in a vaccine for human use. The *C. pneumoniae* cysteine-rich outer membrane protein 2 (Omp2) has been reported by one group to be non-protective when administered via DNA immunization [102], whereas another group has found the antigen to be at least as protective as the MOMP using similar methods of immunization and animal models [110]. The reasons for this discrepancy are unclear.

The recent determination of several chlamydial genome sequences [10–13,13a] has greatly expanded opportunities for chlamydial antigen discovery and vaccine development in the last few years [111,112]. Strategies for the postgenomic discovery of protective antigens fall into two broad categories. In sequence-based strategies, antigens selected from the genome sequence according to predefined criteria are screened for protective efficacy in an animal model of infection [14,101,113,114], whereas in biology-based strategies antigens of demonstrated biological relevance are identified with the help of the genome sequence and then cloned and evaluated for protective efficacy [115]. An example of a sequence-based strategy might be to test all predicted membrane proteins [116], whereas an example of a biology-based strategy might be to sequence MHC-bound peptides by mass spectrometry [117], identify the parent protein from the genome data, then clone and test that protein.

The screening approach has been used with relatively broad selection criteria to test over 200 *C. pneumoniae* ORFs for protective efficacy in a mouse model of *C. pneumoniae* lung infection, resulting in the identification of multiple protective antigens including MOMP, OMP2, an ATP/ADP translocase and a homolog of the 76-kDa antigen [101,110,118]. Interestingly, the *C. pneumoniae* ATP/ADP translocase is highly conserved with *C. trachomatis* and preliminary results show that it elicits protection against *C. trachomatis* in addition to *C. pneumoniae* (Murdin, Lu, and Brunham, unpublished data). Screening approaches utilizing a greater degree of genome analysis to focus on specific antigens, thus limiting the amount of animal testing required, have also

been successful at identifying other candidate protective antigens, including a serine–threonine kinase gene selected because of its potential role as an effector protein secreted by the chlamydial type III secretion system. Whether the protein is actually a type III secretion-associated effector is unknown, but DNA immunization with the ORF encoding the protein elicited partial protection from a *C. trachomatis* MoPn lung challenge in a mouse model [113]. The genome sequence has also played a primary role in identifying and characterizing other potentially protective antigens such as PorB, a novel chlamydial porin [114], and in characterizing the full extent of the family of pmmps [14].

The alternative approach to antigen discovery, the identification and characterization of antigens of known biological relevance, has been used by Fling et al. [115] to identify the protein recognized by a protective *C. trachomatis*-specific CD8<sup>+</sup> T-cell line. Clones of P815 cells transduced with fragments of a *C. trachomatis* expression library were screened for their ability to stimulate the protective T-cell line, and one stimulating clone was identified. The chlamydial DNA fragment from this clone was sequenced and mapped to a predicted *C. trachomatis* ORF, CT529, encoding a 31-kDa inclusion membrane-associated protein, Cap1. The CD8<sup>+</sup> T-cell line and CTLs derived from *C. trachomatis*-infected mice were able to lyse P815 targets pulsed with a nine amino acid peptide derived from Cap1, confirming the immunological relevance of the protein. Fling et al. were then able to complete the final step of the antigen discovery process by demonstrating that mice immunized with a recombinant vaccinia virus expressing a 70 amino acid fragment of Cap1 were weakly but significantly protected from an intravenous challenge with *C. trachomatis* serovar L2.

## B. Adjuvants and Delivery Systems

Based on our current understanding of protective immunity, adjuvants eliciting a Th1-biased response are likely to be most effective at eliciting protection against chlamydial infection. Several adjuvants and delivery systems have been evaluated for their utility in chlamydia vaccines. However, these studies have used different antigens, immunization routes, immunization schedules, challenge protocols, and animal models, so a direct comparison of the efficacy of the various adjuvants or delivery systems used is not possible.

Early *C. trachomatis* vaccine trials in humans made use of mineral oil or alum adjuvants, with mixed results [74,75], but of these adjuvants only alum would be acceptable for human use today, and this elicits a Th2-biased response. All recent studies have focused on animal, usually murine, models of infection, and the evaluation of a particular adjuvant has often not been a central theme of these studies. A number of adjuvants have been used with MOMP or MOMP peptides, again with mixed success. The use of cholera toxin [88] and liposomes containing monophosphoryl lipid A [119] elicited modest serum antibody responses to MOMP, but not protection. In contrast, purified MOMP formulated into ISCOMs did elicit an immune response protective against vaginal challenge with *C. trachomatis* serovar D [95]. Adoptive transfer of peripheral blood lym-

phocytes from immunized mice to naïve recipients was able to confer protection upon the recipients, indicating that MOMP-ISCOMs were able to elicit systemic cell-mediated responses and that such responses could make an important contribution to local immunity at genital mucosal surfaces.

An analogous approach to the use of synthetic lipophilic particles such as ISCOMs and liposomes is the use of bacterial cell walls and outer membranes, or ghosts, to deliver vaccine antigens. In addition to providing a particulate delivery vehicle, ghosts utilize the intrinsic adjuvant properties of many bacterial wall and membrane components and are effective at eliciting cell-mediated and local immune responses [120,121]. As noted above, the use of chlamydial outer membrane complexes has been successful at eliciting quite strong protective responses [85] but potentially risks eliciting immunopathological responses in addition to protective responses. The use of recombinant bacterial ghosts expressing selected chlamydial antigens should allow the antichlamydial response to be focused on selected protective antigens [1]. Preliminary studies of *Vibrio cholerae* ghosts expressing *C. trachomatis* MOMP indicates that this approach has the potential to elicit protective immune responses in a mouse model of *C. trachomatis* genital tract infection (J. Igietseme, personal communication, 2001).

Several live bacterial and viral delivery systems have also been used to deliver chlamydial antigens, although the use of live vectors for chlamydial antigens is lagging behind the use of other adjuvants and delivery systems. The bacterial vectors used include *Salmonella*, which failed to elicit strong immune responses when a *Salmonella* construct expressing *C. trachomatis* MOMP epitopes was tested in mice [122], and *Lactobacillus*, which could express *C. psittaci* MOMP but was not tested for immunogenicity [123]. The use of viral vectors has been more encouraging, but much remains to be done in this area also. MOMP epitopes have been expressed on a filamentous phage vector [124] and upon poliovirus [125–127]. Both approaches were successful at raising antibodies against chlamydia EBs, but only the poliovirus construct has been tested for protective efficacy in an animal model, where it was unable to elicit a protective response against an ocular challenge in monkeys (Caldwell and Murdin, unpublished data). Poxvirus vectors have so far received relatively little attention in the context of *Chlamydia*, although their ability to elicit both humoral and cell-mediated immune responses suggest that they should be effective vectors for chlamydial antigens. Preliminary studies suggest that they may be an effective delivery system for chlamydial antigens, including Cap1 [115] and MOMP (Murdin, Raudonikiene, Millar, and Dunn, unpublished data).

Unlike protein or peptide-based subunit vaccines, DNA vaccination provides protective immunity following endogenous expression of foreign proteins by host T cells, thus allowing the presentation of antigen to the immune system in a manner that may be closer to that which occurs during natural infection with viruses or other intracellular pathogens. In the context of chlamydial infection, the potential advantages of DNA vaccination include the induction of a broad spectrum of immune responses including Th1-like CD4 responses and mucosal immunity. DNA immunization with several chlamydial antigens including the homologous

MOMP gene produces significant protective immunity to lung challenge infection with *C. trachomatis* MoPn [100,113] or *C. pneumoniae* [35,101,102], and elicited cellular and humoral immune responses consistent with a predominantly Th1-mediated response [35,128]. It should be noted that although DNA immunization appears to be able to reliably protect against a lung chlamydial challenge in several different models, it failed to protect mice from a genital chlamydial challenge in the one published account using such a model [129]. Mice immunized with MOMP DNA mounted weak humoral and cell-mediated immune responses but were not protected from vaginal shedding of *Chlamydia* following a vaginal challenge, or from infection-associated infertility. The reason for this failure is unclear, but may indicate that the genital tract is a more difficult site to protect than the lung when using a systemic DNA immunization strategy.

Subsequent studies showed that a MOMP-DNA prime followed by a MOMP-ISCOM boost was highly effective at inducing immunity to pulmonary *C. trachomatis* challenge, eliciting protection comparable to that conferred by a prior infection [130]. This is a significant result because most immunization strategies elicit partial protection significantly weaker than that elicited by a previous infection. The result is consistent with the observation that prime-boost strategies are often superior to single-adjuvant or single-vector strategies for several intracellular pathogens [131], and such strategies probably deserve to receive more attention in the context of *Chlamydia*. It is also worth noting in this context that prime-boost strategies employing a mucosal route of immunization may elicit different responses from similar strategies using a systemic route of immunization [132].

### C. The Importance of Dendritic Cells in Anti-Chlamydia Immunization

Perhaps the most interesting studies in the recent *Chlamydia* vaccine literature are those which have used dendritic cells (DCs) for antigen delivery, or have sought to recruit DCs during immunization. This approach seems to hold considerable promise for establishing firm correlates of anti-chlamydial immunity and for identifying truly effective antichlamydial immunization strategies. The first of these studies, by Su et al. [133], established that DCs pulsed ex vivo with killed *Chlamydiae* could efficiently phagocytose, process, and present chlamydial antigens, accompanied by the secretion of IL-12. Intravenous immunization of mice with chlamydial-pulsed DCs elicited protective immunity against vaginal challenge equal to that obtained after infection with live organisms, and protection was correlated with a *Chlamydia*-specific Th1-biased response similar to that elicited by chlamydial infection. Similar results were subsequently obtained in a mouse lung infection model by Lu and Zhong [42], who showed that *Chlamydia*-pulsed DCs, but not macrophages, could elicit strong protection which correlated with Th1-biased immune responses. In an important additional finding, Lu and Zhong [42] demonstrated the importance of IL-12 secretion by the antigen-pulsed DCs in directing Th1 response. DCs from mice deficient in the IL-12 p40 gene failed to produce IL-12 following an ex vivo

*Chlamydia* pulse, and immunization with these DCs failed to induce either a Th1-biased response or protection against chlamydial infection. Conversely, as might be expected, downregulation of endogenous IL-10 expression of *Chlamydia*-pulsed DCs also enhances Th1 responses and protection [44]. Mice genetically engineered to be IL-10<sup>-/-</sup> were highly resistant to chlamydial genital infection, and induced a greater frequency of *Chlamydia*-specific Th1 responses following *C. trachomatis* infection. The negative effect of IL-10 in the development of a protective response acts at the level of the antigen-presenting DC itself, since immunization with DCs from IL-10<sup>-/-</sup> mice or with IL-10 antisense-treated DCs from wild-type mice was able to elicit strong protective responses in IL-10<sup>+/+</sup> C57BL/6 mice against vaginal challenge with *C. trachomatis* serovar D. These observations suggest that the ability of DCs to efficiently process and present chlamydial antigens to naive T-cells *in vivo* and to direct a Th1 immune response by the secretion of high levels of IL-12 in comparison to IL-10 are important components in eliciting effective antichlamydial immunity.

Recognizing that immunization with live *Chlamydia* elicits stronger protective immunity than does immunization with the inactivated organism, Zhang et al. [41] studied immune responses in mice immunized with viable or UV-killed chlamydia. Immunization with viable chlamydiae induced a Th1-biased response, including high levels of antigen-specific delayed-type hypersensitivity, IFN $\gamma$ , and local IgA, GM-CSF, and IL-12 production, whereas immunization with killed chlamydia induced Th2-biased responses including IL-10 production and IgG1. Interestingly, mice immunized with viable organisms exhibited a recruitment of a DC-like cell population to the site of immunization, consistent with the important role of DCs indicated by the DC immunization studies described above. Developing the hypothesis that early induction of proinflammatory cytokines and the activation and differentiation of DCs may be key to the induction of protective responses by viable organisms, the same group studied the use of an adenovirus vector expressing GM-CSF (Ad-GM-CSF) to recruit DCs to the site of immunization [134]. Mice were inoculated with the Ad-GM-CSF 7 days prior to immunization with UV-inactivated chlamydia. Both routes of immunization recruited DCs to the site of immunization and elicited significant levels of systemic Th1 immune responses, but the intranasal immunization also elicited antichlamydial IgA in the lung. Intranasal, but not intraperitoneal, immunization elicited strong protection against a pulmonary chlamydial challenge, comparable to that elicited by live chlamydiae. Immunization with UV-inactivated chlamydia in the absence of Ad-GM-CSF was not protective. This result provides further support for the importance of DCs in eliciting a protective Th1 immune response and indicates the contribution of local IgA responses to immunity from chlamydial infection. It is not clear that protection was due solely to local IgA in this study; effector T-cells arising from intraperitoneal immunization may not have been recruited to the lung as quickly or efficiently as those arising from intranasal immunization, for example. Nevertheless, the result is a reminder that local antibody responses may have a role to play in protection from chlamydial infection.

Overall, these studies indicate the central importance of DCs in the induction of protective immunity to chlamydial infection. Vaccination strategies based on the use of antigen-pulsed DCs as the immunizing agent are not realistic for mass use, at least with current technology, but vaccination strategies intended to recruit DCs to the site of immunization and to target antigen to those DCs appear to be well worth exploring. Recruitment of DCs might be achieved, for example, by the expression of not only GM-CSF but also other molecules such as IL-1 $\beta$ , TNF- $\alpha$ , MIP-1 $\alpha$ , MIP-1 $\beta$ , MIP-3 $\alpha$ , and RANTES. Achieving a better understanding of the factors influencing the expression of effective immunity at mucosal sites distant from the site of immunization will also be an important goal of studies in this area.

#### D. Routes of Immunization

Route of immunization is a critical variable determining the success of immunization, but the data for chlamydia is fragmented and sometimes contradictory. Several routes have been evaluated in several different models, including conjunctival [88,91], intranasal [95,100,101,108], oral [88,94,107–109,122], vaginal [84], intravenous [122], subcutaneous [85,94,96,108], intramuscular [94–96,100–102], intraperitoneal [94], and presacral [94]. The results from this considerable body of work are often hard to interpret, and it may seem that all that can be concluded is that under some circumstances some routes are effective for inducing antichlamydial immunity. For example, MOMP DNA given intranasally may be more effective than DNA given intramuscularly, at least at protecting the lung [100]. MOMP DNA given intramuscularly will protect the lung [100] but may not protect the genital tract [129], whereas purified MOMP formulated with ISCOMs given intramuscularly will protect the genital tract [95]. Orally administered anti-id to GLXA encapsulated in polylactide microspheres elicits protection versus ocular and vaginal challenge [107,108], whereas orally administered MOMP and LPS elicited little or no protection [88,94,109].

However, at the risk of stating the obvious, some tentative guidelines can be proposed. Firstly, intranasal immunization appears to be one of the more effective routes of immunization at eliciting protective responses in both the lungs and the genital tract, a finding that matches experience with other mucosal pathogens [135,136]. In light of these findings and because of the clear importance of eliciting effective mucosal antichlamydial responses it would make sense to include this route in future evaluations of candidate vaccines. Second, the systemic route of immunization should not be ignored. Intramuscular delivery of both protein and DNA can elicit protective immunity against lung and genital tract challenges [see, e.g., Refs. 95, 96, and 100], and should continue to be evaluated if for no other reason than that it is acceptable and easy to use in humans. It may prove useful to vary the site of intramuscular immunization to target selected (or multiple) draining lymph nodes. Third, given the important role of DCs in eliciting protective immune responses, routes targeting DC-rich sites such as the skin [137] may repay further study, although the experience of Lu et al. [134] indicates that the site at which DCs are targeted

can influence the effectiveness of the subsequent immune response. Finally, the use of multiple routes of inoculation in a single immunization schedule should be investigated. Combined intramuscular and intranasal immunizations have been effective for DNA immunization against *C. pneumoniae* lung infection, for example [101], and in the absence of a thorough understanding of the induction of effective antichlamydial protective immunity in different organs approaches targeting multiple inductive sites may be more effective at inducing widespread distribution of appropriate immune effectors.

#### E. Animal Models for Vaccine Testing

The outcome and interpretation of vaccination studies depend not only upon the vaccine but also upon the species, strain, and age of the vaccinated animal and upon the strain of the pathogen used for challenge. The models most commonly used for recent vaccine studies are mouse models of *C. trachomatis* genital or lung infection [138–140], and mouse models of *C. pneumoniae* lung infection [141], although some important studies have used mouse models of *C. trachomatis* ocular infection [107]. The lung infection model using *C. trachomatis* MoPn is convenient and easy to use, but it should be recognized that MoPn is a murine isolate of *C. trachomatis* [142] that is antigenically distinct from human isolates and more virulent than those in the mouse. Furthermore, human *C. trachomatis* infection targets the eyes or genital tract. *C. pneumoniae* lung infection models have the advantage of targeting a clinically relevant organ. They produce consistent results in different laboratories, although the strain of mouse and the strain of chlamydia used will affect the outcome [141].

With respect to the genital infection models, there are several variations in protocol that can influence the outcome of an experiment and need to be taken into account when designing and interpreting studies. Intrabursal and intrauterine challenge inoculations [138,139] ensure infection of the upper genital tract and are usually used when fertility or salpingitis is an endpoint. However, the route of inoculation is clearly unnatural and bypasses vaginal barriers to infection, both innate and adaptive, which may be significant in vaccination studies. Intravaginal inoculation is more realistic, but older mice in particular may be resistant to chlamydial infection by this route, and infection may not ascend past the cervix, unless the mice are treated with progesterone [139]. This may be acceptable for studies of chlamydial biology and pathogenesis, but because progesterone has strong immunomodulatory properties [143] its use should be avoided when testing vaccines. The use of human *C. trachomatis* isolates for genital tract challenge overcomes the objection that *C. trachomatis* MoPn is not a human pathogen, but many human strains are relatively avirulent in mice, possibly because of increased sensitivity to IFN $\gamma$  [144,145] or differential expression of virulence determinants [146].

When considering testing a *C. pneumoniae* vaccine for cardiovascular disease, several mouse [147–149] and rabbit [150,151] models are available. The murine models are in LDLR $^{-/-}$  or ApoE $^{-/-}$  mice, which will develop atherosclerosis independently of *C. pneumoniae* infection. In these

models *C. pneumoniae* strain AR39 [147–149], but apparently not the Kajaani strain [152,153], is an exacerbating factor in the development of atherosclerosis. However, it should be recognized that the underlying genetic lesion dominates the atherosclerotic process and may influence the outcome of immunization studies.

#### IV. SUMMARY AND FUTURE DIRECTIONS

L. H. Collier, writing in 1966 on the then current status of *C. trachomatis* vaccine development, concluded “that, although some vaccines now being tested are partially effective, much remains to be learned about immunity to trachoma and methods of inducing it artificially” [73]. Thirty-five years later, skeptics might argue that nothing much has changed. Candidate *C. trachomatis* and *C. pneumoniae* vaccines are at best partially effective in animals and have not been tested in humans, the nature of protective immune responses is only partially defined, and methods of eliciting effective protection in animals models are arrived at empirically following strategies that may not be acceptable or effective for human use. This criticism is, of course, too harsh, but does highlight the often frustrating lack of progress caused by the unusually difficult challenges inherent to chlamydia vaccine development [83]. In reality, real and significant progress has been made in our understanding of the chlamydiae and their interaction with their host and specifically with their host's immune system.

The single most important advance in the last few years has been the sequencing of several chlamydial genomes. For an organism such as chlamydia that is not susceptible to genetic manipulation, the ability to analyze and compare the genome sequences has provided an insight into chlamydia biology that was simply not available before. In the context of vaccine development this has allowed the identification of novel protective antigens, in some cases has provided an insight into the biological significance of these antigens, and has generally propelled the field beyond the MOMP-based vaccine studies that characterized the pregenome literature. The recent studies of the role of DCs in immunity to chlamydial infection hold the promise of defining the requirements for the induction of strong, enduring and properly localized protective immune responses. Parallel advances in developing novel adjuvants and delivery systems offer tools with which to present selected antigens to the immune system in such a way that these requirements for the induction of protective immunity can be fulfilled safely and effectively.

In conclusion, it does not seem overly optimistic to paraphrase Collier [73] as follows: most vaccines now being tested are only partially effective, but recent advances in our understanding of the biology and immunology of chlamydial infection should allow the rapid development of effective methods of inducing protective immunity.

## Overview of Vaccine Strategies for Malaria

Michael F. Good and David Kemp

The Queensland Institute of Medical Research, Brisbane, Queensland, Australia

Malaria remains one of the leading causes of morbidity and mortality in the world. Of the approximately 50 million deaths worldwide each year, about 2 million are attributed to malaria. Throughout the last century there were many exciting developments with the promise to eradicate or at least control malaria. These included the discovery of chloroquine and other drugs, and insecticides to kill the mosquito vector. While it was very natural to think of vaccine development as a way to prevent malaria infection, classical approaches such as attenuation and the use of killed organisms were not useful for malaria principally because the parasites require red cells for their growth and it is not practical to culture and administer parasites cultivated in such a manner. Safety considerations would also be of paramount concern. It was thus a time of great excitement when malaria genes were first cloned [1,2], opening the possibility for the development of a subunit vaccine. Chapters 70–73 outline the different approaches in some detail, but the purpose of this chapter is to discuss the overall strategies for malaria vaccine development.

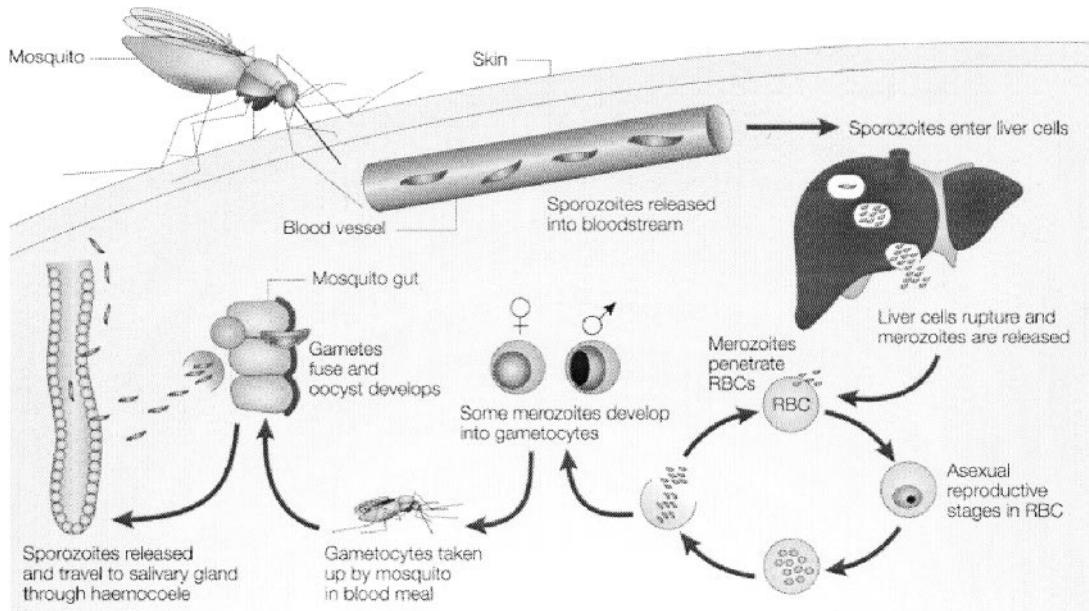

The ultimate goal of a vaccine is to prevent disease. In the case of malaria this can theoretically be achieved by interrupting the life cycle at various stages or possibly by inducing a state of “tolerance” to parasites. Interrupting the life cycle and reducing parasite densities and the prevalence of parasitemia will also reduce parasite transmission between individuals. The life cycle thus provides the strategic framework to vaccine development (Figure 1). The major vaccine programs aim to induce immunity that will kill parasites in different locations either within the body or indeed in the mosquito.

Infection commences with the bite of an anopheline mosquito that injects sporozoites into the circulation. It is difficult to calculate how many sporozoites are inoculated but it is likely that under conditions of natural exposure, very few sporozoites ( $\approx 10$ ) enter the circulation. The pioneering work of Fairley and colleagues [3] demonstrated using blood

transfer between volunteers that sporozoites remain in the circulation for up to 30 min. They can be cleared by various tissues but those that enter hepatocytes are capable of continuing the life cycle. If sporozoites are killed or removed from the circulation prior to entering hepatocytes, the life cycle will be interrupted and disease will not eventuate. Antibodies targeting sporozoite surface proteins are capable of neutralizing sporozoites [4,5].

When the sporozoite enters the hepatocyte there is hepatic schizogony over a period of about 1 week after which merozoites are liberated into the circulation. If infected hepatocytes are destroyed, the life cycle will not continue. T cells ( $CD8^+$  and  $CD4^+$ ) [6,7] are able to kill infected hepatocytes. When merozoite forms of the parasite emerge from hepatocytes they enter normal red blood cells (RBCs). Here they undergo exponential growth. The two major species of human parasites, *Plasmodium falciparum* and *P. vivax*, have a 48-hr lifecycle in RBCs. During this time they develop from ring stages to schizonts that rupture the red cell to release more merozoites (approximately 16) to invade fresh cells. Antibodies directed at merozoite surface proteins can prevent merozoites from entering fresh red cells and so antigens on the surface of merozoites represent one class of potential vaccine candidates. With the sequencing of the malaria genome in recent years, the number of known merozoite surface proteins has increased substantially and at least seven have been described so far. Another class of merozoite proteins that are potential vaccine candidates are proteins of merozoite organelles (rhoptries), which are involved in the invasion of the red cell.

The parasite modifies the red cell significantly both in terms of structure and expression of parasite-encoded proteins on the red cell membrane. An important class of antigens are the variant surface antigens of which PfEMP1 is the best studied [8,9,10]. There are approximately 50 variant copies of PfEMP1 represented in each parasite genome but typically only one is expressed at any time. Determinants

**Figure 1** Life cycle of the malaria parasite. The lifecycle in the mammalian host commences with the inoculation of sporozoites by an infected anopheline mosquito which travel by the circulation to the liver. After about 1 week (depending on the species of malaria) parasites have multiplied intracellularly and merozoites rupture from infected hepatocytes to invade red blood cells (RBCs). For *Plasmodium falciparum* and *P. vivax* there is a 48-hr period inside the RBCs during which merozoites multiply and approximately 16 fresh merozoites are released from ruptured red cells to invade fresh cells. Sexual forms (gametocytes) develop within RBCs and are taken up by the mosquito. These emerge in the gut of the mosquito as gametes, which fuse to form an oocyst, and sporozoites develop. Sporozoites are released and travel to the salivary gland of the mosquito. (From Good, *Nature Review Immunology*, 1:117–125, 2001.)

within PfEMP1 are responsible for adhesion of infected RBCs to host receptors on vascular endothelium and placenta and antibodies that are capable of agglutinating infected RBCs and which likely target PfEMP1 are associated with strain-specific immunity [11]. Although the protein is variant, it is an important candidate for a vaccine against the blood stage of the parasite because certain regions of the protein are conserved and monoclonal antibodies that can agglutinate multiple strains have been described [12]. Other molecules have been implicated in adhesion [13] but their vaccine candidacy has not been established.

Although red cells do not express MHC molecules and would not be directly recognized by either CD4<sup>+</sup> or CD8<sup>+</sup> T cells, there is evidence from animal and human systems that CD4<sup>+</sup> T cells can inhibit parasite growth both in vitro and in vivo [14]. It is likely that antigens from infected red cells are processed by antigen presenting cells and presented to T cells in association with MHC. Activated T cells are thought to inhibit parasite growth via nonspecific effector molecules, such as NO and oxygen radicals [15,16]. Identifying the target antigens of antibody-independent cell mediated immunity represents an additional strategy for vaccine development to the blood stage of the parasite.

The sexual forms of malaria parasites are “gametocytes” and these develop within red blood cells. Once taken up by mosquitoes the gametocytes emerge from the red cell and become “gametes,” which fertilize to give rise to zygotes and then ookinetes which lodge in the wall of the mosquito’s

midgut as oocysts. Immature sporozoites develop within the cysts and then travel to the salivary gland. Antibodies directed to gamete surface antigens are able to either block gamete fertilization or block zygote development. These antibodies do not have an effect within the human host because gametocytes are located within RBCs and are not accessible to antibodies. Gamete surface antigens have been identified and cloned and have been tested in immunogenicity trials in volunteers.

Despite the fact that a number of molecules representing the life-cycle stages and cellular locations described are known and have been cloned and recombinant proteins prepared, hurdles to the development of a malaria vaccine remain. Whatever combination of antigens will be most effective for a human vaccine is not only unknown but difficult to establish. The latter is true because while the parasites can be grown with limitations in a few species of monkeys, human malaria parasites are adapted specifically to humans and trials in human volunteers are time consuming and costly because of the important safety issues that must be addressed. Furthermore, it is not clear which route of administration of a vaccine will be most appropriate. While the concept of DNA vaccines is attractive because of the reduced need for a “cold chain” in tropical areas where a vaccine is most needed, there is as yet no clear evidence for efficacy. Choice between the alternatives of recombinant proteins or peptides and identification of the best adjuvant for use with these, or of live viral vectors, are other out-

standing issues. The combinatorial nature of such problems presents a substantial challenge indeed.

### I. INTRODUCTION

#### A. Imperative for a Pre-Erythrocytic Malaria Vaccine

The march of drug-resistant parasite strains [1], the spread of insecticide-resistant mosquito vectors [2], and the recognition that global morbidity and mortality due to malaria equals that of HIV/AIDS [3] have made malaria vaccine development a global imperative [4]. In broad terms, there are three possible goals for a malaria vaccine. Each goal requires a specific vaccine development strategy targeted against specific parasite stages. A malaria vaccine intended to confer sterile immunity would target pre-erythrocytic stages of the malaria parasite, i.e., the sporozoite, liver stages, or hepatic merozoites prior to initial red cell invasion. A vaccine designed to prevent severe disease or death, but not necessarily preventing parasitemia, should aim immune responses against asexual blood stages or toxins. Lastly, a vaccine designed to prevent transmission of malaria from host to vector to host would direct immune responses against sexual stage antigens present in either the host or the mosquito vector. A long-term goal of researchers in this field has been to develop and license a multistage, multiantigen vaccine against *Plasmodium falciparum* that protects malaria-naïve children and adults against infection, limits morbidity in those who develop infection, and is effective for at least 12 months. This goal may require the inclusion of multiple parasite antigens including antigens from more than one stage of the parasite's life cycle. Since the mid 1980s, our efforts have focused upon the development of a safe, well-tolerated, and effective pre-erythrocytic vaccine. This chapter emphasizes recent progress in our co-development with GlaxoSmithKline Biologicals of the sporozoite-based RTS, S/AS02A vaccine and reviews other protein-based pre-erythrocytic malaria vaccines currently in clinical development.

#### B. Feasibility of a Pre-Erythrocytic Vaccine

As is the case for most parasitic infections, sterile immunity to malaria parasites rarely, if ever, occurs naturally, even under the most intense exposure conditions [5]. However, there is circumstantial evidence that naturally acquired cellular immunity against pre-erythrocytic antigens may reduce disease severity [6,7], and that specific MHC alleles governing T-cell responses to pre-erythrocytic antigens have been positively selected for endemic populations [8,9]. The theoretical feasibility of developing an effective pre-erythrocytic vaccine was established more than 30 years ago by experimental immunization of human subjects with large numbers of radiation-attenuated sporozoites [10,11]. This impractical but effective process rendered immunized subjects completely protected from sporozoite challenge with homologous or heterologous parasites of the same species. However, subjects immunized with radiation-attenuated sporozoites remained susceptible to other plasmodial species and to blood stage infection, thus demonstrating the species and stage specificity of this approach. An ideal pre-erythrocytic vaccine would therefore elicit the same immune responses, capable of eliminating sporozoites from the circulation, or killing all infected hepatocytes, or preventing all hepatic merozoites from invading erythrocytes, thereby conferring "sterile immunity."

#### C. Uses of a Pre-Erythrocytic Vaccine

An effective pre-erythrocytic vaccine would be of great benefit to the nonimmune traveler or deploying member of the military. It would be especially important that a pre-erythrocytic vaccine be highly effective in nonimmune subjects as these individuals would have no effective immunity against blood-stage parasites. Vaccine efficacy for the non-

immune traveler should exceed the protection afforded by available chemoprophylactic drugs, although the vaccine might be used in conjunction with chemoprophylaxis in areas where multidrug resistance is high or other plasmodial species, such as *Plasmodium vivax*, are transmitted. Cost, extended duration of efficacy, and boostability by natural infection would be lesser considerations for nonimmune travelers than for endemic populations. A moderately effective pre-erythrocytic vaccine, even of short-term duration, could be of potential benefit to populations for whom short-term chemoprophylaxis has been beneficial. Such indications would include infants [12] and pregnant women, especially primagravidae [13,14]. Broader public health indications for a pre-erythrocytic vaccine in endemic populations might also include reduction in malaria intensity in a manner analogous to the use of bed nets [15], and as an adjunct to malaria eradication efforts. Ultimately, an ideal pre-erythrocytic vaccine would also include blood stage antigens able to reduce disease severity, and sexual stage antigens able to limit transmission of vaccine-resistant parasites.

#### D. Obstacles to Pre-Erythrocytic Vaccine Development

There is not a licensed vaccine for malaria or any other parasitic affliction of mankind. The obstacles are formidable, chief of which is the inadequate knowledge of the requirements for immunity. Classical vaccine approaches such as immunization with attenuated or killed whole organisms are impractical. Hence development is based upon a subunit approach that seeks to include one or more protective antigens and may lead to a multicomponent formulation. Positive selection factors for antigen development in order of decreasing importance include 1) demonstration that antigen-specific immune responses correlate with those associated with protection in volunteers immunized by exposure to radiation-attenuated sporozoites or in previous pre-erythrocytic stage subunit vaccine trials; 2) accessibility of the host immune system to the targeted plasmodial antigen; 3) demonstration that immunization with the homologous antigen confers protection against sporozoite-transmitted infection in analogous animal models; and, potentially, 4) correlation of antigen-specific immune responses with protection against severe disease in epidemiological studies.

Antigen selection is further complicated by the existence of allelic polymorphisms that have presumably arisen as means of evading protective immunity and may ultimately require the inclusion of more than one allele of the same antigen. Another consideration is the role of host genetic restriction of immune responses to protective epitopes, an additional argument in favor of including more antigens in a vaccine intended for use in genetically diverse populations.

#### E. Design Considerations for a Malaria Vaccine

The design of candidate malaria vaccines involves the selection of antigens that target the parasite at vulnerable portions of its life cycle. Malaria species that have been adapted to robust rodent models, such as *Plasmodium berghei* and

*Plasmodium yoelii*, have been powerful tools for identifying both candidate antigens and immunization strategies. Sporozoites transmitted by the bite of female *Anopheles* mosquitoes can be targeted by antibodies directed against their surface antigens as they travel through the bloodstream [16]. These antibodies block the ability of sporozoites to invade liver cells. A variety of cell-mediated responses, including lymphokines and cellular cytotoxicity, are able to kill infected liver schizonts and thus prevent the maturation and release of mature *P. falciparum* exo-erythrocytic forms into the bloodstream [17,18]. To date, most vaccine candidates tested in humans have been based on a small number of sporozoite surface antigens that have been extensively investigated using these rodent systems.

#### F. Decision Criteria and the Human Sporozoite Challenge Model

Adherence to the critical path for malaria vaccine development requires that definitive decisions be made for each potential improvement to the current vaccine candidate. The human sporozoite challenge model using laboratory-reared *Anopheles* mosquitoes that become infected by feeding on *in vitro* cultured *P. falciparum* was developed at WRAIR to assess the efficacy of candidate sporozoite vaccines and new antimalarial drugs [19]. The model has proven to be safe, standardized, and highly reliable for the experimental inoculation of infectivity controls in Phase 2 trials. Since 1992, we have conducted over 400 experimental infections of malaria-naïve malaria vaccine recipients and concomitant unimmunized infectivity controls. The endpoint for efficacy is the appearance of blood stage infection as detected by light microscopy. Typical pre-patent periods are 9–12 days in the infectivity controls. Comparing vaccine efficacy [20] and the duration of efficacy [21] in malaria-naïve vaccinees to that observed in malaria-experienced vaccinees in the field [22] suggests this model has strong negative and positive predictive value. Thus we have incorporated proof of efficacy in the human sporozoite challenge model as the Go/NoGo decision criteria for incorporation of potential new antigens/adjuvants into a multicomponent pre-erythrocytic malaria vaccine.

### II. CIRCUMSPOROZOITE PROTEIN (CSP) AS THE BASIS OF A PRE-ERYTHROCYTIC VACCINE

#### A. First CSP-Based Vaccines

One of the first malaria genes to be identified through this model was the circumsporozoite (CS) protein [23]. The CS proteins of all malaria species contain a central segment of species-specific amino acid repeat sequences flanked by non-repeat regions. In the case of *P. falciparum*, the central portion contains approximately 40 repeats of the amino acid sequence asparagine–alanine–asparagine proline (NANP) and several asparagine–valine–aspartic acid–proline (NVDP) repeats [24]. The central repeating unit is immunodominant relative to the flanking regions and is the portion of the molecule to which protective antibody responses are principally directed [25]. Two alum-adjuvanted candidate

vaccines based on the CS repeat sequences were developed in the mid-1980s, tested in humans, and found to be safe, but both suffered from generally poor immunogenicity [26,27]. In most of the volunteers, repeated immunization induced relatively low titers of antibodies against the repeat region of the CS protein. Nevertheless, a small number of volunteers who did respond well were protected against homologous experimental sporozoite challenge. These pivotal challenge data confirmed that sterile immunity against malaria could be induced in humans by immunization with a synthetic pre-erythrocytic stage subunit vaccine. Because, in these studies involving a limited number of volunteers, protection seemed to be associated with high antibody levels, it was felt that the development of more immunogenic versions of these vaccines would lead to better efficacy.

Subsequent sporozoite vaccines, also based on the NANP repeat, contained modifications conducive to the enhancement of immune responses, such as conjugation of recombinant CS repeat protein with *Pseudomonas aeruginosa* exotoxin A (R32ToxA) [28], and formulation of a similar antigen (R32NS1) in liposomes containing mono-phosphoryl lipid A (MPL) [29] or an emulsion of MPL, mycobacterial cell wall skeleton, and squalene (Detox®, Ribi Immunochem) [30,31]. Each of these strategies resulted in generally higher antibody levels but surprisingly did not significantly enhance efficacy.

While these clinical studies were in progress, the role of protective T-cell responses directed against the liver-stage form of the parasite was elucidated in greater detail. Studies in rodents and humans immunized with irradiated sporozoites revealed that not only antibodies but also CD4<sup>+</sup>, CD8<sup>+</sup>, and cytotoxic T-cell (CTL) responses and cytokines such as interferon-gamma were important components of the protective immune responses against the pre-erythrocytic stage of *P. falciparum* [32,33]. Target epitopes for these T cells have been localized to the C-terminal region of the CS protein [34–39]. Region II, a charged highly conserved sequence that lies in this portion of the molecule, was implicated in the binding of sporozoites to hepatocytes [40]. The recognition that peptide sequences lying outside the CS repeat were important for induction of humoral and cellular responses against the hepatic stage led to the inclusion of nonrepeat portions of the molecule in the next generation of CS-based vaccines. One such candidate (NS1RLF) was constructed so as to be completely devoid of repeat epitopes and contained both N-terminal and C-terminal flanking regions. This vaccine was formulated as a recombinant protein encapsulated in liposomes and adjuvanted with MPL. The vaccine was found to stimulate a potent CTL response in mice and induced a brisk immune response in humans that included antibodies that recognized sporozoites [41]. Unfortunately, no protection from experimental sporozoite challenge was observed and this vaccine has been abandoned.

## B. Initial Development of Candidate Malaria Vaccine “RTS,S”

In collaboration with then GlaxoSmithKline Biologicals (GSK Bio) our group at the Walter Reed Army Institute

of Research turned to what has become a more promising approach. This strategy was based upon GSK Bio's development of an expression system in which the CS repeats as well as the C-terminal region were incorporated into highly immunogenic HBsAg particles. The components of this new vaccine are two polypeptides (RTS and S) that are synthesized simultaneously in genetically engineered *Saccharomyces cerevisiae* yeast cells. During purification they spontaneously form composite particulate structures (RTS,S) that constitute the vaccine antigen. RTS is a single polypeptide chain corresponding to amino acids 207–395 of the CS protein gene in the 7G8 strain of *P. falciparum* fused to the amino terminus of the hepatitis B surface antigen (HBsAg; adw serotype). S is a polypeptide of 226 amino acids that corresponds to HBsAg. RTS includes 19 copies of the tetrapeptide repeat motif (NANP) plus the C-terminal region of the protein devoid of the hydrophobic anchor sequence. Several formulations of the vaccine were developed and manufactured at GSK Bio and preclinical studies included a series of increasingly potent adjuvants. The initial clinical studies involved one formulation in which RTS,S was adsorbed to alum, and a second in which it was adsorbed to alum to which was added the immunostimulant 3-deacyl-MPL (MPL, see Table 1). This second adjuvant formulation is designated AS04 (formerly SBAS4). Although antibody responses were modest, most volunteers developed proliferative cellular responses against the CS protein. More importantly, following sporozoite challenge, two of eight volunteers in the RTS,S/AS04 group were protected whereas all six volunteers that received the alum formulation developed malaria [42]. Encouraged by these results that suggested that greater immunogenicity would be associated with greater efficacy, two additional formulations were studied in a Phase 1/2a trial [20]. In this and in all subsequent trials, RTS was re-engineered to represent the NF54 strain (3D7 clone) of *P. falciparum*. In that study, the AS04 formulation was tested along with two additional formulations developed by GSK Bio: AS03 (formerly SBAS3) containing a proprietary oil-in-water emulsion, and AS02A (formerly SBAS2) containing the same emulsion plus the immunostimulants MPL and QS21. These new adjuvant systems were chosen on the basis of preclinical studies in rhesus monkeys that demonstrated their safety and immunogenicity. The primate data showed that AS03 promoted strong antibody responses while AS02A induced both humoral and cellular responses (Heppner DG, unpublished data). Human volunteers immunized with either RTS,S/AS03 or RTS,S/AS02A developed some of the highest anti-repeat antibody responses induced by any sporozoite-based vaccine, but both the AS04 and AS03 formulations were only marginally protective following laboratory-based sporozoite challenge. In contrast, an unprecedented six of seven volunteers who received the AS02A formulation were protected. Type 1 cellular responses, especially the production of IFN-gamma upon stimulation with CS peptides, were promoted by the AS02A formulation of RTS,S and were presumed to be an important component of the protective immune responses. Subsequently, expanded safety and immunogenicity trials of RTS,S/AS02A in over 400 malaria-naïve and malaria-immune subjects have revealed the vaccine to be safe and highly

immunogenic, and recent experimental challenge studies involving more than 50 volunteers indicate that the vaccine consistently induces significant protection when given on two- or three-dose schedules [43].

### C. Initial Field Trials of RTS,S/AS02A Candidate Malaria Vaccine

These encouraging preliminary results were followed up recently with GSK Bio-sponsored clinical trials involving malaria-immune adult male residents of The Gambia, West Africa. A Phase I safety and immunogenicity study was conducted by investigators at the Medical Research Council (MRC) laboratories in Banjul, at a study site where there was minimal ongoing malaria transmission. This study indicated that the vaccine was safe, mildly reactogenic, and immunogenic in otherwise healthy malaria semi-immune adults [44]. A follow-up Phase 2b pilot efficacy study was conducted at a separate site characterized by high and seasonal transmission rates in malaria semi-immune adult Gambian men who were immunized during a period of low transmission and followed for the occurrence of new malaria infections during a period of active malaria transmission [45]. In this study, conducted at the MRC Field Station in Basse, Upper River Division, The Gambia, 360 men were randomized to receive three doses of either RTS,S/AS02A or human diploid rabies vaccine, given intramuscularly at 0, 1, and 6 months. The vaccination schedule was timed to coincide with the dry season during which transmission of *P. falciparum* was low. The final dose was administered approximately 1 month before the expected onset of the rainy season. Volunteers were treated with sulfadoxine/pyrimethamine to clear asexual-stage parasites 1 month before the beginning of the 15-week efficacy follow-up period. The vaccine was again found to be safe, mildly reactogenic, and immunogenic in this semi-immune population. Two hundred and fifty of the volunteers enrolled in this study received all three doses of the vaccine and had adequate follow-up data. Vaccine efficacy was estimated to be 71% (95% CI 46–85%) during the first 2 months of follow-up but decreased to 0% during the last 6 weeks of the follow-up period. The reasons for the short

duration of efficacy are likely to be multiple. Subset analysis revealed that younger, less malaria-experienced men became infected in the control group earlier than did the older, more highly immune members of their cohort. As vaccine efficacy waned, the incidence in the RTS,S/AS02A group was being compared to the control group from which the most susceptible subjects had been removed. Antibody responses also declined during the period of follow-up such that the mean levels at the end of the follow-up period were equivalent to those after a single dose of vaccine. As has been seen in other studies of sporozoite vaccines, no boosting of antibody responses was seen following sporozoite exposure. Finally, it is likely that the entomologic inoculation rate was typical of that previously described for this region and was higher at the end of the transmission season than it was at the beginning. Importantly, a fourth booster dose was administered to 158 volunteers a year later and prior to the next peak of malaria transmission. Antibody responses were significantly boosted and, during a 9 week follow-up, efficacy was 47% (95% CI:4–71%; P=0.037). This important field study extended encouraging data previously obtained in studies of malaria-naïve volunteers immunized with RTS,S/AS02A and exposed to sporozoites using the WRAIR standard sporozoite challenge model. First, it confirmed the predictive value of the model—efficacy in the field was similar in magnitude and duration to that observed with the same vaccine in the laboratory-based clinical trial [21]. Second, there was no evidence of strain-specific immunity, as polymerase chain reaction analysis of CS genes from isolates collected from subjects who became infected during the study revealed that the frequency of polymorphic sequence variants at the Th2R and Th3R regions characteristic of the NF54 clone (from which the vaccine was derived) was similar for the RTS,S/AS02A and rabies vaccine groups [46]. Third, it demonstrated that natural boosting through exposure to sporozoites was unlikely to enhance or sustain vaccine-induced immunity. Finally, the data again suggest the importance of high levels of antibodies against CS repeat epitopes as a potential correlate of immunity, although a specific protective cutoff value could not be identified. The results obtained with RTS,S/AS02A in The Gambia must be

viewed cautiously. However, clearly they mark an important milestone—the first time that vaccine-induced protection from infection with *P. falciparum* has ever been observed in a field setting, and the capacity building and experience gained with African co-investigators were invaluable.

#### D. Additional Development of RTS,S

In 2003, RTS,S adjuvanted with AS02A, now renamed AS02, is the only malaria vaccine in clinical development that has been demonstrated to prevent *Plasmodium falciparum* infection. However, further improvements in the magnitude and duration of efficacy are clearly desirable. Parallel efforts are underway to define the benefit of RTS,S/AS02A in pediatric population at greatest risk of malaria and to improve the efficacy of RTS,S through the addition of new vaccination schedules, adjuvants, antigens, and platform technologies.

##### 1. Pediatric Trials of RTS,S/AS02

In January 2000, GSK Bio and the Malaria Vaccine Initiative (MVI) at PATH (Program for Appropriate Technology in Health) entered into a private/public partnership that initiated the clinical pediatric development of RTS,S/AS02. Two sequential Phase 1 studies in children were conducted by the MRC in The Gambia: a study in older children (6–11 years), followed by a second study in younger children (1–5 years). In each study, a double-blind, randomized, controlled, staggered dose-escalation design was used to evaluate 1/5, 1/2, and a full dose. The RTS,S/AS02A vaccine had a good safety profile and there were no serious adverse events related to vaccination. All doses were highly immunogenic for anti-CS and anti-HBs antibodies. Subsequent pediatric development of RTS,S/AS02A is now underway in Mozambique [4].

##### 2. New Schedules and Doses of RTS,S/AS02A Administration

Initial trials of RTS,S/AS02A administered this vaccine on a 0-, 1-, and 6–9-month schedule. Subsequent trials at WRAIR demonstrated no apparent change in efficacy when given as a half (25 µg RTS,S/0.25 ml of AS02A) or full (50 µg RTS,S/0.50 ml of AS02A) dose [43]. A recent Phase 2 trial of RTS,S/AS02A compared the safety, immunogenicity, and efficacy of two accelerated regimens of RTS,S/AS02A. Forty malaria-naïve volunteers were randomized to receive full dose RTS,S/AS02A on either a 0-, 1-, and 3-month or 0-, 7-, and 28-day schedule. Both immunization schedules were well tolerated and comparably immunogenic. Following standard sporozoite challenge, 45% and 38% volunteers were completely protected against parasitemia. The study supported the safety of short-course immunization and underscored the need to improve vaccine efficacy for use in travelers (Kester KE, unpublished data).

##### 3. New Adjuvants

As reviewed earlier, initial formulations of RTS,S with alum, alum and MPL, or oil-in-water emulsions had conferred marginal protection. In contrast, formulation of RTS,S with

AS02A, a proprietary formulation containing MPL®, QS21 and an oil-in-water emulsion, elicited strong antibody and a Th1 cellular immune response (Krzysz U, unpublished data) [47] and unprecedented efficacy. Working closely with GSK Bio, we have systematically compared RTS,S/AS02A to RTS,S formulated with additional new adjuvants using the standardized rhesus monkey safety and immunogenicity vaccine model. One alternative adjuvant, designated AS01B, induced a sustained and improved RTS,S-specific IFN-gamma ELISPOT response and an equivalent antibody response to that seen with the AS02A (Stewart A, unpublished data). A Phase 2a trial in malaria-naïve adults of RTS,S/AS01B versus RTS,S/AS02A to be initiated in late 2003 at WRAIR will compare the magnitude and duration of protection against malaria challenge at 2 weeks and 6 months after the last immunization.

#### 4. RTS,S in Combination with a Second Antigen

*Thrombospondin-Related Anonymous Protein.* *P. falciparum* thrombospondin-related anonymous protein [48] (Pf-TRAP) is a candidate vaccine antigen found in a patchy distribution on the surface and within the micronemes of the sporozoite [49]. Thrombospondin-related anonymous protein is required for the gliding motility and infectivity of sporozoites [50]. *P. falciparum* thrombospondin-related anonymous protein was recombinantly expressed in SF9 insect cells, lyophilized, and bottled as single-dose vials. One formulation contained 20 µg of TRAP per human dose; a second formulation contained 20 µg of TRAP and a standard 50-µg dose of RTS,S. Preclinical safety and immunogenicity testing of these two formulations with the AS02 adjuvant in a standardized rhesus malaria vaccine model demonstrated a good safety and local reactogenicity profile. Serologic analysis as determined by ELISA showed no interference by TRAP in the antibody response to RTS,S; and there was an increase in the IFA titers to RTS,S/TRAP/AS02A as compared to that seen with either antigen alone (Heppner DG, unpublished data). A subsequent Phase 1/2 trial of TRAP/AS02A and RTS,S/TRAP/AS02 given on a 0- and 1-month schedule confirmed the preclinical safety and immunogenicity of these formulations (Kester KE, unpublished data). In the efficacy phase of this study, none (0 of 4) of the TRAP/AS02 vaccinees and only 1 of 12 of the RTS,S/TRAP/AS02A vaccinees was protected. This cautionary result suggests that vaccine development efforts should first determine the marginal utility of additional antigens prior to their incorporation into a multicomponent vaccine, and that attention should be paid to the possibility of immunological interference between the antigens in the combination.

*Merozoite Surface Protein-1.* Merozoite surface protein-1 (MSP-1), the first antigen discovered on the surface of the erythrocytic stage merozoites, is also expressed in merozoites released at the end of hepatic schizogony [51]. Merozoite Surface Protein-1 is the target of protective immunity, particularly the C-terminal portion, against severe disease as suggested by epidemiological studies [52], and as demonstrated by immunization studies of Aotus monkeys with purified native merozoite surface protein [53]. Recently, J. Lyon and E. Angov at WRAIR expressed and produced a

42-kDa C-terminal MSP-1 protein based on the *P. falciparum* 3D7 clone in *E. coli*. In preclinical [54] and Phase 1 clinical trials (Ockenhouse CF, unpublished data), a full dose of 50 µg of MSP-1 formulated with 0.5 ml of AS02A was shown to be safe and well tolerated. Seroconversion to MSP-1/AS02A occurred in volunteers who received a single immunization with a 1/5 ( $N=5$ ), 1/2 ( $N=5$ ), or full dose ( $N=5$ ), and serum antibody from each volunteer recognized native protein as determined by a merozoite immunofluorescence assay. Encouraged by these results, a Phase 2A trial in 2001 evaluated the combination of RTS,S and MSP-1, adjuvanted with AS02A (Cummings JF, unpublished data). The trial demonstrated that the extemporaneous combination of MSP-1/AS02 and RTS,S/AS02A caused no interference in the protective efficacy of RTS,S/AS02A against sporozoite challenge. Accordingly, the MSP-1/AS02A formulation is now in field efficacy trials in Kenya. If successful in reducing clinical disease, the two antigens will be co-formulated and field tested.

## 5. RTS,S and New Platform Technologies

Improved B- and T-cell responses have been achieved in numerous nonmalaria preclinical trials that combine heterologous platform vaccine technologies. This approach, referred to as “prime-boost,” yields results dependent not only upon the vaccines but upon the sequence, interval, and number of immunizations administered. Preclinical proof of concept for enhanced immunologic responses to plasmoidal antigens has been demonstrated for immunizations with protein vaccines in combination with either DNA [55], vaccinia [56], or adenovirus [57] vaccine carriers. Recently, a Phase I clinical trial of a CSP–DNA plasmid vaccine expressing the full-length CS protein was conducted [58,59]. Cytotoxic T-cell responses were observed, but no antibody responses were detected, even at very high doses. Volunteers from this trial were subsequently enrolled into a Phase 1 prime-boost pilot study to evaluate the safety and immunogenicity of boosting these volunteers previously immunized with three doses of a CSP–DNA plasmid given by various routes with two full doses of RTS,S/AS02A at 0 and 1 month. Despite an unfavorable dosing interval, DNA immunization did appear to prime for improved cellular responses to RTS,S (Wang R, and Epstein J, unpublished data).

A second prime-boost approach involves a current Phase 2 trial of RTS,S/AS02 and a modified vaccinia Ankara (MVA) expressing the *P. falciparum* CS gene now underway at the University of Oxford. Detailed immunogenicity assessment and efficacy data will be available in 2003. However, the excellent safety profile, potency, and vectorial capacity of vaccinia are offset by the current prospect of widespread immunization with vaccinia against smallpox that might interfere with subsequent use of vaccinia-based malaria vaccines.

## E. Other CSP-Based Protein Subunit Vaccines

As the only antigen to reproducibly confer protection when used as a subunit vaccine, CSP is a logical target for proof of concept studies for new vaccine platform technologies.

### 1. Multiple Antigen Peptides

Although initial CSP tetrapeptide-based malaria vaccines were poorly immunogenic and gave scant protection, correlations were made between anti-CSP repeat antibody titer and protective efficacy against sporozoite challenge [26,27]. These vaccines were recognized to have potential design deficiencies [60], such as a low malaria epitope density, the potential for carrier epitope suppression when conjugated with tetanus toxoid [61], and the absence of parasite-specific T-cell helper epitopes needed to elicit memory responses upon natural exposure to sporozoites. A second generation of synthetic, well-defined CSP-based vaccines known as “multiple antigen peptides” or “MAPs” were developed that contained the B-epitope (NANP)<sub>3</sub> and a T-helper cell epitope from the CSP repeat region found in all *P. falciparum* isolates known as “T1” [62]. This construct, described as (T1B4)<sub>4</sub>MAP, elicited high titer antibodies in a subset of volunteers whose class II DR or DQ molecules were known to more avidly bind the T1 epitope [63]. Encouragingly, these antibodies recognized native sporozoites in both an IFA assay and in a CS precipitin reaction. No sporozoite challenge was conducted to assess the efficacy of this vaccine. The occurrence of hypersensitivity reactions to this vaccine led to the abandonment of this construct.

In an effort to broaden the immune response, a third generation malaria peptide vaccine was designed that added a second universal T-cell helper epitope found in the C-terminal portion of the CS protein to the T1 epitope and the (NANP)<sub>3</sub> CS repeats [64]. This tri-epitope vaccine incorporated a lipopeptide adjuvant and was constructed by joining epitope modules to a branched lysine core via oxime bonds, hence the short-hand term, “polyoxime.” A Phase 1 trial elicited antibodies in vaccinees of diverse class II haplotypes that recognized native sporozoites in both an IFA assay and in a CS precipitin reaction. Again, no sporozoite challenge to assess for protective efficacy was conducted and the future of this vaccine construct remains uncertain [65].

### 2. Modified Hepatitis B Core Particle as a Carrier

Modified hepatitis B core particles are an immunologically potent carrier of heterologous epitopes [66]. Proof of concept of this platform technology for malaria was first achieved in a *P. berghei* mouse malaria model at WRAIR in the early 1990s [67] and again demonstrated by protection against sporozoite challenge in a *P. yoelii* model [70]. To design a vaccine for human use, a preliminary series of modified recombinant HBc particles containing *P. falciparum* CS protein T- and B-cell epitopes were assayed for immunogenicity in rodents [69,70]. The optimal *P. falciparum* HBc vaccine candidate, termed ICC-1132, contains T- and B-cell epitopes from the CS protein repeat region and a universal T-cell epitope from the C terminus of the CS protein [65]. Preclinical studies in rhesus and cynomolgus monkeys have demonstrated that ICC-1132, formulated in Seppic ISA-720, is a potent B-cell immunogen (Birkett A, personal communication). In mice, a single injection of ICC-1132 elicited strong anamnestic antibody responses following priming with *P. falciparum* sporozoites. Human CD4<sup>+</sup> T-cell clones

specific for the CS-derived universal T-cell epitope proliferated and produced cytokines following in vitro stimulation with ICC-1132. These findings suggest that the candidate vaccine, in addition to inducing strong cellular and humoral immunity in naïve individuals, may have particular utility in enhancing the sporozoite-primed immune responses of individuals living in malaria-endemic areas. ICC-1132, which was developed by Apovia Inc., San Diego, CA, in collaboration with scientists at New York University, entered Phase 1 clinical trials at the University of Tuebingen in November 2002.

### 3. Long Synthetic Peptides as Vaccines

Long synthetic peptides (LSP) are a maturing technology that enable the effective presentation of defined CS protein B- and T-cell epitopes to the immune system. Proof of concept of this approach was first achieved in primates by Roggero et al. who used a 102-amino acid LSP representing the CSP to elicit CD4<sup>+</sup> and CD8<sup>+</sup> T cells and antibodies [71]. A subsequent Phase 1 study in 16 malaria naïve adults evaluated four separate formulations containing either 100 or 300 µg of the LSP adjuvanted with aluminum hydroxide or Montanide ISA-720 [72]. Antigen-specific CD4<sup>+</sup> and CD8<sup>+</sup> T cells were elicited with both formulations; however, only the Montanide ISA-720 formulation induced positive IFA results. The utility of this approach awaits proof of efficacy in experimental Phase 2 trials and definition of manufacturing costs for large-scale synthesis.

## III. CLINICAL TRIALS OF NON-CSP PRE-ERYTHROCYTIC PROTEIN VACCINES

At present, there are no trials of non-CSP pre-erythrocytic vaccines in progress.

However, recent advances in recombinant protein expression and in peptide synthesis suggest such Phase 1/2 trials will occur in the next two years of two antigens, liver stage antigen 1 (LSA-1) and liver stage antigen 3 (LSA-3).

### A. Liver Stage Antigen 1

Since the discovery of *Plasmodium falciparum* LSA-1 [73], mounting evidence supports its development as a vaccine [71]. In studies in endemic populations, protection against malarial disease has been associated with LSA-1-specific cellular and humoral immune responses. Likewise, in studies of irradiated sporozoite-immunized volunteers challenged with infectious sporozoites, cellular responses to LSA-1 were higher in protected than in unprotected volunteers [75]. A recombinant *E. coli*-*P. falciparum* LSA-1 protein is scheduled for Phase 1/2 trials at WRAIR in 2004.

### B. Liver Stage Antigen 3

Liver stage antigen 3 is a 205-kDa protein found in both sporozoite and liver stages. Recent testing of LSA-3 LSP constructs in vitro reveals multiple B- and T-cell epitopes recognized by malaria-immune individuals in Africa [78]. Subsequent studies of either LSA3-LSP formulated in

AS02A or LSA3-lipopeptides in chimpanzees demonstrated induction of antibody and T-helper and T-cytotoxic responses and apparent protection of two chimpanzees against sporozoite challenge [77]. The initial Phase 1 trials of GMP LSA-3 LSP are scheduled for 2003 in Europe.

## IV. CONCLUSIONS

“There must be a beginning of any great matter, but the continuing unto the end until it be thoroughly finished yields the true glory”—Sir Frances Drake

Of all the pre-erythrocytic antigens, none has been exhaustively evaluated, and only CSP has been systematically tested in clinical development. New antigens, adjuvants, and technologies offer great hope. Ultimate success, the development of an effective malaria vaccine, demands bold leadership, undeterred by myriad failures, able to marshal scarce resources against this formidable foe.

## Malaria: A Complex Disease that May Require a Complex Vaccine

### I. THE NEED FOR A MALARIA VACCINE

Malaria, caused by *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, or *Plasmodium ovale*, is a major health problem in most countries in the tropics. For years, it has been estimated that more than 2 billion people live in countries where malaria is transmitted, that there may be 300–500 million new infections and 1–3 million deaths annually caused by malaria, and that the majority of cases and more than 90% of the deaths occur in sub-Saharan Africa, where malaria is, in many places, the leading cause of death among children less than 5 years of age. Recent analyses suggest that the medical impact of malaria may actually have been significantly underestimated [1], and that the enormous economic impact of malaria has never been adequately considered [2]. It has been estimated that malaria reduces annual gross domestic product (GDP) in affected countries in sub-Saharan Africa by more than 1.3% [2]. As we begin the twenty-first century, it is troubling that a treatable infectious disease has such an “intolerable” impact. Yet, the increasing resistance of the *Plasmodium* sp. parasite to chemoprophylactic and chemotherapeutic agents, the resistance of the *Anopheles* sp. mosquito vector to insecticides, including the pyrethroids used in insecticide-impregnated bed-nets, and the inability of the most affected countries to mobilize and sustain the resources required for malaria control, as evidenced by the resurgence of malaria in areas formerly free of the disease, highlight the urgency for developing an effective malaria vaccine. A vaccine would dramatically improve the chances of optimally controlling, and eventually eradicating, malaria.

Additionally, malaria remains a major public health threat to nonimmune visitors to areas where malaria is transmitted. Of the nearly 700 million international tourist

arrivals recorded worldwide in 2000, approximately 9 million were bound for West, Central, or East Africa, 37 million were to Southeast Asia, 6 million to South Asia, and 10 million to Oceania [3]. Although it is not possible to ascertain what proportion of these travelers visited malaria-endemic areas, an estimate of 30% would yield 18 million international travelers to areas potentially exposed to malaria transmission. This estimate can be supplemented by arrivals to malarious areas of the Middle East, the Caribbean, and South America, and by nontourist travel, such as deployment of military personnel. Serological studies of various traveling populations suggest that from 2% to 21% (but as high as 80%) of travelers are actually inoculated with *Plasmodium* spp. sporozoites during their stay in the tropics [4]. In addition to international travelers, a growing number of people residing in malaria-free regions of malaria-endemic countries travel locally to areas where malaria is transmitted [5]. Whether the purpose is tourism, family visits, business, government service, military deployment, religious service, emigration or escaping civil strife or persecution, malaria is one of the most significant health risks faced by travelers today. Factors associated with use of chemoprophylaxis, such as availability, costs, contraindications, side effects, inconvenience, and compliance, along with the many cases of malaria in returning travelers, and the threat of increasing drug resistance, form the rationale for a traveler’s vaccine for the prevention of malaria. In order to be used as a substitute for chemoprophylaxis, such a vaccine would have to provide greater than 85–90% protective efficacy for a sustained period, perhaps at least 6 months.

There are four chapters on malaria vaccine development in this book. In this chapter, we summarize our perspective on the current efforts to develop malaria vaccines. We emphasize the work we performed to utilize a sequential

immunization approach (DNA prime and recombinant virus or protein boost) to maximize the antibody and T-cell responses against the sporozoite, liver, and asexual erythrocytic stages of the parasite life cycle, and introduce recent work to develop an attenuated whole sporozoite *P. falciparum* vaccine.

## II. THE POTENTIAL FOR DIFFERENT MALARIA VACCINES FOR DIFFERENT TARGET POPULATIONS

Many malariologists believe that different types of malaria vaccines may be necessary for different populations. The primary requirement is to reduce the incidence of severe malaria and malaria-associated mortality in infants and children with heavy exposure to *P. falciparum*, such as those living in sub-Saharan Africa (Type 1 vaccine). At the other extreme is the requirement to prevent all clinical manifestations of malaria in individuals from areas with no exposure, who travel to regions where malaria is endemic, primarily malaria caused by *P. falciparum* and *P. vivax* (Type 2 vaccine). This "extremes" approach to malaria vaccine development does not take into account specific populations affected by malaria which fall between these extremes, such as individuals in endemic regions at high risk of *P. vivax* infections [6]. In fact, as Type 1 and Type 2 vaccines are developed, they will need to be assessed in many different populations.

For the Type 1 vaccine designed to reduce mortality among children in sub-Saharan Africa, the problem is complicated by the varied epidemiology of the disease. In areas with extremely intense transmission, such as northern Ghana, it is primarily infants who die of malaria, with severe anemia as a major cause of death. In areas with less intense transmission, such as The Gambia, 2- to 5-year-olds appear to face the greatest risk of dying, with cerebral malaria as the major cause of death [7]. It is even possible that different vaccines or vaccination strategies, tailored to the predominant pathophysiology of a particular region or targeting the age groups at greatest risk, may be the most effective response to this heterogeneous epidemiology.

For the Type 2 vaccine designed to prevent all clinical manifestations of malaria in nonimmune travelers to malaria-endemic areas, the target populations are also varied. One generally thinks that the major recipients of such a vaccine would be travelers from North America, Europe, Japan, Australia, and other highly developed malaria-free areas of the world. However, there are hundreds of millions of people living in nonmalarious areas of malaria-endemic countries who travel to malarious areas of their own country. For example, it is not infrequent for someone born in western Kenya, where transmission is high, to attend a university in Nairobi, where there is no malaria transmission, and then settle in Nairobi. The children of these Nairobi residents are nonimmune to malaria, and the parents themselves may lose their immunity if sufficient time passes. When they, their children, or other Kenyans born in Nairobi visit western Kenya on holidays, they are at high risk of contracting malaria and rapidly developing

severe disease. There is little mention in the malaria literature of the increasing numbers of nonimmunes living in countries with endemic malaria who must receive short-term protection against malaria by a vaccine. Because of their susceptibility to rapidly developing severe disease and because of their brief exposure to transmission, we think that these in-country travelers, including their children, would require a vaccine with the same protective profile as a vaccine for travelers from North America or Europe.

There is a third type of vaccine being developed, a transmission-blocking vaccine. This vaccine is designed to protect the entire community rather than the immunized individual, by reducing transmission intensity. The target populations for such a vaccine are not yet clearly defined. Such a vaccine could eventually be combined with the Type-1 and -2 vaccines described above. Such a vaccine would unquestionably be of great value, perhaps even on its own, in islands with malaria or in areas with only modest transmission. It might also be useful during prolonged epidemics. It is not clear how useful such a vaccine will be in areas such as sub-Saharan Africa, where transmission is intense. However, a recent article has suggested that such a vaccine could be quite useful, particularly when combined with vaccines targeting other parasite stages, for preventing a selective process favoring the emergence of fast-growing, and therefore, virulent parasites [8]. Even if not able to impact overall transmission levels, a transmission-blocking component included in a Type 1 or Type 2 vaccine could block the escape of resistant mutants, thus preserving vaccine efficacy in the community and preventing the emergence of virulent parasite strains.

## III. THE FEASIBILITY OF A MALARIA VACCINE IS SUPPORTED BY HUMAN MODELS

Functional human models demonstrate that both pre-erythrocytic stage and erythrocytic stage vaccines are feasible. In humans, pre-erythrocytic stage immunity can be induced by exposure to irradiated sporozoites [9], and a clinically important degree of erythrocytic stage immunity can be induced by exposure to repeated blood stage infection [10,11].

The first model, immunization with radiation-attenuated sporozoites, is for the design of a vaccine to prevent all clinical manifestations of malaria. In 1967, it was demonstrated that mice immunized with *Plasmodium* sporozoites attenuated by radiation, such that they could invade the host hepatocyte and undergo limited development but could not mature into blood-stage parasites, were protected against challenge with live sporozoites [12]. In late 1973 and early 1974, two groups independently reported that human volunteers could likewise be protected against infectious sporozoite challenge by immunization with radiation-attenuated *P. falciparum* sporozoites [13–15]. The attenuated sporozoite vaccine is administered by exposing vaccinees to at least 1000 bites of irradiated, infected mosquitoes over the course of several months. These attenuated parasites undergo partial development in the liver but do not progress to the blood-stage. They stimulate an immune response that is

sporozoite- and liver-stage-specific and, provided the number of immunizations is sufficient, are able to sterilize subsequent challenge with intact sporozoites for up to 42 weeks [9]. This cumbersome procedure presents a technical barrier to large-scale immunization that has not yet been overcome. Nonetheless, the induction of sterile immunity by attenuated sporozoites provides proof-of-principle regarding the feasibility of making a sporozoite/liver-stage malaria vaccine that prevents blood-stage infection and clinical disease entirely.

The second model of immunity to malaria in humans is for a vaccine to prevent death and severe disease without preventing erythrocytic-stage infection, and the model is naturally acquired immunity [11]. In areas where malaria is transmitted, individuals that survive past a certain age will become reinfected and may become clinically ill, but will not develop severe disease or die. In areas with stable transmission, there is little to no severe disease or malaria-associated deaths after the age of 7–10 years; in areas with very intense transmission, this transition may occur as early as the second or third year of life. The decrease in the incidence of *P. falciparum* infections, the prevalence and density of parasitemia, and the morbidity and mortality associated with *Plasmodium* spp. infection with natural exposure is consistent with acquisition of antimarial immunity in humans [7,16]. The existence of naturally acquired immunity provides a strong rationale for including blood-stage antigens designed to induce antibody responses as the second “tier” of a “two-tiered” vaccine: pre-erythrocytic components to destroy the majority of developing parasites during the 5-day window of liver stage development, and erythrocytic components to protect against severe disease and death in individuals who experience breakthrough blood-stage infections.

In the case of naturally acquired immunity, the genetics of the human host, the transmission dynamics of the parasite, and probably even the age of the host, contribute to the complexity of the immune response to infection and therefore may add to the difficulty of developing a vaccine. Although it is clear that sickle-cell trait protects against severe disease, and that other genetic traits may influence outcome, our understanding of the relationship between host genetics and the response to infection is limited. The elucidation of the sequence of the human genome and the development of scientific tools to use these data should lead to a better understanding of the role of host factors in determining the severity of disease associated with infection.

#### IV. APPROACHES TO MALARIA VACCINE DEVELOPMENT

Vaccines have eliminated the natural transmission of smallpox from the world, nearly eliminated polio, and eliminated *Hemophilus influenza* as a cause of severe disease in industrialized countries. We know that it is possible for the immune system to control malaria, yet despite much effort, there is currently no commercially available malaria vaccine. It is not possible to consider immunizing people by

exposure to live infectious parasites, which is what occurs in naturally acquired immunity, because the individuals would become clinically ill. It has not been considered practical to immunize by the bite of irradiated, infected mosquitoes, or by intravenous injection of live radiation-attenuated sporozoites, to duplicate the immunity elicited by the irradiated sporozoite vaccine.

During the past 20 years, therefore, there has been considerable work performed to develop subunit vaccines that provide protective immunity comparable to that of the human models of radiation-attenuated sporozoite immunization and naturally acquired immunity. However, no vaccine has yet provided comparable protection. There are numerous potential explanations for the lack of current success. One is that exposure to the whole parasite elicits a more potent, protective immune response than the subunit vaccines tested thus far. However, in the case of people protected by the irradiated sporozoite vaccine or by naturally acquired immunity, T-cell and antibody responses against current candidate antigens or against whole parasites (in the case of antibody responses) are generally modest at best and often lower than those achieved by subunit vaccination. A more likely explanation is that immunization with only one or a few parasite proteins cannot duplicate the immunity elicited by exposure to a parasite that has thousands of proteins.

The disappointments in the initial clinical trials considered in the context of the two human models have resulted in a reappraisal of malaria vaccine development strategies. The general approach has been to attempt to delineate the immune responses responsible for the protective immunity seen in models, determine the antigens against which these protective immune responses are directed, package these antigens or their critical epitopes in a vaccine formulation that is immunogenic and suitable for manufacture and administration, and develop a vaccine delivery system that would induce the required responses against the identified targets. During the past decade, significant progress has been made in each of these areas. Three general approaches to malaria vaccine development have been delineated. A fourth approach has been added in the past 6 months.

The most work has been done and progress achieved on an approach focused on maximizing the magnitude and quality of immune responses to a single or a few key antigens, such as the circumsporozoite protein (CSP) and the merozoite surface protein-1 (MSP1), by immunizing with synthetic peptides or recombinant proteins in an adjuvant. These vaccines are being designed to primarily induce antibody [17] and CD4<sup>+</sup> T-cell responses [18], but there is also interest in eliciting CD8<sup>+</sup> T-cell responses. Researchers focusing on this approach consider that the subset of parasite antigens currently identified as potential vaccine targets is adequate, and that the major obstacle to fielding an effective vaccine lies with optimizing the induction of the desired immune response by vaccination. Some success with this approach has been shown with the demonstration that a vaccine composed of partial-length *P. falciparum* circumsporozoite protein (PfCSP) fused to hepatitis B surface antigen and expressed together with unfused HbsAg (called

RTS,S) formulated in adjuvant provided short-term protection of malaria-naïve volunteers against experimental challenge [19,20], and of semi-immune adults resident in The Gambia against naturally transmitted malaria [21]. These results support the potential for RTS,S as a core component for a vaccine. However, the transient nature of the RTS,S-induced protection and the inability of the vaccine to induce the class I restricted responses considered important for pre-erythrocytic stage protection, despite the induction of class II-restricted anti-PfCSP IFN- $\gamma$  responses and antibody responses, establish that the vaccine is not yet optimal as currently formulated. These data clearly indicate that this vaccine will not be adequate for preventing all clinical manifestations of malaria in travelers and military personnel, but do not preclude the possibility that this vaccine, on its own, could reduce severe morbidity and mortality in children in Africa. For this reason, it is now being tested in field trials in children in Africa.

The second approach to malaria vaccine development is to induce good or optimal immune responses against each of approximately 5–15 identified potential target antigens, by immunizing with DNA vaccines or recombinant viruses, and boosting with either DNA, recombinant viruses or bacteria, or recombinant proteins in adjuvant, or replicons. The goal here is to elicit CD8 $^{+}$  and CD4 $^{+}$  T-cell as well as antibody responses. To date, the primary target antigens at the pre-erythrocytic stage, those antigens expressed by *P. falciparum*-irradiated sporozoites within infected hepatocytes, include CSP, SSP2, LSA1, and Exp1 [22]. Recently, LSA3 has been proposed as an additional candidate [23]. Researchers focusing on this multivalent, multi-immune response approach are skeptical regarding the ability of a vaccine based on a single antigen to protect against a parasite as complex as *Plasmodium*, considering the problems posed by the severe genetic restriction of the host immune response and parasite variation of target epitopes. Efforts to date on the development of a multivalent and multi-immune response malaria vaccine have primarily focused on the technology of DNA-based vaccines, with both whole-gene and multiepitope vaccines being evaluated in the clinic [24,25] (AVS Hill, unpublished results; TL Richie, unpublished results). In the case of the whole gene, the *P. falciparum* circumsporozoite protein (PfCSP) has been used to provide the foundation and establish the proof-of-principle for safety, tolerability, and immunogenicity of DNA-based vaccines in normal healthy humans. Initial Phase I studies have established that DNA vaccines are safe and well tolerated [26,27], and that antigen-specific and genetically restricted CD8 $^{+}$  T-cell responses can be induced by vaccination with plasmid DNA [28,29] (Figures 1 and 2). However, these first-generation DNA vaccines are suboptimal, as indicated by the frequency and magnitude of induced immune responses in humans, and by the demonstrations in multiple animal models of the potential of a number of immune enhancement strategies. In particular, prime-boost approaches involving priming with DNA and boosting with poxvirus or recombinant protein in adjuvant offer an excellent means of inducing protective antibody and T-cell responses of significantly greater magnitude than DNA vaccine approaches on their own [30].

The third approach is to develop a subunit vaccine that duplicates the whole-organism immunity induced by immunization with radiation-attenuated sporozoites or by natural exposure to malaria. Success in this area will be dependent on utilizing data from the malaria genome projects [31,32] and developing methods for exploiting this genomic sequence data. It remains to be established how such multiantigen vaccines will be constructed, but it is likely that DNA-based vaccines will be the core technology used for this approach.

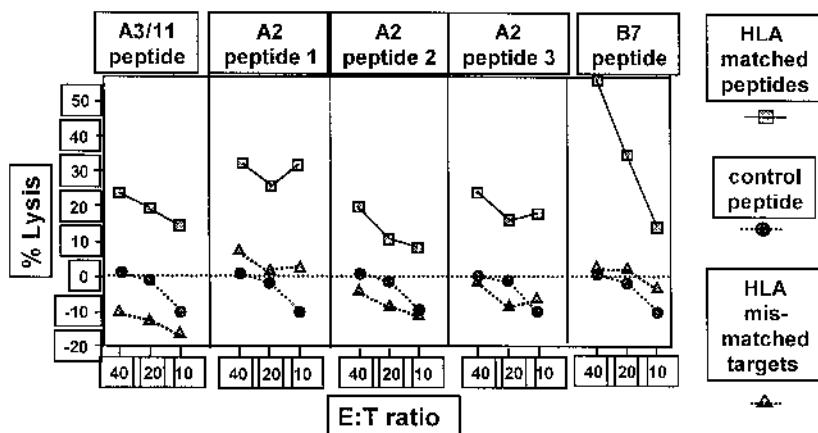

The fourth approach is to develop a practical nonreplicating, metabolically active (attenuated) *P. falciparum* sporozoite vaccine that provides the sustained greater-than-90% protection in humans that has been achieved by exposing volunteers to the bites of irradiated mosquitoes carrying *P. falciparum* sporozoites in their salivary glands [9]. Success of this approach will require development methods of practically producing sterile sporozoites, and demonstrating that administration in the skin, subcutaneous tissue, or muscle of the sporozoites by needle and syringe, or some other practical method provides protection.

## V. RATIONAL DESIGN OF SUBUNIT VACCINES

Although many approaches have been adopted by various laboratories for vaccine development, there is a rough consensus regarding certain principles for rational subunit malaria vaccine design.

### A. Consider Evolutionary Selection Pressures

Because of *P. falciparum*'s history of circumventing interventions through evolutionary change, designing vaccines which are minimally susceptible to the development of resistance should be a priority. Review of the history of malaria control reveals that despite the deployment of highly effective drugs (e.g., chloroquine, which enjoyed many years of 100% efficacy against all species of human malaria parasites in most tropical regions) and insecticides (e.g., DDT, which has had the greatest impact on malaria transmission to date of any specific intervention), malaria remains deeply entrenched in most tropical countries. This is because the basic reproduction rate (i.e., the number of individuals who will become infected if one infected individual enters an area with *Anopheles* mosquitoes) often far exceeds the minimum rate required to maintain the parasite's life cycle, thereby making it very difficult to interrupt transmission through control measures. This "excess" transmission also results in the potential for evolutionary change in the parasite and vector populations when selection pressures are applied through the application of drugs or insecticides. In other words, both parasite and vector populations can be dramatically reduced in numbers, yet still maintain transmission, allowing the emergence of resistant genotypes. For example, chloroquine resistance by *P. falciparum*, which probably originated independently at least four times [33], is now widespread and increasing, and is also expanding to *P. vivax* [34,35] and to *P. malariae* [36]. Studies of the *P. falciparum* genome highlight the genetic complexity of the organism and its potential for evolutionary

**Figure 1** DNA-induced CTL responses against the PfCSP are restricted by multiple HLA alleles. Fresh peripheral blood mononuclear cells (PBMCs) from a volunteer immunized with 500 µg PfCSP DNA, who expressed the alleles HLA-A2, -A3, and -B7, were assayed for antigen-specific, genetically restricted CTLs against PfCSP-derived peptides. The assay was repeated with coded frozen PBMCs that were collected before and after vaccination; the results confirmed that the peptide-specific (the same five peptides), genetically restricted CTLs were induced by vaccination with plasmid DNA. (From Ref. 29.)

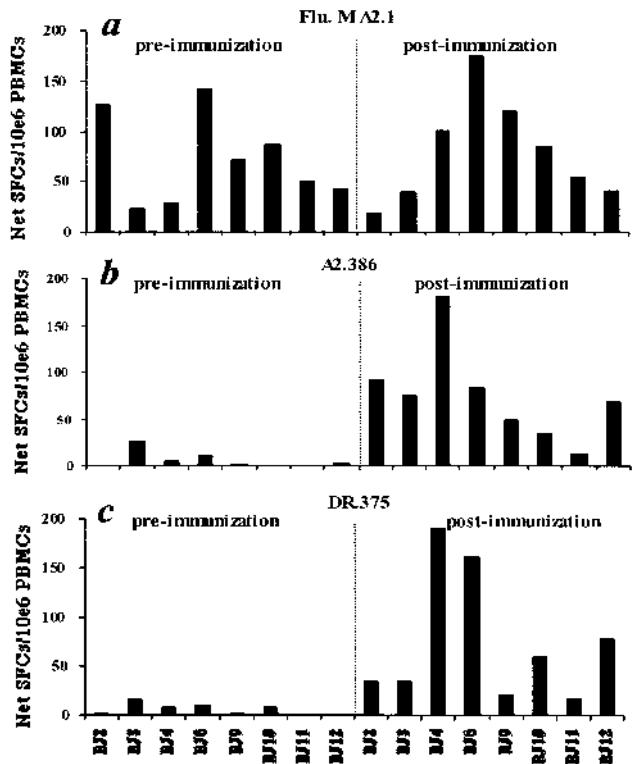

change [37]. It is imperative that vaccine developers consider the parasite's potential for evolutionarily "escaping" susceptibility to the immune responses induced by a vaccine, leading to lost efficacy of hard-won vaccine antigens. Vaccines targeting travelers may not exert significant selection pressures, because infections in this population would, in most cases, have little impact on within-country malaria transmission, and therefore would not contribute to the evolution of resistance to the vaccine by the parasite. However, widespread use of an effective vaccine in endemic areas favors the transmission of resistant genotypes.

### B. Define the Immune Responses to Be Induced by Vaccination

1. For irradiated sporozoite-induced immunity, protection is thought to be primarily mediated by T cells directed against peptide epitopes from parasite proteins expressed in infected hepatocytes (function-independent killing via elimination of infected host cells) (Figure 3). More specifically, CD8<sup>+</sup> T cells specific for parasite-derived peptide/class I MHC molecule complexes on the surface of infected hepatocytes [38] are considered the primary immune effectors, where elimination of the infected hepatocytes is mediated by interferon-gamma (IFN-γ) released by CD8<sup>+</sup> T cells (as well as other cells) and not by direct cytolysis of the infected hepatocyte by parasite-specific CD8<sup>+</sup> T cells [39,40]. Humans immunized with radiation-attenuated sporozoites [41–43] (Doolan, submitted) or naturally exposed to malaria [44–48] have been shown to have CD8<sup>+</sup> cytotoxic T lymphocytes and CD8<sup>+</sup> IFN-γ responses against pre-erythrocytic stage proteins. However, data regarding the importance of T cells in the immunity elicited by radiation-attenuated sporozoites come entirely from rodent experiments [39,40,49–53], in which T-

cell subsets were depleted or adoptively transferred. In rodent models, protection is absolutely dependent on CD8<sup>+</sup> T cells and IFN-γ, and often dependent on IL-12 and nitric oxide [39,40] (Fig. 3). Also, CD8<sup>+</sup> T cells eliminate *Plasmodium berghei*- or *Plasmodium yoelii*-infected mouse hepatocytes from in vitro culture in an MHC-restricted and antigen-restricted manner [38,54]. Nonetheless, CD4<sup>+</sup> T cells that recognize parasite-derived peptide/class II MHC molecule complexes on hepatocytes are also thought to play a role in sporozoite-induced protection, because the adoptive transfer of antigen-specific CD4<sup>+</sup> T cells can protect against sporozoite challenge [55,56], and depletion of CD4<sup>+</sup> T cells can eliminate protection in some strains of genetically inbred mice [40]. Finally, antibodies against sporozoite surface proteins, such as CSP, that neutralize the infectivity of sporozoites for hepatocytes (function-inhibiting activity) may also be involved [22,57,58]. Sporozoite-induced protective immunity is complex with a number of different cell types, cytokines, or chemokines potentially playing roles in a multifaceted and integrated fashion. Attempts to dissect this immunity using molecular immunology are underway. Other areas of uncertainty regarding sporozoite-induced protective immunity include the site of immune induction, the infected hepatocyte as the target of protective CD8<sup>+</sup> T cells, the infected hepatocyte as the antigen presenting cell (APC), the role of dendritic cells, macrophages, and other professional APCs, the mechanism of antigen processing and presentation, the mechanism for and factors influencing induction of long-term protective immunity, the requirement for persistence of antigen for induction of long-term protective immunity, and identification of appropriate in vitro correlate(s) of protective immunity.

In general, the immune responses induced by immunization with irradiated sporozoites are not as robust as those

**Figure 2** Antigen-specific IFN- $\gamma$  responses against the PfCSP induced by DNA vaccination. IFN- $\gamma$  responses against: (a) HLA-A2.1-restricted positive control peptide from influenza matrix protein (Flu. A2.1); (b) HLA-A2.1-restricted peptide from PfCSP (A2.386); or (c) HLA-DR-restricted peptide from PfCSP (DR.375) with coded and double-blinded frozen PBMCs collected from eight volunteers pre- and postimmunization with PfCSP DNA administered by Biojector® intramuscularly (BJ2, -3, and -4), by Biojector® intramuscularly and intradermally (BJ6, -9, and -10), and by needle intramuscularly (BJ11 and -1). (From Ref. 28.)

induced by subunit vaccination. We favor the hypothesis that irradiated sporozoite-induced protective immunity reflects the sum of many immune responses of low magnitude against multiple targets, where the low magnitude of response results from density of epitope presentation. However, there may be other explanations; a single or few "key" antigens could be responsible for the protection and are as yet unidentified.

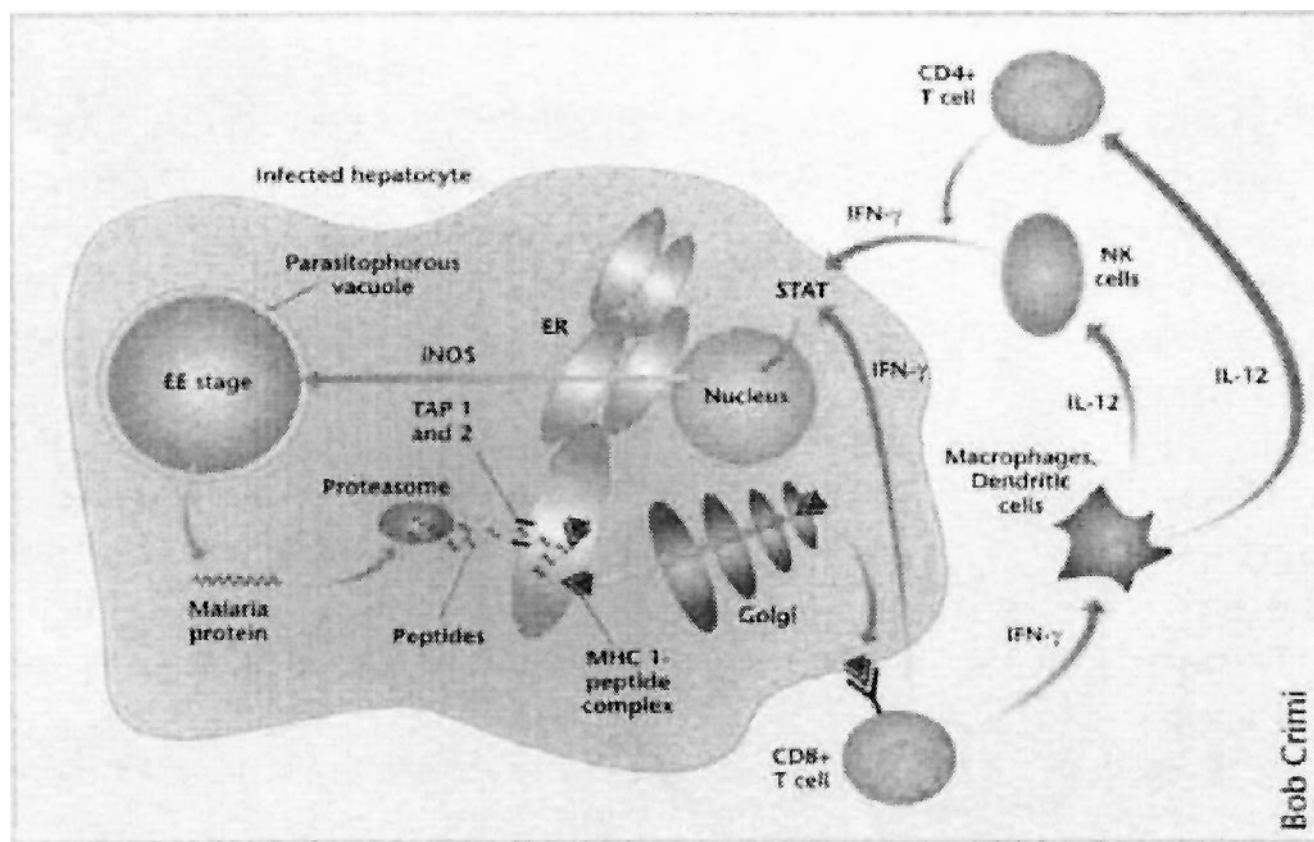

2. With regard to naturally acquired immunity, passive transfer experiments in humans indicate that antidisease/antiparasite immunity is mediated, at least in part, by antibodies against parasite proteins expressed on the surface of infected erythrocytes and merozoites and in merozoite apical organelles. Passive transfer of immunoglobulin derived from adults with naturally acquired immunity following lifelong exposure to endemic malaria rapidly reduced parasitemia and led to resolution of symptoms in parasitemic recipients [59–62]. Antibodies directed against parasite proteins ex-

pressed on the surface of erythrocytes that prevent sequestration in the microcirculation (function-inhibiting) [63], antibodies directed against parasite proteins expressed on the surface of merozoites that prevent invasion of erythrocytes (function-inhibiting) [64], and antibodies expressed against either type of parasite protein that are capable of mediating antibody-dependent cellular inhibition (ADCI) [65], whereby biologically active molecules, including cytokines, nitric oxide, and free oxygen intermediates are released from reticuloendothelial or other cells after activation through the Fc component of the bound antibody molecule (function-independent killing), are implicated. One such protein is *P. falciparum* erythrocyte membrane protein 1 (PfEMP1), which mediates cytoadherence and sequestration. Cytoadherence of infected erythrocytes to endothelial cells in the microcirculation during maturation of the parasite, thereby preventing removal of the infected erythrocyte in the spleen, is thought to be responsible for the microcirculatory obstruction important to the pathogenesis of severe disease. Biologically active molecules released from CD4 $^{+}$  T cells after an antigen-specific interaction also probably contribute to naturally acquired immunity. Furthermore, pathogenesis of the clinical disease [66–68] may be mediated by these same host-derived biologically active molecules, or by toxins released from the infected erythrocytes [68–70], and neutralization of these toxins via antibodies may contribute to naturally acquired immunity.

Finally, antibody responses against sporozoites as well as T-cell responses against parasite proteins expressed within infected hepatocytes also probably contribute to naturally acquired disease modulating immunity. By reducing the number of *Plasmodium* spp. parasites maturing within the host hepatocyte, these pre-erythrocytic stage protective immune responses would be expected to reduce the initial blood-stage parasite burden and consequently the magnitude of the subsequent asexual stage amplification. In both hospitalized populations and semi-immune populations, most investigators have demonstrated a direct correlation between *P. falciparum* parasite density and morbidity and mortality associated with *P. falciparum* infection [71–75].

### C. Identify the Antigenic Targets of Protective Immune Responses

The parasites causing malaria are more complex than the viruses and bacteria that heretofore have been controlled by vaccination, this complexity being reflected in their genetic make-up and their multistage life cycle. When *P. falciparum* sporozoites are inoculated into humans by *Anopheles* mosquitoes, they circulate extracellularly in the bloodstream for less than 30 min before entering the liver. Within the hepatocyte, a uninucleate sporozoite develops into a schizont with an estimated 10,000–40,000 uninucleate merozoites. These merozoites rupture from the hepatocyte and each can invade an erythrocyte, initiating the cycle of intraerythrocytic-stage development, rupture, and reinvasion that leads to a 10- to 20-fold increase in the number of parasites in the bloodstream every 48 hr. The asexual erythrocytic stage parasites are responsible for the clinical manifestations and pathology of malaria. Sexual erythrocytic stage parasites

**Figure 3** Proposed mechanism of protective immunity directed against the *Plasmodium*-infected hepatocyte. Protective immunity directed against pre-erythrocytic stage (EE stage) malaria is primarily mediated by antigen-specific CD8<sup>+</sup> T cells which recognize parasite-derived peptides presented in association with class 1 MHC molecules on the surface of infected hepatocytes. Short peptides are derived from the cytoplasmic malaria protein by the proteolytic action of proteasomes. The peptides are imported into the endoplasmic reticulum (ER) via the transporters associated with antigen processing, TAP1 and TAP2. In the ER, the peptides associated with the MHC class 1 molecule, and the peptide/MHC complex pass through the Golgi apparatus to the cell surface where they can be recognized by the T-cell receptor on the surface of CD8<sup>+</sup> T cells. IFN- $\gamma$  is produced as a direct consequence of the CD8<sup>+</sup> T-cell activation, and subsequent production of IFN- $\gamma$  may be upregulated by a positive feedback loop involving IL-12 (produced by dendritic cells, macrophages, or other cells), NK cells and/or CD4<sup>+</sup> T cells, depending on the host. IFN- $\gamma$ , via signal transducers associated with transcription (STAT), activates nitric oxide synthase (iNOS) and induces the L-arginine-dependent NO pathway to eliminate the infected hepatocyte or the intrahepatic schizonts. (From Hoffman SL, Doolan DL. Malaria vaccines-targeting infected hepatocytes. Nat Med 2000;6:1218–1219.)

(gametocytes) are ingested by mosquitoes and develop over a period of 14–21 days to sporozoites.

Elucidation of the genomic sequence of the *P. falciparum* parasite [31] and its proteome [76] reveals that *P. falciparum* has approximately 5400 genes [31]. In general, proteins expressed at each of the stages in the parasite life cycle are antigenically distinct. Thus, if a vaccine elicits protective antisporozoite antibodies, those antibodies will often fail to recognize asexual erythrocytic stage parasites. Furthermore, for many of the genes/proteins characterized to date, allelic or antigenic variation has been demonstrated, and a single individual can be infected simultaneously with at least eight different strains [77] that may vary at critical T- and B-cell epitopes. This allelic heterogeneity is expanded by extensive antigenic variation present within a single isolate. PfEMP1 is

encoded by 59 different genes in the sequenced 3D7 isolate of *P. falciparum*, each with some variation in its sequence [31]. The parasite likely expresses only one at a time, each new variant escaping from antibodies induced by the previous variant and therefore capable of generating a new wave of parasitemia.

In summary, the large number of parasite proteins, stage-specific expression of proteins, the presence of multiple antigenically distinct strains in nature, and within-strain antigenic variation are critical to the parasite's survival; these factors are also unfavorable for the host and greatly complicate the challenge for vaccine developers. Nonetheless, the malaria genome project [31] and the single nucleotide polymorphism (SNP) projects currently nearing completion may provide knowledge of all potential targets and

their variability at the epitope level, thereby laying the foundation for duplicating whole-organism immunity with subunit vaccines.

#### D. Select the Antigenic Target(s)

Antigens meeting the following criteria are likely to be good candidates for inclusion in a vaccine.

1. Accessibility to the immune system due to expression on the surface of free parasites or on the surface of infected host cells, with characteristics thought to be critical for induction of protective immunity (e.g., T-cell epitopes for vaccines to induce cellular immunity, secondary structures, and transmembrane domains for antibody vaccines). There is no algorithm that can be used to identify the targets of protective antibody or T-cell responses from genomic sequence data. In the case of antibody responses, one approach has been to focus on predicted surface or secreted molecules presumably accessible to antibody. In the case of T-cell responses, the subcellular location and function of the target protein are important as well as the presence of appropriate MHC binding epitopes in the sequence. Therefore, in order to select appropriate vaccine target candidates, one approach is to identify stage-specific expression of proteins encoded by all open reading frames (ORFs) from the genomic sequence and to determine subcellular localization of the proteins at least to the level of distinguishing between cytoplasmic, surface, and secreted organellar proteins.

2. Conserved antigenic structure among diverse strains (reduced chance of evolutionary “escape”).

3. Mediation of critical biological functions. The assumption is that as long as the role played by a target antigen in the functioning of a critical molecular pathway, such as host cell invasion [78], depends on the molecular structure of the target antigen, and as long as that structure constrains the variability permissible in the peptide sequence (in the case of T-cell responses) or the epitope specificity (in the case of antibodies) of the target antigen, the parasite will be evolutionarily restricted. In other words, mutations that allow escape from the immune response via alterations in amino acid sequence would also necessarily negate biological function, selecting against such escape mutants. Antigens derived from “low complexity regions,” such as the tandem repeats present in many parasite molecules, might be poor choices in that these rapidly evolving nonglobular domains are thought to be nonessential for protein function [79]. There must be cognizance that critical biological functions may possess redundant pathways (e.g., nine distinct receptors on endothelial surfaces and four on uninfected erythrocytes mediate binding of *Pf*-parasitized erythrocytes [80]), and that each pathway must be simultaneously blocked to achieve the desired vaccine effect.

4. Elicitation of protective responses in animal models. It is a reasonable assumption that the *P. falciparum* orthologs of murine or simian malarial antigens shown to be protective in animal models will be good candidates for a human vaccine.

5. Antigens containing promiscuous epitopes recognized by superfamilies of HLA alleles. Such antigens provide

broader population coverage for eliciting genetically restricted T-cell responses [81].

6. Compatibility with other antigens in the mixture. This question—compatibility of antigens combined into a cocktail—is potentially a major issue in vaccine design (see E(6) below).

#### E. Determine the Number of Antigenic Components to Include in a Vaccine

Neither of the two human models described above, the irradiated sporozoite vaccine nor natural exposure to malaria, elicit immune responses of great magnitude, suggesting that immune responses against many parasite proteins are responsible for protection. Modest immune response against multiple parasite proteins may be additive or synergistic. Preliminary data (Doolan et al., submitted) support this contention. It is likely that a multiantigen vaccine will be required to produce comparable protective immunity.

The most advanced candidate malaria vaccine, RTS,S, consists of a recombinant fusion protein of a portion of the *P. falciparum* circumsporozoite protein (CSP) with the surface protein of hepatitis B. This vaccine consistently protects 40–50% of volunteers against experimental challenge for a period of at least 2–3 weeks after last immunization [19,20] and protected 70% of adult, lifelong residents of endemic areas from parasitemia for a period of up to 2 months [21]. If the magnitude and duration of protection could be increased, the simplicity of a single protein vaccine would make this any extremely attractive vaccine. However, there are significant potential limitations associated with a univalent vaccine.

1. Improved efficacy: Combining antigens, each with a partially protective effect, should synergize to improve overall vaccine efficacy [82], provided that they do not interfere with each other. However, few systematic experiments have been conducted to determine whether more antigens are better than a few. In the *P. yoelii*-rodent model, combining two antigens given as DNA vaccines (PyCSP and PyHep17) [82] and combining two antigens (PyCSP and PySSP2) given as recombinant tumor cells conferred additive protection [83]. In the *P. knowlesi*-rhesus model, protection has been demonstrated by immunization with four antigens (two pre-erythrocytic and two erythrocytic) in heterologous DNA prime/virus boost vaccination regimens [84,85], but the protection of the tetravalent vaccine has not been dissected to determine the relative role of the individual components. It will not be easy to determine in humans if adding antigens improves protection.

2. Genetic restriction of the host immune response: Cell-mediated immune responses directed against T-cell epitopes are genetically restricted; the genetic background (MHC haplotype) of the vaccine recipient determines which epitopes can bind to MHC molecules, interact with the T-cell receptor, and be recognized by vaccine-induced T cells. Immune responses directed against a single epitope will generally be insufficient to protect hosts with different MHC types, and sufficient numbers of T-cell epitopes derived from one or more antigens and recognized in the context of multiple

genetic restrictions must be included in a vaccine to protect individuals of all genetic backgrounds. Using DNA vaccines, it has been shown that epitopes from multiple antigens are required to elicit a high degree of protective immunity against *P. yoelii* parasite challenge in genetically distinct inbred mice [82]. Multivalent vaccines can circumvent the problem of genetic restriction by increasing the likelihood of "offering something for everyone" [86,87].

3. Parasite heterogeneity: Many *P. falciparum* genes exhibit antigenic heterogeneity; a malaria vaccine may require several forms of these proteins to protect against all *P. falciparum* strains. This may stem from allelic heterogeneity at a single locus (e.g., there are two major antigenic families of the leading blood-stage antigen merozoite surface protein-1, MSP1 [88]), or from the presence of multiple copies of a single gene. The best example of the latter is the *var* (variable) gene family [63], which encodes PfEMP1, a molecule expressed on the surface of infected erythrocytes that mediates their adhesion to endothelial cells. Fifty-nine [31] members of this family are present in the 3D7 *P. falciparum* genome, each encoding an antigenically variant molecule. Variant forms are expressed sequentially on the surface of infected erythrocytes, with each newly expressed variant allowing escape from immune responses generated against the previously expressed variant, resulting in recurring waves of parasitemia. For immune responses PfEMP1 is a natural target, but a vaccine would have to include all members of the family or else employ conserved domains of the molecule. With regard to the pre-erythrocytic stage, it has been demonstrated that CSP polymorphism primarily maps to identified CD8<sup>+</sup> and CD4<sup>+</sup> T-cell epitopes [89], and cytotoxic T-lymphocyte (CTL) responses to some variants do not cross-react [90–92], suggesting that polymorphism has been evolutionarily selected to allow parasite evasion of host immunity [93]. In African children with malaria, the CTL epitope variants present may be influenced by the presence of an HLA type that restricts the immune response to the epitope [86]. In the same individuals, these variants can lead to the inhibition or impairment of CTL responses by altered peptide ligand antagonism. Variant epitopes may narrow the CTL repertoire by interfering with T-cell priming [92].

4. Stage-specific antigen expression: Stage-specific expression of many malaria parasite antigens indicates that to protect against both pre-erythrocytic and erythrocytic stages of the parasite, vaccines must include antigens which are expressed at each of these stages. Moreover, as also discussed above, it is likely that even within one stage of the life cycle, many antigens will be needed to confer protection.

5. Evolution of resistance: If the protection afforded by each antigen in a vaccine is independent of that afforded by others, a multivalent vaccine provides insurance against the evolution of resistance by the parasite. The likelihood that spontaneous mutations would simultaneously circumvent *multiple* immune responses is low (the product of the individual likelihoods if protective effects are truly independent).

6. Downsides to multiantigen formulations include interference among antigens, as well as issues associated with dose reduction for each component relative to single-antigen formulations. Current formulations of DNA vaccines

are limited to approximately 4 mg/mL of solution, resulting in a several fold dose reduction for each component of a multiplasmid cocktail as compared with the concentration achievable if each component were formulated separately. Furthermore, interference and dose reduction significantly reduce immunogenicity of vaccine components, potentially negating the advantages of a multicomponent vaccine. To avoid this, careful selection of antigens is needed. This can be accomplished by "subtraction experiments," in which a full cocktail is tested for immunogenicity against the same cocktail minus one of its components. If all combinations are assessed, it may be possible to identify suppressive antigens that can be removed, partially or completely restoring the immunogenicity of the remaining antigens (Sedegah, submitted). However, because these mixing studies can be only performed in mice or other small animal models (requirement for large numbers) and immunogenicity but not protection can be assessed (because of the unnatural host-parasite combination), it is uncertain as to whether these studies actually predict compatible antigen mixtures for humans.

#### F. Select Vaccine Delivery Systems that Induce Required Immune Response(s) Against Identified Target(s)

A major challenge is how to induce the appropriate responses against each antigen included in a vaccine. A range of subunit vaccines based on whole gene/protein (all epitopes) and partial gene/protein (defined epitopes; multiple epitopes) have been considered, including recombinant proteins, linear synthetic peptides, multiple antigen peptides, recombinant or attenuated viruses/bacteria, plasmid DNA, and replicons. Exposed parasite targets, such as proteins on the surface of extracellular sporozoites, merozoites, gametes, and ookinetes, and on the surface of infected erythrocytes are amenable to neutralization by antibodies, as demonstrated by antibody-mediated in vitro assays, and by the effectiveness of IgG infusions in humans for resolving the symptoms of blood-stage infection and for reducing parasitemia. Destruction of intracellular parasites such as those in infected hepatocytes and infected erythrocytes relies primarily on cell-mediated responses. Certain adjuvants may direct the response appropriately, but the challenge of how to direct immune responses toward antibody production for some antigens and T-cell responses for others, when the antigens are mixed together in a cocktail, has not been solved. Approaches include splitting the vaccine into liver-stage and blood-stage formulas that are injected into separate sites, or trying to induce both cellular and antibody responses to all antigens in the cocktail. Other considerations include route of immunization, dose, and kinetics of response. The choice and validity of animal models in preclinical studies (mice, rhesus monkeys, *Aotus* monkeys, cynomolgus monkeys, etc.) also warrant attention. A major obstacle to adopting the "right kind" of immune response is that as yet, there is no established specific immunological correlate of immunity. Finally, for a vaccine to be optimally effective it must elicit

protective immune responses that are sustained over time, either due to vaccine administration or boosting by exposure to parasites. Progress has been made, but no delivery system has been shown to be optimal or adequate for delivering the multiple antigens likely required to induce immune responses comparable to those elicited by natural exposure to parasites or by the irradiated sporozoite vaccine.

## VI. WHOLE, ATTENUATED PARASITE VACCINE DEVELOPMENT

The only proof thus far of significant, sustained protection against malaria in humans comes from immunization of humans with the whole parasite, irradiated sporozoite vaccine, and naturally acquired immunity. Nonetheless, there has been little to no effort expended on developing an attenuated parasite vaccine during the past 20 years. It was deemed impractical (or impossible) to develop such a vaccine, and with the advent of monoclonal antibodies and molecular biology, it was generally considered not necessary. However, given the difficulty in producing effective subunit vaccines, and the general consensus in the field of how long it will take to launch such vaccines [94], we are now focusing efforts on developing an attenuated (nonreplicating, metabolically active) *P. falciparum* sporozoite vaccine that is expected to completely prevent all manifestations of infections in nonimmune travelers and military personnel, and reduce severe morbidity and mortality in infants and children in Africa.

## VII. THE CHALLENGE OF DESIGNING AND EXECUTING FIELD TRIALS OF MALARIA VACCINES

It will be critical to consider which outcome variables to measure in field trials of malaria vaccines, and which population groups to study. For vaccines designed to prevent asexual erythrocytic stage infections and thereby prevent all clinical manifestations of malaria, clinical trials are quite straightforward to design. However, for vaccines not expected to prevent infection in all recipients, but expected to prevent severe disease and mortality, trials will be more difficult and much larger. There is a potential problem that a vaccine may be discarded as a result of initial studies because the proper outcome variables were not measured. It will be difficult to use severe disease and death as the primary outcome variables in initial studies, because of the very large sample sizes required. It is important to identify groups at highest risk so that sample sizes can be reduced. Current investigations seek to identify surrogates of severe disease and death: parasitological, hematological, biochemical, or clinical manifestations that are predictive of severe outcome.

Several other areas of field research could provide data to help vaccine development. The most important area is the identification of target groups for vaccines in different areas (see above) and the exclusion of groups, like those with sickle-cell trait, who are at decreased risk and do not need to be immunized. It is important to determine if there are measurable outcome variables that have a high predictive

value for severe disease- and malaria-associated mortality. The impact of bed-nets and other interventions on epidemiology and the age-specific attributable reduction in mortality must be assessed. More data are needed on the effects of radical cure (elimination of all parasites from the body) on host protective and clinical immunity so as to design trials better. Better assays are needed for predicting protective immunity, involving more detailed characterization of the proteins and epitopes on these proteins involved in protective immunity.

## VIII. FUTURE PROSPECTS REGARDING MALARIA VACCINE DEVELOPMENT

The human models (attenuated sporozoite and naturally acquired immunity) indicate that the development of a malaria vaccine is feasible. An intense effort at making the attenuated sporozoite vaccine practical may prove to be the most direct route to a licensed, deployed malaria vaccine, but several years of studies will be required to prove the principle that this approach is feasible. However, genomics, proteomics, molecular biology, molecular immunology, vaccinology, population genetics, population biology, and quantitative epidemiology have created great expectations for the development, licensing, and deployment of effective malaria vaccines. It will be a formidable task to determine which antigens/epitopes from specific stages of the life cycle are required for sustainable protection, how to measure immune responses that predict protection, which vaccine delivery systems are optimal, who and when in life to immunize, and how to establish surveillance systems able to assess the true impact of a malaria vaccine on public health. At a recent scientific meeting [94], scientists, many of whom have devoted their careers to malaria vaccine development, were polled as to when they thought a vaccine might be launched. Responses ranged from 7 to 25 years. We believe that the next 7–25 years will bear witness to the development of effective malaria vaccines, and that these will be used to control the effects of the disease worldwide and, when combined with other interventions, will be able to eradicate malaria from many areas.

The importance, difficulty, and cost of this task must not be underestimated. We are still far from controlling the enormous suffering and loss of life caused by malaria. Every day, 2500–8000 children die of malaria, and no research finding during the past 25 years in molecular biology, cell biology, genomics, immunology, vaccinology, or protein chemistry has resulted in the saving of a single life from malaria. We believe that the development of malaria vaccines will be crucial to the successful, widespread control of malaria.

### **I. INTRODUCTION AND LIFE CYCLE OF PLASMODIUM**

Humans are the definitive host of four plasmoidal species that cause malaria: *Plasmodium falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*. The four species exhibit differences in their periodicity of paroxysms (chills, fever) because of differences in replication time in the red blood cell, preferences for different aged erythrocytes, and different geographical distributions. *P. falciparum* infection is the most dangerous as it can cause life-endangering complications such as cerebral malaria and severe anemia.

Infection begins when a female mosquito of the genus *Anopheles* takes a blood meal from a host (e.g., a human). When a mosquito feeds, she injects an anticoagulant from her salivary glands into the subcutaneous tissue and less frequently the blood stream; this is normally accompanied by injection of the sporozoite stage of the parasite if the mosquito is infected. The sporozoites then invade the liver and form the nonpathogenic pre- or exo-erythrocytic schizont stage. During this time (5–15 days), the parasite grows and multiplies, resulting in the lysis of the infected hepatocyte and the release of thousands of merozoites. One exo-erythrocytic schizont may contain 10,000–30,000 merozoites [1a]. During the next stage of development, the merozoites target the red blood cells (RBC) for invasion, and once inside become an erythrocytic trophozoite, which ingests and digests hemoglobin and asexually multiplies to become an

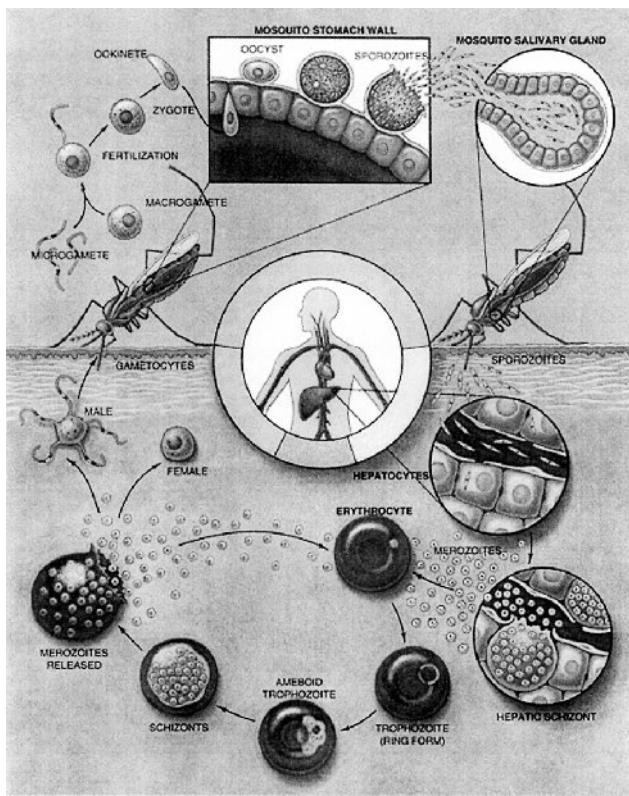

erythrocytic schizont. Two to three days after entry into the RBC (depending on the species of *Plasmodium*), 6–24 new merozoites are released upon rupture of the cell and rapidly invade new blood cells. This asexual reproductive cycle is repeated several times. It is this repeated cycle of multiplication that causes the symptoms of malaria including the periodic fever initiated by the release of pyrogens when infected red blood cells burst.

The red blood cell stage is the phase of exponential growth of the parasite within the host. As the life cycle starts with so few parasites and the number of red cells is so large, it takes several days of parasite multiplication (the prepatent period) before parasites can be detected by microscopy. More sensitive detection methods (e.g., polymerase chain reaction, PCR) can detect parasites in the blood before they can be microscopically detected [1].

Some asexual parasites differentiate into gametocytes, the sexual form of the parasite, which mature to extracellular gametes in the midgut of another female mosquito. This is followed by fertilization of the gametes, producing a zygote, which becomes a motile ookinete that burrows into the midgut wall, encysts on the outer surface, and becomes an oocyst. Within the oocyst, the sporozoites develop and are shed into the insect's hemocele and migrate to the salivary glands.

All malaria parasites have a similar life cycle (Figure 1), with some exceptions. The prepatent period for malaria varies from species to species; it can be as short as 9 days, but typically 12 (*P. falciparum*) to 30 days (*P. malariae*) from the time of initial infection. *P. vivax* and *P. ovale* differ from *P. falciparum* in their ability to cause true relapses as the sporozoites are able to lay dormant in liver stages (such resting stages are known as hypnozoites), and become active

\*Current affiliation: National Institutes of Health, Rockville, Maryland, U.S.A.

**Figure 1** The life cycle of the malaria parasite. (From Ref. 141.)

at a later stage, releasing merozoites months after the initial infection. This is in comparison with *P. malariae*, which can remain dormant in the blood for years, without causing any sign of disease, but may suddenly cause clinical symptoms. This reappearance of parasite is known as a recrudescence.

Four species of parasites that can infect rodents, *P. yoelii*, *P. berghei*, *P. chabaudi*, and *P. vinckei*, are frequently used to model human disease. Although they are not exact replicas of the human situation, the rodent parasite models allow examination of the interactions between the hosts' immune system and the different stages of the parasite. They are used in concert with different rodent strains, with the combinations resulting in different disease patterns [2]. The rodent malaria parasite spends only 24 hr within each red blood cell. This may in part explain the higher parasite densities observed in the blood of rodents compared with those in humans [3].

## II. VACCINE APPROACHES AND DESIGN

There have been numerous vaccine success stories with smallpox eradication and the virtual elimination of polio being the best examples. However, the development of a malaria vaccine is a major challenge. The parasite's complex biology contributes to this, with the parasite existing in different forms in different tissues and in the mosquito (Figure 1). Different stages of the parasite express different

antigens (stage-specific antigens) and many of these exhibit degrees of antigenic polymorphism. For each stage, different vaccine strategies must be employed. An alternative approach is the multicomponent vaccine, which involves either combining antigens from the various life cycle stages (multistage vaccine) or combining multiple antigens from a single life cycle stage (multivalent vaccines). Other hurdles to overcome include immunological nonresponsiveness to vaccine antigens (especially low molecular weight antigens), heterogeneity of the human immune response as determined by HLA type, the technological hurdles encountered in folding recombinant antigens, and the lack of potent adjuvants for use in humans.

Although the possibility of developing live-attenuated vaccines for malaria has been discussed, logistical problems have focused malaria vaccine development on the subunit approach. This review will discuss different strategies being taken to develop a blood stage malaria vaccine. However, it is critical to properly understand the nature of malaria immunity before considering vaccine strategies. Immune mechanisms are the least understood for the blood stage of malaria, responsible for all the symptoms and pathology, and present the greatest challenge.

Because the parasite density in blood is generally proportional to disease severity, a vaccine must limit parasite density. It may not be necessary to induce sterile immunity (complete eradication of parasites) but this may be possible and would be advantageous as it would prevent parasite transmission from infected humans to mosquitoes. However, it is worth considering the immune state of adults living in malaria endemic regions. They have nonsterile clinical immunity characterized by low-density parasitemia and absence of clinical symptoms. This type of immunity may ultimately be a more realistic and achievable goal.

## III. THE ACQUIRED SPECIFIC IMMUNE RESPONSE AGAINST MALARIA

Specific immune responses induced by infections with *Plasmodium* spp. provide protection against the consequences of subsequent infections. Naturally acquired immunity to the malaria parasite requires years of exposure in an endemic region, presumably as this allows the development of antibodies to multiple parasite strains and continual boosting of existing immune mechanisms. Although highly effective immunity is slow to develop and not sterilizing, recent studies in Kenya have shown that some protection against severe disease is provided by a single *P. falciparum* infection [4]. Two separate types of antimalarial immunity can be distinguished: immunity that limits parasite development (antiparasite immunity); and immunity to disease-causing parasite "toxins" (antitoxic immunity) [5,6].

### A. Antiparasite Immunity

#### 1. Antibodies

Although parasite density is not a precise predictor of the clinical consequences of infection, the acquisition of im-

munity in children living in endemic areas is associated with a very significant reduction in mean densities of asexual blood-stage parasitemias. Thus the mean density of parasitemias in 5–9 year olds living in the Wosera region of Papua New Guinea is <20% of the mean density of 1–4 year olds in the same communities and the older group of children suffer little malaria morbidity [7]. Much information has accumulated about the nature of immune effector mechanisms that inhibit parasite development, either in vitro or in human and animal hosts, but there is no consensus concerning the nature or the specificity of the immune effector mechanisms responsible for limiting the development of asexual blood-stage parasites in semi-immune individuals living in endemic areas.

Antibodies clearly have a role in antiasexual blood-stage immunity in humans and the transfer of immunoglobulins from immune adults to infected children results in a significant decrease in the density of parasitemias in the recipients. Such antibodies may directly act, either by preventing merozoite invasion of host erythrocytes or by blocking cytoadherence of infected erythrocytes to vascular endothelium, and thereby increasing the likelihood of clearance by phagocytic cells in the spleen. Alternatively, antibodies may indirectly act as mediators of cellular effector mechanisms. Druilhe and colleagues have provided extensive evidence that a process of antibody-dependent cellular inhibition (ADCI), where antibodies to merozoite antigens activate monocytes to kill intra-erythrocytic parasites, is a major effector mechanism regulating the density of asexual blood-stage parasitemias [8,9]. Although studies with *P. falciparum* in vitro have shown that human antibodies can inhibit parasite development in the absence of effector cells the unusual bias towards cytophilic IgG isotypes in the human antibody response to a number of merozoite surface antigens is consistent with the operation of antibody-dependent cellular effectors [10]. Studies in animal models, particularly using rodent parasites and in-bred strains of mice, have provided much evidence that both antibody and non-antibody effector mechanisms limit the development of asexual blood-stage parasites.

## 2. Cell-Mediated Immunity

Cell-mediated immunity (CMI) generally refers to CD4<sup>+</sup> T cells acting in the absence of antibody to limit parasite growth. A number of studies elegantly showed that CMI can be effective in controlling parasite growth [11–13]. CD4<sup>+</sup> T cell lines and clones can limit or eradicate parasites following adoptive transfer [14–16].

CD4<sup>+</sup> T cells are thought to exert their antiparasite effect in the spleen following processing of parasites by antigen-presenting cells and ending with the death of parasites following phagocytosis and via inflammatory molecules such as oxygen and nitric oxide radicals [15,17,18]. Cell-mediated immunity is regulated by interleukin 12 (IL-12) and involves interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α) [17–19]. Although most data has been generated in the mouse, it has recently been shown that humans can be immunized by exposure to ultralow doses of parasites and that in this situation immunity is apparently entirely

mediated by CMI (involving IFN-γ and upregulation of nitric oxide synthase) and the complete lack of any detectable antibodies [20].

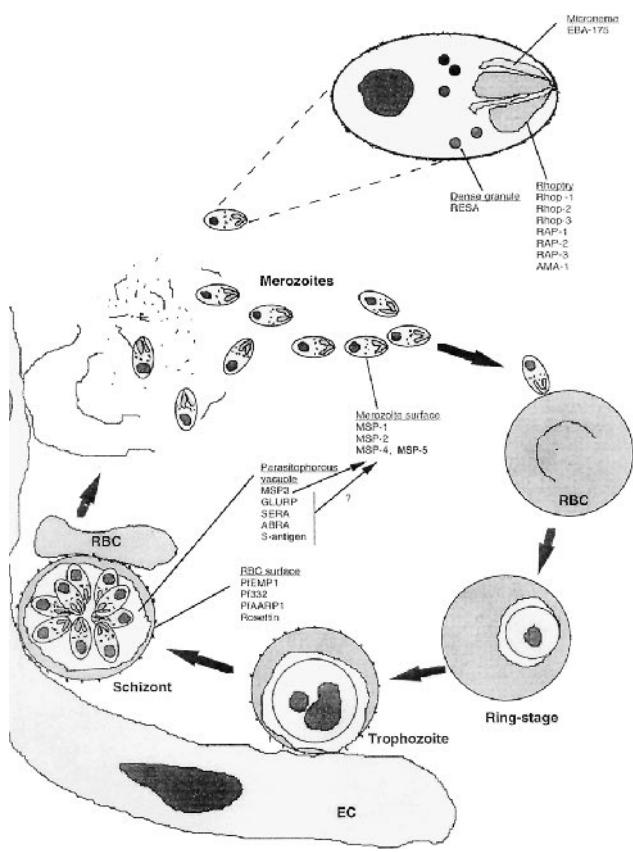

γδ T cells (expressing γδ receptors) may also play a role in immunity and may act independently of CD4<sup>+</sup> T cells and antibody [21,22]. Although protective CMI can be induced in both mice and humans, the role of CMI in natural immunity to malaria is much less clear. A number of studies have examined the impact of human immunodeficiency virus (HIV) on malaria severity and prevalence as a means to ascertain the role of naturally occurring CMI. The greatest impact of HIV is on pregnancy-associated malaria (PAM). The human immunodeficiency virus delays the development of immunity to PAM. The evidence that HIV affects CMI to malaria is less convincing. This has recently been summarized and discussed [23].

## B. Antitoxic Immunity

Exposure to infection induces immunity to the toxic effects of asexual blood-stage parasitemias more rapidly than to the parasite itself so that after some exposure children in endemic areas will remain asymptomatic despite having parasitemias that would cause severe disease in malaria-naïve individuals. Tumor necrosis factor-α plays a central role in the pathogenesis of severe malaria [24–26] and there is considerable evidence that the glycosylphosphatidylinositol (GPI) anchor released from merozoite surface proteins, such as MSP1 and MSP2, induces the release of TNF-α from monocytes [27]. This GPI structure is conserved across more than 20 geographically distinct isolates of *P. falciparum* examined so far [28]. Monoclonal antibodies specific for malarial GPI can neutralize the production of TNF-α and nitric oxide in response to whole parasite extracts [29] and a synthetic vaccine based on the GPI of *P. falciparum* successfully immunized mice against *P. berghei* ANKA infection [6] and prevented cerebral malaria and respiratory distress syndrome. An antidisease vaccine such as the synthetic GPI vaccine trialed in mice, which induces immune responses that neutralize the TNF-α-inducing activity of these GPI moieties, could be highly effective at reducing the incidence of severe morbidity. However, a vaccine that does not limit parasite development will be difficult to evaluate and test in preclinical and clinical human vaccine trials.

## IV. VACCINE CANDIDATES ON THE MEROZOITE

There are essentially three groups of antigens associated with the merozoite, and all have been identified as potential vaccine candidates (Figure 2). The first group is found on the merozoite surface, including merozoite surface proteins. To date, eight different *P. falciparum* MSPs designated MSP1–MSP8 have been described [10,30–36]. The second group includes soluble proteins including the serine repeat antigen (SERA). The third group consists of proteins in the apical organelles and includes apical membrane antigen 1 (AMA-1) and the rhoptry associated proteins, RAP1–RAP3.

**Figure 2** Subcellular localization of *P. falciparum* erythrocytic stage vaccine antigens. (Modified from Ref. 142.)

### A. MSP1

Merozoite surface protein 1 (MSP1) is a 185–220 kDa glycoprotein (depending on the parasite species) found on the surface of the free merozoite and is synthesized during schizogony. The function of MSP1 is still unclear, but it is thought that the intact unprocessed protein may be involved in the initial recognition of the erythrocyte and attachment to receptors on the red cell surface [37,38]. As these proteins are found on the surface of the parasite, their exposure to the hosts' immune system makes them a target of the immune response.

Upon merozoite release from the rupturing erythrocyte, the high molecular weight precursor is proteolytically cleaved into four smaller fragments (MSP1<sub>83</sub>, MSP1<sub>30</sub>, MSP1<sub>38</sub>, and MSP1<sub>42</sub>) that form a noncovalently associated complex held together by the 42-kDa fragment on the surface of the merozoite [30]. Just prior to invasion of a new RBC, a secondary proteolytic processing step, which is critical for invasion, occurs with the 42-kDa carboxyl terminal fragment cleaved into a 19-kDa fragment (MSP1<sub>19</sub>) and a 33-kDa fragment (MSP1<sub>33</sub>) [39,40]. MSP1<sub>33</sub> is shed with the other fragments forming the complex [41], while MSP1<sub>19</sub> remains on the surface of the merozoite and is the only part of MSP1 carried into the RBC [42].

Antibodies raised against MSP1 could work in a number of ways: neutralization by agglutination or opsonization of merozoites, prevention of invasion of the red blood cell, or inhibition of the growth of the parasite within the red blood cell. Parasite-specific antibodies may act by binding to a portion of MSP1 (MSP1<sub>19</sub>) on the surface of the merozoite thereby blocking invasion of the RBC [42]. Alternatively, they may prevent a crucial processing step of the protein. For example, the secondary processing step of MSP1 to MSP1<sub>19</sub>, thought to be critical for initiation of the invasion process [43], can be inhibited by specific antibodies. Recently, a class of blocking antibodies have been identified that act in the parasite's favor. Anti-MSP1 monoclonal antibodies have been identified that compete with the binding of processing-inhibiting antibodies to their epitopes [44,45]. Additionally, it was shown that naturally acquired antibodies in humans specific for a region within the N-terminus of MSP1 could block the ability of an anti-MSP1 monoclonal antibody to inhibit the processing step [42,44,46]. The potential for these blocking antibodies to interfere or even abolish protection induced by immunization or infection cannot be underestimated. To this end, mutant forms of recombinant MSP1<sub>19</sub> have been designed that are no longer recognized by known blocking antibodies but retain the structure necessary for immune recognition [45].

MSP1 shows much promise as a vaccine candidate. Studies involving MSP1 purified from *P. falciparum* showed partial or complete protection following challenge in primates [47,48]. Additional studies using recombinant proteins produced similar results [47,49].

The structure of MSP1 is critical for the protein's antigenicity and immunogenicity. Various expression systems for the production of recombinant protein have been utilized in an effort to maintain correct conformation. Recombinant MSP1 has been produced using bacterial [50], mammalian [51], baculovirus [52,53], and yeast systems [54,55].

It is the C-terminus of this molecule, from which MSP1<sub>19</sub> is derived, that has been the focus of most attempts to elucidate the immune response to this molecule. MSP1<sub>19</sub> is cysteine-rich and contains two epidermal growth factor (EGF)-like domains [56]. The native conformation is dependent on the correct formation of multiple disulfide bonds within each domain. Reduction and alkylation of these disulfide bonds in recombinant MSP1 or MSP1<sub>19</sub> abolishes or greatly reduces the recognition by polyclonal and monoclonal antibodies [57–59]. Most of the antibody-binding sites in MSP1<sub>19</sub> appear to be conformation dependent requiring both EGF-like motifs for the formation of the dominant epitopes [60].

Studies using the rodent model of malaria have shown that protection induced by MSP1<sub>19</sub> immunization is MHC restricted, correlating with genes present in the H-2 loci [61]. T cells from C57BL/6 (H-2<sup>b</sup>) and BALB/c (H-2<sup>d</sup>) mice immunized with MSP1<sub>19</sub> proliferate in response to different regions within MSP1<sub>19</sub>, indicating they recognize different T cell epitopes [62]. In addition, C57BL/10 (H-2<sup>b</sup>) and BALB/c (H-2<sup>d</sup>) mice are protected when immunized with GST-MSP1<sub>19</sub> expressed by *Escherichia coli* while B10.BR (H-2<sup>k</sup>)

mice are not [61]. This appears to reflect the level and type of antibody present at the time of challenge.

High-titer MSP1<sub>19</sub>-specific antibodies present in the serum of the mice are required at the time of challenge for protection [61,63–65]. These specific antibodies do not function via Fc-mediated interactions as evidenced by the ability of passively transferred antibodies to reduce parasite burden in Fc-receptor-deficient mice [66,67]. It was further found that vaccination of B cell deficient mice with MSP1<sub>19</sub> did not result in protection [65] nor could adoptively transferred CD4+ T cells, specific for defined MSP1<sub>19</sub> T helper epitopes, protect normal mice [62]. This not only emphasizes the vital role for MSP1<sub>19</sub>-specific antibodies but it also suggests that the antibody-mediated parasite clearance is not reliant on antibody-dependent cell-mediated cytotoxicity and Fc-mediated phagocytosis.

Although it has been shown that antibodies are required at the time of challenge to reduce parasite density, high titer passively transferred MSP1<sub>19</sub> antibody is unable to completely eradicate parasites from mice lacking a functional immune system [68]. It is apparent that even in the presence of high-titer antibody, a complete immune response including B cells and CD4+ T cells is required for protection in mice. The high-titer MSP1<sub>19</sub> antibodies most likely act to reduce the parasite burden, providing the recipient time to mount a protective immune response independent of the vaccine [23]. Whether this reflects the situation in humans following vaccination with MSP1<sub>19</sub> is yet to be determined.

The relevance of MSP1 to human malaria has been shown by longitudinal studies, which demonstrate that reduced susceptibility to clinical malaria is associated with elevated antibody levels and T-cell proliferative and cytokine responses to the C-terminal region of MSP1 [60,69,70]. T cell epitopes have been identified in both the conserved [71,72] and variant regions [73] of MSP1<sub>19</sub>.

MSP1 has been included in a number of combination antigen human vaccine trials [74,75,77] with varying degrees of success. Yet, MSP1 remains one of the leading malaria vaccine candidates with varied forms of the antigen being developed for further Phase I clinical trials.

## B. MSP2

Merozoite surface protein 2 (MSP2) is a 43–56 kDa polypeptide attached to the surface of the merozoite [32,78]. The primary structure consists of three domains: highly conserved N- and C-terminal regions flanking a central dimorphic variable region. Based on the variable region, MSP2 genes can be grouped into two main families [79].

Initially, the importance of MSP2 was identified when specific monoclonal antibodies resulted in the inhibition of *P. falciparum* growth in vitro [78,80]. Further studies found that the acquired antibody response in humans is primarily directed against the polymorphic central region [81,82], although antibodies to conserved regions may develop in an age-dependent manner following extensive malaria exposure [81]. Recent epidemiological studies have associated the presence of antibodies against the conserved region of MSP2 with the reduced frequency of clinical malaria [81]. In a malaria endemic region, a Phase I/IIb trial of a vaccine

containing RESA, MSP1, and MSP2 showed a vaccine-induced selective pressure exerted on the reinfesting parasites. This resulted in a skewing of the parasite population towards the alternate dimorphic form of MSP2 not included in the vaccine [76]. This argues for the inclusion of all important allelic types of a parasite antigen to be included in a vaccine; in the instance of MSP2, both allelic families should be included. An alternative approach to a vaccine based on MSP2 might be to include just the conserved regions.

Polyclonal antibodies to MSP2 have been identified that enhance the invasion of RBC by merozoites resulting in an increased proportion of RBC containing more than one ring-stage parasite [83]. It has been proposed that multiple invasion may reflect the ability of merozoites cross-linked by the antibody to reorientate so that their apical surfaces can contact the RBC surface. Alternatively, it is possible that the separation of previously cross-linked parasites attracted to the same RBC enables them to invade the same cell individually [83,84]. The identification of deleterious antibodies emphasizes the need to identify minimal epitopes capable of inducing protective antibodies for inclusion in malaria vaccines.

## C. MSP3

MSP3 has an N-terminal secretion signal but no structural features characteristic of an integral membrane protein or signal for a GPI anchor. It is now assumed to associate with the merozoite surface as a peripheral membrane protein after being secreted into the parasitophorous vacuole of schizonts [85]. The major form of MSP3 on the merozoite surface is derived by proteolysis from full-length MSP3, but the site of cleavage is unknown.

A striking feature of the MSP3 primary structure is three blocks of heptad repeats in the N-terminal half of the polypeptide. Such sequences are highly predictive of a coiled-coil structure and a model of how the three blocks of heptads could form an intramolecular three-stranded coiled-coil has been proposed [86]. The C-terminal half of MSP3 is highly charged with aspartate, glutamate, and lysine residues comprising ~50% of the 164 residues C-terminal to the third block of heptads. A central 51-residue segment of this region of MSP3 is particularly acidic containing 36 glutamate or aspartate residues. Diversity in MSP3 appears to be restricted to the N-terminal heptad-containing half of the polypeptide and again much of the diversity reflects an underlying dimorphism [87,88]. Additional mutational events have added to the diversity in MSP3 and one of the sequenced alleles (D10) appears to have been generated by intragenic recombination between alleles representative of each dimorphic family [88]. The bias towards nonsynonymous substitutions seen in the genes of many malarial antigens is also seen in *msp3* genes, consistent with diversifying selection of protective immune responses directed against MSP3.

MSP3 was originally detected as a target of cytophilic human antibodies that induce monocytes to inhibit the development of asexual blood-stage parasites in a process known as antibody-dependent cellular inhibition (ADCI) [10]. Druilhe and colleagues have extensively documented

the activity of MSP3 antibodies in ADCI using *P. falciparum* cultured in vitro [9]. Additional evidence implicating anti-MSP3 antibodies in ADCI has been obtained using *P. falciparum*-infected BXM mice that were reconstituted with human erythrocytes [89]. The anti-MSP3 antibodies used in these ADCI studies were affinity purified on a 64-residue recombinant fragment of MSP3 or on MSP3b, a 27-residue synthetic peptide derived from the 64-residue fragment of MSP3. Despite the extensive documentation of the ADCI phenomenon, it seems improbable that the dominant specificity of antibodies acting to limit the development of *P. falciparum* asexual blood stages is restricted to such a short, linear sequence of one merozoite antigen.

#### D. MSP4 and MSP5

MSP4 and MSP5 are both 40-kDa proteins attached to the surface of the merozoite by a GPI anchor and contain a single EGF-like domain in the C-terminal region [31,33]. In *P. falciparum*, the genes that encode MSP4 and MSP5 are closely linked on chromosome 2, next to the gene encoding MSP2 [33]. Homologs of the *P. falciparum* proteins have been identified in *P. berghei*, *P. chabaudi*, and *P. yoelii*, and are represented by a single gene in the rodent *Plasmodium* strains [90,91]. A recombinant *P. yoelii* MSP4/5 protein was used in murine immunization studies and was effective at protecting mice from lethal challenge [92]. A significant correlation between prechallenge antibody titers and peak parasitemia was observed. Antibodies in sera from individuals living in malaria endemic areas recognized at least four different epitopes within MSP4 and were mainly of the IgG1 and IgG3 isotypes [93,94]. Disruption of the disulfide bonds in the C-terminus of the protein abrogated the binding of antibodies to epitopes both within and removed from the EGF-like domain, indicating the recognition of conformation-dependent epitopes.

#### E. SERA (SERP)

The serine repeat antigen (SERA) or serine-rich protein (SERP) is a 126-kDa protein found within the parasitophorous vacuole in late-stage parasites [95]. Following schizogony, the protein is cleaved into 73- and 50-kDa fragments. It is a conserved protein, rich in serine (as the name suggests), and very similar in structure to cysteine proteases [96]. It was demonstrated that monoclonal antibodies specific for SERA act to block entry of *P. falciparum* merozoites into red blood cells [97,98]. Immunization of nonhuman primates with SERA purified from parasites [99] or recombinant protein [100,101] could induce varying degrees of protection.

#### F. AMA-1

Apical membrane antigen-1 (AMA-1) is an 80-kDa integral membrane protein and is probably found in micronemes. At the time of merozoite release, the 83-kDa molecule is at the apical pole while a 66-kDa N-terminally processed form is distributed on the merozoite surface [102,103].

Immunization of monkeys and rodents with native [104] or recombinant [105–108] forms of the protein resulted in protection from homologous challenge. Passive immunization of mice with AMA-1-specific antibodies protected them from lethal challenge with *P. chabaudi* [107]. This indicated an important role for anti-AMA-1 antibodies in mediating protection from malaria. Maintenance of the conformation is critical for recognition of epitopes by the antibodies as reduction and alkylation of AMA-1 abrogates the protection seen in previously protected mice [107].

Additional studies have also suggested a role for T cells. Depletion of CD4+ T cells in mice immunized with AMA-1 partially affects their ability to control parasitemia, despite the presence of anti-AMA-1 antibodies, indicating a role for antibody-independent T-cell-mediated immunity [109]. This was consistent with an earlier study showing protection following the adoptive transfer of CD4+ T cells specific for a cryptic epitope on AMA-1 into T-cell-deficient mice [106]. Therefore both AMA-1-specific antibodies and CMI contribute to protection against malaria.

Early human clinical trials have commenced with *P. falciparum* AMA-1, and the immunogenicity and safety assessed in an escalating dose–response Phase 1 trial. In this study, immune responses were poor, and further analysis has been hindered by vaccine formulation problems [110]. The development of AMA-1 for use in human Phase 1 clinical trials continues, with protein from various recombinant expression systems being explored.

#### G. RAP1, RAP2, and RAP3

A number of proteins located within the rhoptries of *P. falciparum* have been identified ranging in size from 37 to 86 kDa, which form the low molecular mass rhoptry complex. Rhoptry-associated proteins 1 and 2 (RAP1 and RAP2) form a tightly associated complex in the rhoptries [111]. Recently, it has been shown that RAP3 can also complex with RAP1 [112]. The RAP2 and RAP3 proteins are closely related and are highly conserved across *Plasmodium* species. RAP1 appears to act as a chaperone protein facilitating the intracellular trafficking of RAP2 and presumably RAP3 to the rhoptries [113]. However, the precise function of the RAP complex is unknown. It has been suggested that RAP2 and RAP3 play a role in merozoite invasion [112].

The proteins of the RAP complex have long been considered candidate vaccine antigens and the antigenic diversity that presents a major difficulty for other antigens is less problematic for the RAP complex proteins. Antibodies to RAP1 can inhibit parasite invasion and immunization with purified native RAP complex has protected against *P. falciparum* challenge in *Saimiri* monkeys [114,115]. Recombinant forms of RAP1 and RAP2 were found to be immunogenic in mice and rabbits [116,117]. Studies in nonhuman primates using recombinant and parasite-derived protein established a significant correlation between antibody titers to RAP2 and the degree of protection [118]. Additionally, naturally occurring antibodies to RAP1 and RAP2 have been measured in humans residing in malaria endemic areas; recognition was found to correlate with age [119]. These serum antibodies are also capable of

recognizing epitopes present in the recombinant protein. Presently, only RAP2 is currently undergoing development for human vaccine trials.

## V. VACCINE CANDIDATES ON THE INFECTED RED BLOOD CELL

### A. PfEMP1

*P. falciparum* erythrocyte membrane protein-1 (PfEMP1) is a variant protein found expressed on the surface of infected erythrocytes [120]. It is involved in the cytoadherence of the infected RBC to vascular endothelium [121], and is thought to play a role in the pathogenesis of cerebral malaria. It may also serve as a ligand for rosetting [122]. A multigene family, containing between 50 and 150 *var* genes, occurring on multiple parasite chromosomes [123] encodes this protein [124,125]. The differential expression of these genes is thought to be responsible for the different binding properties to adhesion molecules during sequestration exhibited by different strains of the parasite [126,127]. It also forms the basis for the extensive antigenic variation associated with the parasite. During infection, switching of the *var* genes results in expression of different PfEMP1 variants on the surface of the infected RBC [126–128]. This process allows the parasite to multiply in the presence of antibodies that were directed at PfEMP1 variants previously expressed.

The extraordinary antigenic variation means that the development of a vaccine using this molecule will need to focus on conserved yet functional domains. The regions of this protein that mediate the binding of the merozoites to the RBC, or infected RBC to endothelium, are potential candidates. A recent study immunized monkeys with a minimal fragment derived from PfEMP1, known to function in the binding of CD36 [129]. The immunized animals experienced lower parasite densities than control animals and this protection occurred despite the expression of different *var* genes during waves of recurrent parasitemia.

### B. RESA (Pf155)

Ring-infected erythrocyte surface antigen (RESA) is found in the dense granules of the apical organelles in merozoites [130]. Following invasion, it is released from the merozoite when it translocates to the cytoplasmic side of the erythrocyte membrane [131]. This protein contains two regions of tandem repeats [132] containing both B and T cell epitopes [133,134]. The antigen appears not to be expressed on the surface of the parasitized RBC [135], although a portion of it is accessible to the immune system [136]. Epidemiological studies in malaria endemic regions have presented conflicting results with some studies demonstrating a correlation between repeat region-specific antibody levels and reduced parasitemias and clinical episodes. Additional studies have been unable to establish a correlation [137–139]. It is thought that this may reflect differences in human genetics and patterns of endemicity [139,140]. Ring-infected erythrocyte surface antigen has been included in a number of combination antigen vaccines for human trials [75,76].

## VI. THE FUTURE

The prospects of developing a subunit malaria vaccine are good. We now understand to a significant degree the nature of protective immune responses and have defined a number of subunit vaccine candidates that are targets of antiparasite antibodies and antitoxin antibodies. We are also in the process of defining target antigens for CMI. However, most importantly, we are now aware of many of the great difficulties involved in developing an effective malaria vaccine.

While it would be ideal, but unlikely, that a single antigen were to be a successful blood-stage subunit vaccine, it is more likely that success will come from combining multiple antigens that each stimulate different types of protective immune responses. In parallel, it is hoped that there will be success in developing vaccines that target the parasite at the pre-erythrocytic stage and in the mosquito. Success in one or more of these three major strategies will have an enormous impact on world health.

## ACKNOWLEDGMENT

We gratefully acknowledge the input of Dr Louis Miller who kindly reviewed the manuscript.

## Malaria Transmission-Blocking Vaccines

Allan Saul

*Malaria Vaccine Development Unit, National Institutes of Health, Rockville, Maryland, U.S.A.*

### I. INTRODUCTION

By any criterion, malaria is a disease of major global significance. The World Health Organization (WHO) estimates that approximately 1 million people die each year from malaria, primarily children in Africa. However, this is just the “ears of the hippopotamus.” The number of clinical cases is estimated at perhaps 500 million per year and 1.5 billion people at risk [1]. Besides the disease, malaria is a major economic problem, directly through the cost of health care and the cost of maintaining control programs that prevent the spread of malaria, and indirectly through the loss of productivity [2]. Vector control and the detection and drug treatment of human cases remain the only weapons available. Although innovative ways of using existing technologies are being developed by programs such as Roll Back Malaria [3], these programs face technical difficulties with the spread of insecticide resistance in mosquitoes and the spread of drug resistance in the parasite [4]. Drug resistance and insecticide resistance are not the only impediments—malaria is overwhelmingly a disease of poverty. This leads to logistical difficulties in establishing and maintaining the infrastructure to continuously deliver vector-based control and human treatment and prophylaxis in areas with very limited health resources. For all these reasons, malaria vaccines have been promoted as having the potential to make a quantum difference. A long-lived vaccine may provide a cost-effective prophylaxis against the disease without requiring a major investment in infrastructure.

Malaria is caused by four species of *Plasmodium* parasites, *Plasmodium falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*. Of the four, *P. falciparum* and *P. vivax* are responsible for most of the diseases, and *P. falciparum* is responsible for most of the deaths. These four species are sufficiently different that a vaccine directed against one species will probably not protect against the others. Although common in some localities, *P. malariae* and *P. ovale* are not responsible for enough diseases to currently attract vaccine development. Because of its importance in causing death and because it is

the only human malaria parasite that can be cultured, most vaccine developments are aimed at producing a vaccine for *P. falciparum* alone. However, the development of transmission-blocking vaccines (TBVs) for both *P. falciparum* and *P. vivax* is proceeding in parallel. In the low to medium endemic areas that are the prime targets of transmission-blocking vaccines, diseases caused by *P. vivax* and *P. falciparum* are both of considerable importance, and both components will be required as part of integrated control programs.

Several types of antimalaria vaccines are being developed (see other chapters). Vaccines are commonly described by the stage of parasite they target. These include the following:

Preerythrocytic vaccines that target the form of the parasite, the sporozoite injected by the mosquito, or the resulting liver stage parasites. These stages of the parasite cause no disease, but an effective vaccine would stop the infection from developing into the next stage, the erythrocytic stage, which does cause diseases. Preerythrocytic vaccines are likely to be of particular importance for travelers.

Erythrocytic stage vaccines that target the forms of the parasite that replicate in the bloodstream. This is the stage of the parasite that causes disease. Vaccines directed against this stage are seen as particularly important in endemic areas, where, in conjunction with natural immunity, they may protect against severe disease and death even if they do not provide sterile immunity.

Mosquito stage vaccines, commonly called “transmission-blocking vaccines” that target the sexual and subsequent stages of the parasite as it develops in the mosquito. These vaccines are designed for people living in endemic areas and are aimed at preventing new infections. Although they provide no immediate direct benefit for the person immunized, malaria transmission is highly localized, so a successful transmission-blocking vaccine would result in con-

siderable indirect benefits to the individual vaccinated (e.g., through decreased malaria infection rates in other family members and neighbors).

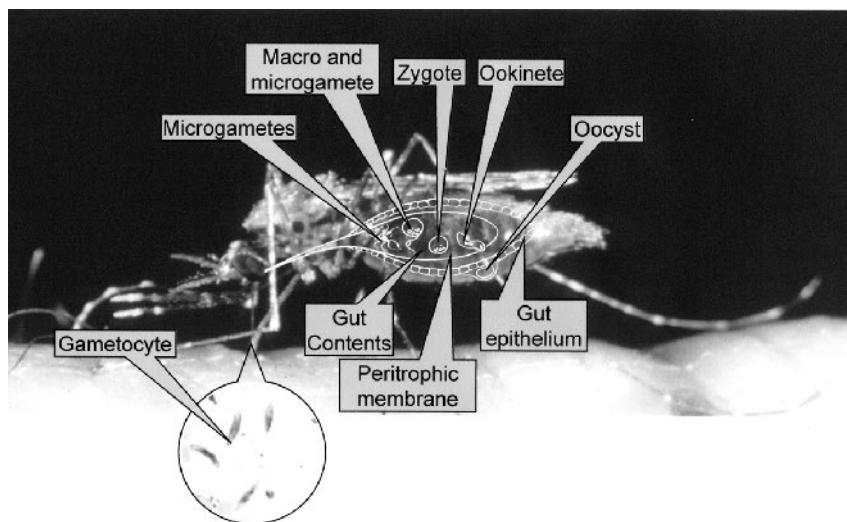

Vaccines against all stages of malaria potentially block transmission. Preerythrocytic stage vaccines are designed to prevent the transmission of malaria from mosquitoes to people. Erythrocytic stage vaccines, either by decreasing the probability of becoming infected or by decreasing the time that a person remains infectious, would decrease the reservoir of infection in a community, thereby decreasing transmission. In fact, computer models of malaria transmission in areas of low endemic malaria or seasonal malaria predict that preerythrocytic, erythrocytic stage, and mosquito stage vaccines could all have similar effects on malaria transmission [5]. However, this review will only discuss vaccines aimed at directly blocking transmission from people to mosquitoes (Figure 1).

Within this definition, the current design of malaria transmission-blocking vaccines involves several unusual concepts:

Malaria TBVs are designed to work outside the person or animal vaccinated. This both simplifies and con-

strains the vaccine design. These vaccines appear to work primarily through antibody-mediated effects [6]. Therefore, TBVs aim to obtain high-level and persistent antibodies. Ideally, protective antibody would last for several years. However, for areas of seasonal or epidemic malaria, protection that lasted a minimum of one transmission season (typically 4 months) would be useful in the context of integrated control programs. Fortunately, mosquito stage antigens are exposed for many hours, so transmission-blocking immunity (TBI) is unlikely to require the very high antibody levels required to block merozoite invasion [7].

Some target antigens (e.g., Pfs48/45 and Pfs230) are expressed in gametocytes. Naturally occurring antibodies against these proteins can be detected in exposed human populations. However, other targets (e.g., Pfs25) are only expressed in the mosquito midgut [8]. It is unlikely that these proteins have ever been under significant immune pressure. Consistent with this idea, these antigens have minimal sequence diversity. Transmission-blocking vaccines based on these may avoid some of the complica-

**Figure 1** Targets of transmission-blocking immunity. Parasite and mosquito targets for transmission-blocking immunity are shown diagrammatically superimposed on a feeding *A. gambiae*, one of the most dangerous mosquito vectors. Gametocytes in the blood meal are ingested with uninfected blood cells. In the mosquito, each gametocyte rapidly transforms, escaping from its host red cell to produce approximately eight microgametes ( $\delta$ ) or a single macrogamete ( $\varphi$ ). These fuse to form a zygote that transforms into a motile ookinete. This penetrates the peritrophic membrane, an acellular membrane secreted by the mosquito to surround the blood meal, and then crosses the mosquito gut wall to form an oocyst. Approximately 10 days after taking a blood meal, the oocyst ruptures to release thousands of sporozoites (not shown) that travel to the salivary glands. When injected with a subsequent blood meal, the sporozoites may infect another person.

Potential vaccine targets (listed in the text) on these stages are:

Gametocyte	Gametes	Zygote	Ookinete	Oocyst	Gut contents	Gut epithelium
Pfs48/45	Pfs48/45	Pfs230	Pfs25	Pfs25	Trypsin	Surface macromolecules
Pfs230	Pfs230	Pfs25	Pfs28 Chitinase CTRPs	Pfs28	Other proteases	

tions that vaccines aimed at other stages face with antigenic diversity but cannot be boosted by natural infection.

In addition to protecting the vaccinated individual, most vaccines aimed at infectious diseases have a major herd immunity effect, protecting people not immunized by reducing the human reservoir of infection. However, TBVs are only designed to protect communities through a herd immunity effect and will not immediately protect the person vaccinated against the disease.

Four distinct uses for transmission-blocking vaccines are anticipated [8,9].

(1) *As a component of integrated control programs to eliminate endemic malaria in low to mesoendemic areas.* To eliminate malaria, a control program needs to reduce the potential number of new cases of malaria resulting from each existing case to less than one (i.e., in epidemiological terms, to reduce the  $R_0 < 1$ ). We anticipate that a TBV alone could realistically achieve a threefold reduction in  $R_0$  (e.g., a vaccine inducing high levels of antibody in vaccinees, with a 70% compliance). This would be sufficient in some areas but, coupled with other measures such as the use of insecticide-treated bed nets (ITNs) and better early case detection and treatment, could eliminate malaria from much of the world at risk from low to mesoendemic malaria. This includes almost all areas of *P. vivax* transmission and most of the world population at risk outside of Africa. Approximately 1.4 billion people are at risk outside Africa, with 50 million cases of *P. falciparum* malaria and 65 million cases of *P. vivax*

malaria annually [10]. Within Africa, the pattern is more complex, with a significant proportion of the 550 million people at risk from malaria living in areas of such high transmission that these measures would not interrupt transmission. However, even in sub-Saharan Africa, the epidemiology of malaria is not uniform. A recent study [11] of endemicity in West Africa, excluding Niger, found that of the 219 million at some risk of malaria in this region, 50 million live in low endemic areas (areas with a malaria prevalence in 2- to 10-year-old children <30%) where transmission-blocking vaccines could form part of an elimination program (Table 1). People in such sites are bitten by very few [1,2] infectious mosquitoes each year [12]. There are a further 153 million in areas of moderate endemicity (30–70% prevalence in 2- to 10-year-old children), where TBVs alone will not be effective but may be a component of an effective integrated control program. Only 16 million lived in high endemic areas (>70% prevalence in 2- to 10-year-old children) where elimination is not feasible in the foreseeable future [11].

(2) *To protect populations against epidemics of malaria in low endemic areas.* Epidemics of malaria usually occur as a result of unseasonable weather conditions, or accompany natural or man-made disasters in tropical areas. Although a high proportion of the population can be infected in an epidemic, the biology of the parasite limits the rate at which such epidemics can build up. For example, following the bite of an infectious mosquito, for *P. falciparum*, it takes 6 days before parasites are released into the blood, a further 6 days before the parasite density is high enough to generate significant numbers of gametocytes, another 10 days before these are mature enough to infect mosquitoes, and another

**Table 1** Malaria Prevalence in West Africa

Country <sup>a</sup>	Percentage of total population in each risk category <sup>b</sup>			
	Predicted prevalence of <10%	Predicted prevalence of 10–30%	Predicted prevalence of 30–70%	Predicted prevalence of >70%
Benin	0	5	43.4	12
Burkino Faso	0	17	76	0
Cameroon	1	16	58	2
Côte d'Ivoire	0	4	75	0
Gambia	0	8	44	0
Ghana	1	15	46	17
Guinea	1	12	57	3
Guinea Bissau	2	30	13	0
Liberia	0	1	81	2

Mauritania	20	30	6	1
Nigeria	0	8	48	8
Senegal	1	22	41	2
Sierra Leone	0	0	79	2
Togo	0	0	39	38
Entire region	2.4	14.8	52.7	5.4
Total population at risk	7,006,869	42,941,669	152,779,264	15,698,929

<sup>a</sup> Excludes Niger for which statistics were not available.

<sup>b</sup> Percentages do not add up to 100% as urban populations have been excluded and parts of some countries lie outside of the area for which statistics were available.

Source: From Ref. 11.

10 days before a mosquito feeding on an infectious person will become infectious—a minimum of 32 days for one person receiving an infectious bite before that could result in a secondary infectious mosquito bite. *P. vivax* has a faster life cycle, but even for this parasite, the minimum generation time is about 4 weeks. In low to mesoendemic areas, it takes, on average, several days or weeks before a vector mosquito feeds on a potentially infectious person, happens to get infected, happens to survive long enough to transmit to another person, and happens to successfully transmit parasites. In practice, mean generation times from one person becoming infected to the next infection will be substantially longer than these minimum times. Computer modeling shows that relatively modest reductions ( $3\times$ ) in the transmission rate, which could be achieved by transmission-blocking vaccines alone, could have a major impact on the total number of cases of malaria that will occur before seasonal or other factors change to limit an epidemic [5]. Furthermore, the long malaria generation time allows adequate time to instigate a vaccination program at the first sign of an epidemic, provided rapid immunity can be achieved after vaccination. In areas prone to epidemics, one could envisage a strategy to combine TBV and the childhood Expanded Program on Immunization (EPI) program so that a rapid response could be achieved from a single booster vaccination when required.

(3) *To decrease disease in high endemic areas.* Two types of studies show that the incidence of disease caused by malaria in medium to high endemic areas correlates with the transmission intensity.

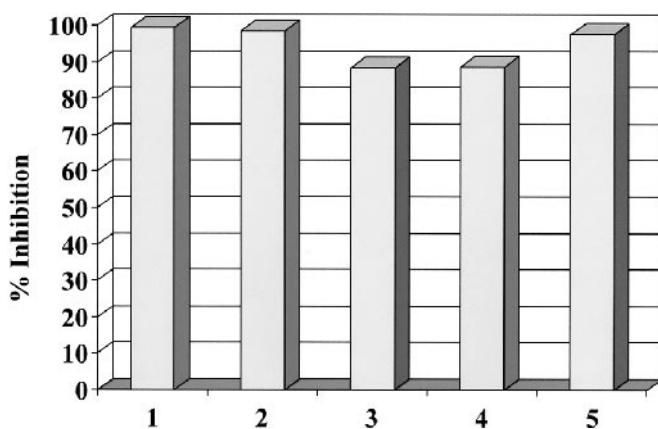

- (a) Although initial studies suggested that morbidity from malaria is independent of transmission rates in Africa [13], a more recent and more comprehensive study has shown a highly significant correlation between transmission and death in infants [14]. In this study, a 10-fold reduction in transmission in the high endemic regions would be expected to result in a decrease of about 20 deaths per 1000 infants per year.
- (b) Insecticide-treated bed nets in areas of relatively high transmission rates, where they reduce but not prevent transmission, have still resulted in significant reductions in mortality and morbidity due to malaria [15] with a measured reduction in mortality of six children per 1000 protected. Insecticide-treated bed nets work in two ways: by protecting individuals against infectious mosquito bites and by preventing uninfected mosquitoes from biting infectious people. Transmission-blocking vaccines will have an action similar to the latter. However, unlike bed nets that only work while a person is using the bed net, vaccination will give 24-hr protection and, after vaccination, requires no further active participation. The relative merits of ITN and TBV (and preferably both) will depend on the exact epidemiology and human behavior in a particular environment. However, the experience with ITNs strongly suggests that TBV will lead to a substantial reduction of malaria deaths in high endemic areas.

(4) *To slow the spread of drug-resistant or vaccine-resistant mutant parasites in all endemic areas.* A tragedy of malaria control has been the loss of safe, inexpensive, and effective antimalarial drugs through the development and spread of drug resistance. In the case of chloroquine, molecular typing of the chloroquine resistance locus and linked microsatellite markers suggests that chloroquine resistance present in *P. falciparum* has probably arisen from just four mutated parasites followed by its spread throughout the world over a period of 10–20 years [16]. Chloroquine-resistant *P. vivax* has now emerged in Papua New Guinea and adjacent areas in Indonesia, and may similarly spread [17]. Even in areas where a transmission-blocking vaccine may not decrease parasite prevalence, it would slow the spread of resistance mutants. Unfortunately, we anticipate that the problems observed with the spread of drug-resistant malaria will be mimicked by the spread of vaccine-resistant parasites as effective preerythrocytic or blood stage vaccines are developed. The incorporation of a transmission-blocking vaccine with vaccines targeting these stages may be an important strategy to preserve their effective life.

Three different types of TBV may be required:

1. A *P. vivax*-only vaccine. From WHO country profiles, there are approximately 130 million people living in regions where *P. vivax* is the only—or overwhelmingly dominant—parasite with a reported 700,000 cases. The actual number of cases will be much larger. For example, the Roll Back Malaria [18] program estimates that the number of cases of *P. vivax* malaria in Afghanistan alone was approximately 2–3 million in 2000.
2. A *P. vivax/P. falciparum* combination vaccine. The majority of the world's population at risk from malaria live in areas affected by both species. Mendis et al. [10] estimate that approximately 1.4 billion people outside of Africa live in malaria risk areas, experience approximately 116 million cases of malaria, with *P. vivax* accounting for 60% of these. Even in Africa where *P. falciparum* dominates, some areas (e.g., Sudan, Ethiopia, and other East African countries) have significant rates of *P. vivax* [10].
3. A *P. falciparum*-only vaccine. This vaccine would be required for most of Africa and countries where the population is primarily of West African origin (e.g., Haiti). About 500 million people are at risk in these areas, resulting in 200–300 million cases of malaria and approximately 1 million deaths annually [10,19].

The concept of a malaria TBV was demonstrated by vaccination of chickens with formalin-treated or X-irradiated blood drawn from birds infected with *P. gallinaceum* [20], or with partially purified preparations of extracellular gametes of *P. gallinaceum* [21]. These birds were not immune to the blood stage infection, but were markedly less infectious to *Aedes aegypti*, one of the mosquitoes that can transmit *P. gallinaceum*. With multiple immunizations with extracellular gametes, 99.99% suppression of infectivity was achieved

**Figure 2** Membrane feeding assay of transmission-blocking immunity. Blood containing mature gametocytes is mixed with a test antiserum and placed in a small glass chamber whose base is sealed with a thin membrane. A glass jacket through which warm water circulates surrounds the chamber. Mosquitoes attracted to the warm blood feed through the membrane. Mosquitoes are then held in an insectary until oocysts have developed, the gut has been removed and stained, and the number of oocysts has been counted. (From Refs. 31,32,34,135.)

Transmission-blocking activity is measured by either (a) the decrease in the average number of oocysts on mosquitoes fed test antisera compared with mosquitoes fed control sera (i.e., a decrease in the intensity of infection), or (b) the decrease in the proportion of mosquitoes that have at least one oocyst (i.e., a decrease in the frequency of infection).

A decrease in the average number of oocysts is used in our laboratory to assess experimental vaccines because the mosquitoes and source of parasites have been chosen to give reproducibly high infection rates to maximize the statistical significance of the assay. In part, this is achieved by using relatively high gametocyte densities that tend to produce high oocyst numbers. Under these conditions, antisera that gave even a 90% blockage of oocyst development may have a minimal impact on the proportion of mosquitoes infected.

In the field, the efficacy of a vaccine is likely to be proportional to the number of mosquitoes that fail to become infected at all (i.e., have zero oocysts). In predicting the impact of a TBV, it will be critical to know the distribution of oocysts in naturally infected mosquitoes. The data available from wild caught feeds and laboratory simulations show that this distribution is highly skewed, with most mosquitoes infected with very few (often only one or two) oocysts but a small number of mosquitoes infected with large numbers. (From Refs. 164–168.) Under these conditions, predictions of vaccine efficacy based on reduction in oocyst numbers in the laboratory will overestimate field efficacy because the vaccine will probably fail to prevent the infection of a small proportion of mosquitoes that would have been infected with a large number of oocytes. However, provided that most natural infections result in few oocysts per gut, then this error will not be large. On the other hand, because of the very great differences in the average numbers of oocysts per gut in laboratory infections compared with field data, predictions of efficacy based on the proportion of mosquitoes failing to be infected in the laboratory are likely to grossly underestimate field efficacy.

[22]. Panels of monoclonal antibodies (mAbs) that inhibited transmission [23] and immunoprecipitated proteins of 240,000, 56,000, and 54,000 kDa [24] on the surface of male and female gametes were developed. As detailed below, homologs of these proteins and other targets of transmission-blocking immunity have been identified on *P. falciparum*, *P. vivax*, other primate malarias, and rodent malarias. Many studies with monoclonal antibodies used in vitro or by passive transfer of polyclonal antibody raised against parasite-derived and recombinant gamete, zygote, or ookinete proteins have demonstrated that blocking transmission through vaccination is feasible (see later sections for specific references).

Antibodies to the *P. falciparum* homologs, Pfs230 and Pfs48/45, can be demonstrated in populations living in highly endemic areas who have a high prevalence of infection with gametocytes [25–30]. As assayed by the ability of sera to block the infection of mosquitoes when mixed either with parasites ex vivo or laboratory-derived parasites and fed to mosquitoes via an artificial membrane (Figure 2) [31,32], naturally occurring TBI can be demonstrated [25,33–41]. Correlations have been found with the level of TBI for both anti-Pfs230 [25,42] and anti-Pfs48/45 antibody [38,39].

## II. TARGETS OF TRANSMISSION-BLOCKING VACCINE

The potential components of TBV can be conveniently grouped in four categories:

- The six-cys motif gamete and zygote surface antigens
- The epidermal growth factor (EGF) domain ookinete surface antigens
- Other malaria proteins
- Mosquito proteins.

### A. The Six-Cys Motif Gamete and Zygote Surface Proteins

Early studies of gamete surface proteins identified three proteins that are synthesized in both male and female gametocytes. Following the release of the gametes from their red cells, these proteins are found on the surface of gametes. They coprecipitated with polyclonal and monoclonal antibodies that blocked transmission. These three proteins from *P. falciparum* had apparent sizes of 230, 48, and 45 kDa on reducing sodium dodecyl sulfate (SDS) polyacrylamide electrophoresis [43,44]. The 230-kDa protein can be separated from the 48- and 45-kDa proteins by phase separation using Triton X-114 [45]. Subsequently, it was shown the 48- and 45-kDa proteins are different forms of a single protein [46] (although the reasons for the two forms are still not understood) and so these gamete proteins were described as Pfs230 and Pfs48/45. When the genes encoding these proteins were cloned, it became clear that both belong to the same superfamily of genes, characterized by domains with up to six cysteines [47]. Genes encoding at least seven proteins in this family are now known in the *P. falciparum* genome [48]. The repeating motif in these proteins has not been found outside

the genus *Plasmodium*. The predicted proteins all have signal peptides and some have a C-terminal hydrophobic peptide that probably is recognized as a GPI anchor signal by the parasite.

### 1. Pfs48/45 and Orthologs

The genes coding for the Pfs48/45 orthologs (P48/45 proteins) have been cloned from *P. falciparum* [46], *P. reichenowi* [49], *P. vivax*, and *P. berghei* [50]. The four orthologs show considerable similarity: the *P. berghei* and *P. vivax* proteins share 54% and 55% amino acids, respectively, with the *P. falciparum* sequence. Pfs48/45 is 448 amino acids long, starts with a signal peptide, contains three copies of the six-cys motif, and terminates with a putative GPI anchor. Consistent with the presence of a GPI anchor, Pfs48/45 can be labeled with [<sup>3</sup>H]glucosamine or [<sup>3</sup>H]mannose [44,51]. In *P. falciparum*, *P. vivax*, and *P. berghei* genomes, the gene encoding P48/45 is adjacent to a similar gene encoding P47, another member of the six-cys domain family. Presumably, this arrangement has arisen by gene duplication [50].

Four epitopes were defined on Pfs48/45 by monoclonal antibodies [44,52,53] and human recombinant antibodies [54]. Epitopes I, II, and III are reduction-sensitive. Monoclonal antibodies directed against epitope I are efficient at blocking transmission either as the intact antibody or as a Fab fragment [52,55]. At least one mAb (1A3-B8) directed against epitope II has transmission-blocking activity that increases in the presence of a complement. Another mAb (IIC5-B10) directed against region III has weak transmission-blocking activity, although no transmission-blocking activity of other rat and mouse antiepitope II and III mAbs has been observed [55]. However, marked synergistic blocking (>98% inhibition of transmission) was found when mosquitoes were fed a mixture of epitope II and epitope III mAbs 1A3-B8 and IIC5-B10 [52,56].

Based on reactivity with different parasites, mAbs directed against region II can be divided into two groups: the panspecific IIb and the polymorphic allelic forms IIa/IIC. Binding to the latter correlates with two adjacent amino acid substitutions in the second six-cys motif [47,57]. A further three amino acids have been observed to be polymorphic in the third motif [57], but as yet, these have not been associated with antigenic diversity. The geographical distribution of these polymorphisms is highly biased [58–60].

Gene knockout experiments confirm the essential role of Pfs48/45 and its *P. berghei* ortholog, Pbs48/45, in fertilization. Knockout mutants form gametocytes and gametes but have greatly reduced zygote formation. Although P48/45 is on both male and female gametes, surprisingly, the gene knockout only affected the male gametes. Female knockout gametes were efficiently fertilized by wild-type male gametes, but not vice versa [50].

So far, the expression of Pfs48/45 for use as a vaccine has not been achieved. In *Escherichia coli*, the full-length protein (including signal peptide and C-terminal transmembrane domain) was toxic to the host cells. A truncated protein missing the last two cysteines of the third six-cys motif was expressed at a high level as an insoluble inclusion

body, as the free protein, or as a GST fusion protein. When solubilized and used to immunize mice and rabbits, the GST fusion protein gave high-titer antibody, but this did not recognize gametes or block transmission [61]. Expression in eukaryotes is complicated by the presence of seven potential glycosylation sites that are not used in *P. falciparum*. Attempts to express the protein in eukaryotic systems with a variety of constructs—with and without the glycosylation sites removed, or with optimized codon use in *Saccharomyces*, *Pichia* [62], or in a vaccinia system [63]—have not yielded materials suitable for human vaccines.

### 2. Pfs230

When the gene coding Pfs230 was cloned and sequenced [64], the full-length protein was much larger than the apparent size of 230 kDa observed in immunoprecipitates of surface-labeled gametes. The gene encodes a 360-kDa protein, consisting of a signal peptide, a relatively unremarkable 260-amino-acid N-terminal domain, a stretch of 25 consecutive glutamic acids, 16 copies of a tetrapeptide repeat (EEGV), and 14 copies of the six-cys motif. These 14 motifs are arranged in seven pairs, with the odd-numbered motifs containing only one or two of the consensus three consensus disulfides [47]. Other than the signal peptide, Pfs230 has no transmembrane domain and the mature protein is presumably anchored to the gamete surface through its interaction with Pfs48/45 [45].

The protein is present in gametocytes as the 360-kDa form predicted from the gene sequence. On transformation to gametes, Pfs230 is cleaved to give proteins of 300 and 307 kDa on the gamete surface. Cleavages occur between amino acids 477–487 and 523–555, respectively [65], resulting in a mature protein that lacks the poly-glutamic acid region and the EEGV repeats. It has been speculated that the N-terminal region may act as an immune evasion mechanism to divert an immune system response to this N-terminal region shed on the emergence of the gametes in the mosquito [66]. Consistent with this hypothesis, EEGV repeat was the region recognized most frequently by sera from adults living in a highly endemic region of The Gambia [67], although this study may not have detected antibodies directed against conformational epitopes. It is also consistent with the early observation in the *P. gallinaceum* model that gametes were much more effective in inducing transmission-blocking antibodies than gametocytes [22].

Full-length sequences are available from four isolates [68] (GenBank locus AF269242; Z. X. Shan et al., unpublished) and partial sequences from two other isolates [60]. By comparison with asexual stage surface proteins, Pfs230 is highly conserved. In the ~300-kDa gamete form, only 18 of 2650 amino acids are polymorphic. In addition, there is a short, low-complexity region (amino acids 2413–2420 in the 3D7 sequence) in which there is some variation in an EEQQ repeat. Consistent with this lack of sequence diversity, 17 mAbs out of a panel 18 of mAbs, known to recognize at least nine different epitopes, bound to gametocytes from all isolates tested [53,69].

At least 15 anti-Pfs230 mAbs, which block the transmission of parasites to mosquitoes, have been identified [69–

72]. With one exception (a mAb that recognizes a linear epitope present on at least three gamete proteins [73] and whose transmission-blocking target is therefore not clear), all recognize reduction-sensitive epitopes, all are of complement-fixing IgG2a or IgG2b subclasses, and all require the presence of active complements to kill parasites. As judged by competition experiments, these mAbs recognize at least five different epitopes. In fact, all known anti-Pfs230 IgG2a and IgG2b mAbs are able to block transmission in a complement-dependent manner [69,70,72]. Transmission-blocking activity in the mosquito correlates with the lysis of female gametes and zygotes in vitro [69,70]. The dependence for complement fixation was dramatically illustrated by the subclass switching of a nonblocking IgG1 mAb to transmission-blocking, complement-dependent IgG2a and IgG2b subclass mAbs [71].

The size, the number of cysteines, and the apparent requirement for correct folding make the expression of full-length Pfs230 suitable for use as a vaccine, a daunting task. Williamson et al. [74] and Bustamante et al. [75] have approached vaccine development by expressing domains of the protein in *E. coli*. One region covering the first pair of six-cys motifs and expressed as a maltose-binding protein chimeria (r230/MBP.C) elicited significant transmission blocking, although this was substantially lower than the transmission-blocking activity of monoclonal antibodies. None of the domains gave a strong signal on Western blotting with 19 anti-Pfs230 mAbs, suggesting that *E. coli*-expressed proteins are not correctly folded [67].

As for P48/45, the development of a transmission-blocking vaccine based on Pfs230 remains an attractive goal, but will require the development of ways of efficiently expressing correctly folded six-cys motifs.

## B. The P25 and P28 EGF Domain Zygote, Ookinete, and Oocyst Antigens

Two proteins with sizes of 26 and 28 kDa on reducing SDS gels were identified by surface labeling of *P. gallinaceum* zygotes and ookinetes. These proteins were present on ookinetes but not earlier stages [43,76–78]. The 26-kDa protein appeared about 2 hr postfertilization and the 28-kDa protein appeared 3–5 hr postfertilization [43]. Both could be labeled with glucosamine and palmitic acid [51]. Monoclonal antibodies directed against these proteins blocked the development of parasites in mosquitoes, identifying them as potential targets of transmission-blocking antibodies [76,78].

A similar 25-kDa protein was identified on the surface of *P. falciparum* ookinetes as the target of transmission-blocking antibody [79,80]. When the gene coding the *P. falciparum* 25-kDa protein was cloned and sequenced, it was found that the protein consisted of four-tandem EGF-like domains [81]. As expected for a surface protein, the sequence encoded a typical signal peptide. The translated protein sequence ended with a hydrophobic domain and, consistent with earlier observations that the protein could be labeled with glucosamine and palmitic acid [44], this sequence probably is replaced by a GPI anchor in the mature protein.

Subsequently, the genes encoding the 26-kDa *P. gallinaceum* protein [82] and the ortholog from *P. reichenowi* [83] were cloned. As expected from their close evolutionary relationship, the *P. falciparum* and *P. reichenowi* genes are closely related. Surprisingly, a striking similarity was also found between the genes from the more distantly related *P. falciparum* and *P. gallinaceum* parasites [82]. Subsequently, the Pfs25 orthologs (P25 family) have been cloned from *P. berghei* [84], *P. yoelii* [85], *P. vivax* [86], and *P. ovale* [87].

The cloning of the 28-kDa surface protein from *P. gallinaceum* (Pgs28) showed that this protein had a structure similar to those Pfs25 and Pgs25, with a signal peptide, four EGF domains, and a C-terminal anchor sequence [88], but differed in the last EGF domain, which was truncated and ended with a short repeat region.

A 21-kDa protein, Pbs21, had also been identified on the surface of zygotes and ookinetes of the rodent malaria, *P. berghei*, as the target of monoclonal antibodies that blocked transmission [89,90]. Affinity-purified Pbs21 was able to induce transmission-blocking immunity in mice [91]. When the corresponding gene was cloned and sequenced, it was found that this protein was also a member of this four-EGF domain surface antigen family, the ortholog of Pgs28 [92]. Pgs28 orthologs (P28 family) have been cloned from *P. falciparum* [93], *P. yoelii* [85], *P. chabaudi* [94], *P. vinckei* [94], *P. vivax* [86], and *P. ovale* [87]. Unlike all other species so far examined, *P. ovale* has three members of the EGF surface protein family: Pos25, Pos28-1, and Pos28-2.

The expression of P25 and P28 family members has been studied in *P. gallinaceum*, *P. berghei*, *P. falciparum*, and *P. vivax*. Kumar and Carter [51] showed that in *P. gallinaceum*, Pgs25 is synthesized from approximately 2 hr postgametogenesis and continues to be synthesized for about another 8–10 hr. The expression of Pgs28 starts later, 3–5 hr postfertilization, but this continues until at least 22 hr postfertilization.

The low-level synthesis of Pfs25 was detected in immature *P. falciparum* gametocytes, but production dramatically increased following gametogenesis and fertilization [44]. In contrast, Fries et al. [95] only detected synthesis postinduction of gametes. Pfs28 is synthesized later. By immunofluorescence, Pfs28 is first observed on retort stages, the transitional stage between a zygote and an ookinete [93]. Similar results have been obtained with the P25 and P28 proteins from *P. vivax*. Anti-Pvs25 antibodies stained parasites ranging from zygotes to mature ookinetes, whereas anti-Pvs28 antibodies mainly stained retort and mature ookinete stage parasites [96]. In *P. berghei*, the protein expression of both the P25 (Pbs25) and P28 (Pbs21) proteins commenced in the macrogamete, with Pbs25 detectable 30 min following gamete activation and Pbs21 detectable after 2 hr [97]. The expression of Pbs21 reached the peak level approximately 10 hr postfertilization [98]. Surprisingly, the transcription of the Pbs25 and Pbs21 genes occurs in gametocytes prior to the release of gametes; thus, the translation of protein is subject to some unknown posttranscriptional controls [92,97]. Pbs21 is shed during the invasion of mosquito epithelial cells [99], but presumably, further synthesis results in the presence of antigens for at least 6 days [99,100]. Similarly, Pfs25 is also present in *P. falciparum* oocysts until rupture [101], and anti-

Pfs25 antibody has been used to improve the detection of early-stage oocysts in mosquito midguts [102].

Pfs25 and Pfs28 are closely linked to chromosome 10 [88]. Preliminary data available from both the *P. falciparum* and *P. yoelii* genome projects show in both species that the *P25* and *P28* genes are located approximately 1.5 kb apart. The close proximity of the genes and their related structure suggests that these proteins have arisen through gene duplication that preceded the speciation of the present-day *Plasmodium*.

Studies of the P25 and P28 proteins suggest that they are functionally redundant. In *P. berghei*, knockout of either the *P25* or the *P28* gene had little impact on the viability of ookinetes or the ability to invade the mosquito gut wall to form oocysts, but in the double knockout, the formation of ookinetes was significantly inhibited and the double knockout ookinetes had a much reduced capacity to transform into oocysts [103]. A variety of roles have been proposed for the P25 and P28 proteins. These include a surface coat to protect the parasite against lethal factors in the mosquito gut [103–106], and as specific receptors for endothelium and basal membrane proteins. The *P. berghei* P25 protein has been shown to interact with laminin [107], whereas the *P. gallinaceum* P28 has been shown to interact with both laminin and collagen IV [108].

Many studies show that antibodies against these two proteins can disrupt several stages in the development of parasites, including killing of zygotes/ookinetes and the prevention of the interaction of the ookinete with the mosquito midgut epithelium [8,78,88–91,93,96,97,109–126]. In mosquito feeds, intact monoclonal antibody, FAb fragments, or recombinant single-chain antibody targeting the P28 protein in *P. berghei* (Pbs21) were approximately equally efficacious at blocking transmission, suggesting that complement activation or interaction with cells via Fc receptors is not required *in vivo* [121,124,126]. These studies contrast with results obtained in culture, where intact antibodies and the presence of peripheral blood leukocytes were critical [125]. A mAb directed against Pgs25 in *P. gallinaceum* failed to affect the development of ookinetes *in vitro*. When taken up with gametocytes in a blood meal, it did not slow the development of ookinetes, but prevented oocyst formation [127]. That study concluded that antibodies bound on the ookinete prevented ookinetes from crossing the peritrophic membrane, rather than preventing the invasion of the gut epithelium. The peritrophic membrane separates the blood meal from the endothelial cells of the midgut, and must be crossed by malaria ookinetes before they can invade the actual gut wall.

*In vivo*, the available mechanisms for killing parasites will be further limited by the life of antibodies in the mosquito blood meal [128]. Although not conclusive, the available data suggest that both monoclonal and polyclonal antibodies against the P25 proteins are more efficient at preventing transmission than antibodies against the P28 proteins. This has been observed with monoclonal antibodies recognizing the Pgs25 and Pgs28 proteins of *P. gallinaceum* [78], monoclonal antibodies recognizing the Py25 and Pys28 of *P. yoelii* [118], and polyclonal antibodies directed against Pvs25 and Pvs28 of *P. vivax* [129].

Early results suggested that antibodies to a fusion protein of Pfs25 and Pfs28 were much more potent in transmission blocking than antibodies to Pfs25 alone [112]. However, subsequent studies with more highly characterized antigens failed to confirm these results. Antibodies to Pfs25 gave better transmission blocking than antibodies to the chimeric Pfs25–Pfs28 [110]. The trend that anti-P25 antibodies are more potent than anti-P28 antibodies is consistent with the earlier expression of the P25 proteins, suggesting that early events in the killing of parasites are important in transmission-blocking immunity.

Two studies have shown that the P25 and P28 proteins persist in the oocyst wall for up to 8 days, and that these remain accessible to antibodies. Mosquitoes typically feed every 2–4 days; thus, oocysts would be potentially susceptible to antibodies directed against P25 and P28 proteins taken up with feeds several days after becoming infected. Mouse polyclonal anti-Pfs25 taken up on days 3 and 6 following a feed containing *P. falciparum* gametocytes reduced the number of resulting sporozoites [101]. Monoclonal antibodies recognizing the P28 protein in *P. berghei* (Pbs21) reduced the number of oocysts present and the subsequent number of sporozoites when added to a second mosquito blood feed. The effect was greatest with a second feed 2 days after the primary feed [124]. These experiments have an important implication for transmission-blocking vaccines used in endemic regions where mosquitoes are highly anthropophagic: vaccines may be more effective than expected at less than 100% coverage because there will be several chances for transmission to be blocked following a feed by a mosquito on an infectious person.

## 1. Antigenic Diversity and Natural Immunity

As the P25 and P28 proteins are not expressed at significant levels in the vertebrate host, there is probably no immune selection driving antigenic diversity. Indeed, serological surveys failed to find antibodies directed against Pfs25 in human sera from highly endemic areas [130,131]. Some antigenic diversity has been reported from one study of field isolates. Foo et al. used a panel of monoclonal antibodies that recognized two epitopic regions of Pfs25. Two mAbs recognizing the “epitope II” recognized all 45 Malaysian isolates tested by an immunofluorescence assay (IFA) [53]. Three epitope I mAbs tested on the same parasite panel showed some variation in the IFA positivity. Several isolates gave no or weak fluorescence with one or more mAb. However, it is not clear if these weak IFA results represent true antigenic diversity because sequence data are not available to confirm these observations. The limited polymorphism seen in this study contrasts with the ability of an anti-Pfs25 mAb to block transmission in 13 of 13 field isolates from Cameroon [119] and the very limited diversity found by direct sequencing of the genes. For Pfs25, two amino acids have been found to be polymorphic from isolates tested from eight laboratory lines, 14 isolates from Brazil and 20 from Papua New Guinea [132,133]. Both of these substitutions were highly conservative: an alanine/glycine substitution at amino acid 131 and an alanine/valine substitution at amino acid amino acid 142.

The antigenic diversity of Pfs28 has not been studied. Very limited sequence polymorphism has been observed with a single arginine/lysine substitution observed in seven laboratory lines and 32 field isolates from the Philippines [134]. Greater sequence variation has been seen in Pvs25 and Pvs28 with three amino acid substitutions in Pvs25 and seven point substitutions in Pvs28, and with variation in the number of C-terminal repeats from four isolates [86]. One of the substitutions in the Pvs28 was nonconservative (a lysine/threonine polymorphism substitution at amino acid 65). The remainder conserved amino acid properties.

The low substitution frequencies, the conservative nature of the substitutions, and the likelihood that these have not been selected as a result of immune pressure [94,135] suggest that antigenic diversity will not be a major issue for P25- and P28-based vaccines.

## 2. P25/P28 Vaccine Development

Two major issues face the production of an effective P25- or P28-based vaccine: the production of the antigen in immunologically active form and the development of a formulation that generates a high-level, long-lasting antibody response.

Not surprising in view of the 10 or 11 disulfides present in the mature proteins, initial studies with Pfs25 and Pbs21 showed that antigens produced in *E. coli* were effective at eliciting antibodies, but these had poor transmission-blocking activities [114,136]. Three approaches have been taken to circumvent this obstacle:

- Search for linear epitopes that induce transmission-blocking immunity
- Use of live viral vectors and DNA vaccines to generate folded antigen in situ
- Use of eukaryotic expression systems to produce correctly folded antigen.

Although most mAbs that recognize the P25/P28 proteins are sensitive to reduction of the protein, at least two monoclonal antibodies, 32F81 [137] and 4B7 [116], both block transmission and recognize linear or at least denatured proteins [138]. Based on this observation, Quakyi et al. [139] constructed a series of overlapping peptides spanning the sequence of Pfs25 and tested their ability to elicit transmission-blocking antibodies in mice. Peptides that gave consistent transmission-blocking activity were found, but the levels were low compared to the transmission-blocking activity induced by recombinant proteins, vaccinia constructs, or DNA vaccines (see below).

Although common in extracellular proteins of higher animals, EGF domains have not been found in any lower eukaryotes other than malaria parasites. Consistent with this phylogeny, they are not efficiently synthesized and correctly folded in prokaryotic or lower eukaryotic expression systems [140]. Therefore, vaccination by in situ expression of P25 and P28 family proteins in the vertebrate host is attractive because correct secretion and folding are likely to occur. Vaccinia constructs containing Pfs25 used to immunize mice gave potent transmission-blocking activity at relatively low antibody titers [117]. Pfs25 expression on the surface of

HeLa cells infected with Pfs25 containing vaccinia was readily detected and rhesus monkeys immunized with these constructs made fair titers of anti-Pfs25 antibodies that were able to react with Pfs25 on the surface of zygotes [141]. Thirty-six of 39 human volunteers vaccinated with NYVAC-Pf7, a vaccinia expressing seven *P. falciparum* antigens, had detectable antibodies against Pfs25. However, none of the sera had detectable transmission-blocking activity when mixed with infected blood and fed to mosquitoes in a membrane feeding apparatus [142], although several volunteers generated significant TBI when boosted with a recombinant Pfs25 adsorbed to alum [169].

The DNA vaccines expressing Pfs25 have been tested in mice [109,143]. High antibody levels were obtained with a vector containing a tissue plasminogen activator secretion signal, but not when the Pfs25 was expressed in the absence of a secretion signal [109]. Antibodies induced by this construct gave 95% transmission blocking when assayed in a membrane feeding experiment.

Three approaches have been taken to the expression of correctly folded antigen: expression in baculovirus [120,122, 123] and expression in *Saccharomyces cerevisiae* [96,110–116, 129,140,144].

The baculovirus system has been used to investigate vaccine production and immunization strategies using Pbs21, the *P. berghei* P28 protein. Expression of the full-length Pbs21 resulted in a GPI-anchored, hydrophobic protein that was difficult to purify [145]. Nevertheless, the immunization of mice with crude homogenates of insect cells expressing recPbs21 elicited similar anti-Pbs21 antibody titers as the native protein, and both were comparable at blocking transmission [123]. The removal of the C-terminal hydrophobic sequence resulted in a soluble secreted protein [120,145]. On nonreduced Western blots, this protein lacking the GPI anchor was strongly recognized by a mAb reacting with a linear epitope, but compared to the GPI-anchored recombinant protein, it was weakly recognized by a conformationally dependent anti-Pbs21 mAb. After two immunizations, either intramuscularly or subcutaneously with no adjuvant, native Pbs21 elicited higher antibody levels than the GPI-anchored recombinant Pbs21 and much higher levels than the secreted recPbs21 when assayed on native protein. After a third immunization, the secreted Pbs21 was able to generate high-level antibody and all three gave substantial transmission-blocking activity [120]. It is not clear if the difference in immunogenicity is due to structural differences of the antigen, adjuvant activity in the GPI anchor, or a combination of these. If baculovirus-produced P28 requires a membrane anchor for optimal immunogenicity and structure (as determined by the binding of mAbs recognizing conformational epitopes), then this makes it less attractive for vaccine manufacture.

Initial results of the expression of a recPfs25 (TBV25B) in *S. cerevisiae* were encouraging. The secreted recombinant protein induced transmission-blocking antibodies in mice and monkeys when immunized with Freund's adjuvant or MF59 adjuvant containing muramyl tripeptide, even though a truncation in the construct must have resulted in an incompletely formed fourth EGF domain [116]. This protein reacted with several conformationally dependent mAbs but

not as well as native proteins, suggesting that its conformation was not optimal. Subsequently, it was shown that in mice and Aotus monkeys, the protein was poorly immunogenic without adjuvants, but that alum was significantly more potent as an adjuvant than the MTP/MF59 combination [114,115]. A second-generation construct, TBV25H, which had a complete fourth EGF domain, was prepared, and production conditions were developed for producing materials suitable for Phase I human trials. With alum, TBV25H was more immunogenic than the earlier TBV25B but still showed some heterogeneity on nonreducing SDS electrophoresis [113]. TBV25H bound to alhydrogel has been used in a Phase I trial [169]. This trial was stopped when one of the volunteers experienced an atypical hypersensitivity reaction.

Although a similar *Saccharomyces* system has been used to express a number of P25 and P28 proteins for experimental use, close examination shows that a substantial proportion of EGF domains in malarial proteins expressed by *Saccharomyces* are incorrectly folded [140]. Detailed examination showed that only about 10% of Pfs25 or Pvs25 expressed in this system has all four EGF domains correctly folded. These observations led to a third-generation experimental vaccine based on Pfs25 and Pvs25 that relies on very high expression levels and an efficient purification system to prepare homogeneous, correctly folded antigen. Clinical-grade Pfs25 and Pvs25 have been produced. A Phase I clinical trial with Pvs25 is underway and a trial of Pfs25 will commence in the near future. In preclinical studies, Pvs25 and Pfs25 are able to elicit antibodies that efficiently block the transmission of malaria to mosquito using adjuvants that are, in principle, suitable for human vaccines. For example, when mixed with chimpanzee blood infected with *P. vivax* and fed to mosquitoes in a membrane feeding apparatus,

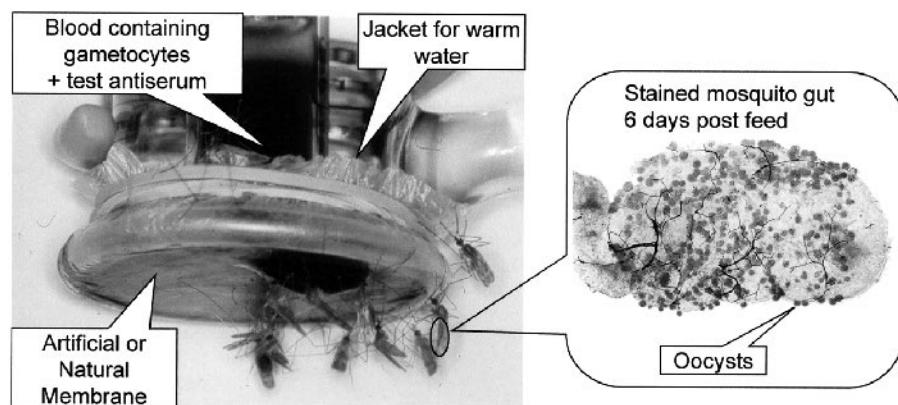

sera from rhesus monkeys immunized with Pvs25 emulsified in Montanide ISA720 adjuvant gave near-total transmission blockage (Figure 3).

At least for Phase I/II trials, a satisfactory method of producing antigen appears to have been achieved. The next challenge that can only be addressed in human trials will be to find a formulation that is well tolerated and elicits long-lasting and potent antibodies.

### C. Other Malaria Proteins

Besides the six-cys motif and the EGF domain proteins, parasite-encoded chitinase and the circumsporozoite protein and thrombospondin-related protein (TRAP)-related protein (CTR) [146] have been identified as having potential as transmission-blocking vaccine components.

Mosquitoes secrete an acellular chitin-containing membrane, the peritrophic membrane, that separates the blood meal from the endothelial cells of the midgut, which malaria ookinetes must cross before they can invade the actual gut wall. Ookinete secrete a prochitinase, activated by endogenous mosquito proteases, that facilitates the passage of the oocinete through the peritrophic membrane [147,148]. Ingestion of allosamidin, a chitinase inhibitor, with the blood meal prevented oocyst formation. Two distinct chitinases secreted by *P. gallinaceum* ookinetes were separated by high-performance liquid chromatography [149] and the gene (*PgCHT1*) encoding one of these has been cloned [149]. An ortholog of this gene, *PbCHT1*, has been identified in *P. berghei* [150] and a gene *PfCHT1* encoding a chitinase in *P. falciparum* [151]. From the structure of the genes and the corresponding proteins, *PbCHT1* is probably the ortholog of *PgCHT1*, whereas the *P. falciparum* *PfCHT1* is likely to be a paralog of the *PbCHT1* and *PgCHT1* and an ortholog

**Figure 3** Transmission blockage of *P. vivax* to mosquitoes by anti-Pvs25 sera from immunized rhesus monkeys. Five rhesus monkeys were immunized with two injections at a 4-week interval with 25 µg of Pvs25H emulsified in Montanide ISA720. Sera were collected 2 weeks after the boost immunization and a 1:2 dilution was mixed with chimpanzee cells infected with *P. vivax* and fed to *A. stephensi* mosquitoes. Control mosquitoes received infected cells mixed with a 1:2 dilution of preimmunization serum from each monkey. Mosquitoes were dissected after 10 days and the number of oocysts present in the mosquitoes fed on the prevaccinated and postvaccinated sera was counted. Percent inhibition was calculated as the  $100 \times [1 - (\text{Number of oocysts in postvaccination feeds}) / (\text{Number of oocysts in prevaccination feeds})]$ . Mosquitoes fed prevaccination sera plus infected red cells had an average of 80 oocysts per mosquito (unpublished data).

of the as yet uncloned gene coding for the second chitinase in *P. gallinaceum* [152]. The two groups of chitinases differ in several aspects. PfCHT1 lacks a putative chitin-binding domain found in PgCHT1 and PbCHT1. It also lacks the proenzyme domain and is fully active when expressed in *E. coli* [151]. Interestingly, an ortholog of PbCHT1 cannot be identified in *P. falciparum* genome, nor can an ortholog of PfCHT1 be identified in the *P. yoelii* genome project, although the PbCHT1 ortholog is present in this database. Therefore, it is likely that *P. falciparum* and the rodent malarias have only one chitinase, whereas *P. gallinaceum* has two genes: one of each type. For both *P. falciparum* [153] and *P. berghei* [150], knockout of the identified chitinase gene reduces the infectivity of ookinetes. Recombinant parasite chitinases will now make it possible to test if this enzyme has potential as a vaccine candidate [8,154].

The CTRP is found in the microneme organelle at the apical end of mature ookinetes [155]. This protein has six copies of an integrin I adhesion domain (also found in extracellular vertebrate proteins such as von Willebrand factor) followed by seven copies of another binding domain, the thrombospondin type I domain [146]. Integrin I and TSP I domains are also found in another *Plasmodium* protein, TRAP, and a TSP I domain is found in the circumsporozoite protein. Similar genes encoding CTRP have been identified in *P. falciparum* [146] and *P. berghei* [156]. Knockout of the CTRP gene from *P. berghei* [155,157] or *P. falciparum* [158] interferes with the motility of the ookinete, invasion of the mosquito midgut, and transformation to oocysts.

Both chitinase and CTRP appear to play critical roles in the development of the mosquito stage parasites. However, both are expressed relatively late in the development cycle of the parasite in the mosquito midgut. It is not clear if sufficient antibodies against these proteins would survive the digestion of blood meal by mosquito proteolytic enzymes long enough to impact on parasite development to make them useful vaccine targets.

#### D. Antimosquito Approaches

The development of a commercial veterinary vaccine for protecting cattle against infestation with cattle ticks [159,160], and for preventing tick-borne disease such as babesiosis demonstrated the feasibility of producing transmission-blocking vaccines by attacking the concealed antigens in the vector. Several target antigens that may form the basis of a TBV have now been identified in mosquitoes.

A trypsinlike protease is secreted by the mosquito gut following a blood meal. Antitrypsin antibodies are able to block the activity of this enzyme and prevent parasite development [161]. Interestingly, these antibodies appear to have no detrimental effect on the mosquito survival or fecundity, and appear to work, not by preventing the digestion of the blood meal, but by preventing the activation of the prochitinase secreted by the ookinete. Because this is required for the parasite to cross the peritrophic membrane, blocking trypsin effectively prevents the escape of the ookinete out of the blood meal bolus.

Polyclonal antibodies raised against midgut proteins of *Anopheles gambiae* block the transition of *P. falciparum* and

*P. vivax* ookinetes to oocysts [162]. Three monoclonal antibodies derived from mice immunized with midgut preparations blocked parasite development, gave a small decrease in mosquito survival, and decreased fecundity. Periodate treatment of extracted gut proteins prevented the binding of two of the mAbs, suggesting that their targets are oligosaccharides.

Unexpectedly, monoclonal antibodies directed against 29- and 100-kDa proteins in the salivary gland, when present in the blood meal, are able to attain a high-enough concentration in the mosquito hemolymph to partially block the invasion of sporozoites into the salivary gland [163]. The mechanism by which antibodies can cross the gut wall and appear in the hemolymph is not known, although there are several reports to show that this is not limited to these particular antibodies.

### III. HUMAN TRIALS AND VACCINE DEVELOPMENT PLANS

With two vaccine candidates Pvs25 and Pfs25 entering Phase I human trials in 2002, issues of how to test and develop TBV are now assuming greater importance.

On one hand, transmission-blocking vaccines have a number of features that simplify their development. These include:

- A well-defined mechanism of action (i.e., neutralization of parasites by antibody)

- A powerful in vitro test, the membrane feed (Fig. 3), that is believed to provide a useful prediction of protection

- Target groups in which the presence or absence of naturally occurring immunity is not likely to be a major modulator of the efficacy of the vaccine.

As a result, it should be feasible to experiment with different formulations, dose, etc., to give optimal transmission blocking in a series of relatively small Phase I vaccine trials. Importantly, from a vaccine development perspective, these tools should provide a solid basis for a decision not to proceed to field trials if the level of transmission-blocking activity elicited in a Phase I trial has been insufficient. Effectively, much of the information (i.e., a demonstration of a biological effect on parasites) that would require Phase II trials of other vaccines will be obtained as part of a Phase I study with transmission-blocking vaccines.

Provided the encouraging results obtained so far with Pvs25 and Pfs25 in preclinical studies translate to human trials, progress through Phase I studies is likely to be relatively rapid. On the other hand, Phase III and preregistration trials of transmission-blocking vaccines, where the aim is to document the level of village-wide reduction in malaria transmission, will require considerable resources. Because these vaccines are unlikely to attract substantial commercial investment, the development of appropriate partnerships between the public and private sectors for the development, manufacture, and deployment of transmission-blocking vaccines will be as important as the underlying biotechnology. An important step toward this goal has been the creation of a

collaborative network of researchers interested in developing and testing transmission-blocking vaccines [8] under the umbrella of the Malaria Vaccine Initiative at the Program for Appropriate Technology in Health (PATH) through a grant from the Bill and Melinda Gates Foundation [8].

## ACKNOWLEDGMENTS

I thank my colleagues at the Malaria Vaccine Development Unit and the MVI Transmission-Blocking Vaccine Consortium, Dr. John Beier, Professor Robert Sinden, and Professor Richard Carter for review of the manuscript and their suggestions. Thanks to Dr. Robert Gwadz for the photographs.

### I. INTRODUCTION

More than a dozen identified and characterized species of the genus *Leishmania* cause diseases, ranging from simple self-healing cutaneous lesions to debilitating and lethal (if untreated) visceral leishmaniasis (VL) known as kala-azar (Table 1). Other less frequent forms are mucosal leishmaniasis (ML), a highly disfiguring disease of oral and nasal cavities, and diffuse cutaneous leishmaniasis (DCL), with hundreds of nodular lesions spread over the body. Self-limiting visceral infections with some *Leishmania* species (*Leishmania infantum* [1], *L. donovani* [2], and, possibly *L. tropica* [3]) may also occur. These asymptomatic individuals as well as cured cases would later develop disease if their immune responses are depressed by drugs or human immunodeficiency virus (HIV) infection, indicating nonsterile immunity following cure [4]. The persistence of parasites in resistant mouse strains long after the recovery of the initial lesion has been documented [5,6], and leishmaniasis recidivans (reappearance of new satellite lesions) around the original healed lesion is occasionally seen with *L. tropica* infection. In this respect, leishmaniasis is considered as an opportunistic infection [7]. All forms of leishmaniasis are naturally transmitted by the bites of female sandflies either from infected humans (anthropontic leishmaniasis) or from infected animals (zoonotic). Generally, there is a good association between the organism and the type of disease it produces in humans (Table 1). However, *L. tropica*, usually the causative agent of anthropontic cutaneous leishmaniasis (ACL), may cause VL as was seen in U.S. soldiers returning from the Desert Storm operation [3], and *L.*

*infantum*, the causative agent of zoonotic VL, can cause CL [8]. Approximately 350 million people are believed to be at risk of infection and the annual incidence of new cases is about 2 million, mostly in children and young adults (1.5 million CL and the rest VL). The current estimated prevalence is 12 million, distributed in 88 countries [9]. These figures do not include epidemics, which can claim the lives of tens of thousands of individuals, eliminate communities, and cause massive migration [10].

With resistance to first-line drugs (antimonials) up to 60%, in certain parts of India, the mortality rate from VL is very high [11]. The pattern of disease has changed dramatically in the past decade in southwestern Europe where HIV infection has shifted from what was a pediatric disease to one of adults. In different countries of Southern Europe, between 25% and 75% of all cases of VL emerge from people infected with the HIV. Moreover, 1.5–9.5% of all patients with acquired immunodeficiency syndrome (AIDS) suffer from newly acquired or reactivated VL (<http://www.who.int/inf-s/en>) in different countries of Europe.

Leishmaniasis is present in all continents except in Oceania, but is restricted to temperate and tropical climates (45° north to 35° south) perhaps due to the survival and activity period of the vectors. More than two dozen sandfly species are vectors of leishmaniasis (*Lutzomyia* in the Americas and *Phlebotomus* in the rest of the world). Transmission by contaminated needles in drug abusers has been documented [12]. Leishmaniasis has diverse epidemiological characteristics, and transmission occurs intradomiciliary or paradomiciliary, or in the wild, with forests, deserts, and mountains making reservoir or vector control difficult or impossible. The first-line drugs (antimonials) developed almost a century ago require repeated injections (4 weeks of daily injections for VL), are costly, are often associated with side effects, and are becoming ineffective in many endemic foci. Therefore, an effective, safe, and affordable

**Table 1** Most Common Etiological Agents of Human Leishmaniasis

Disease	Old world	New world
Cutaneous leishmaniasis	<i>L. tropica</i>	<i>L. mexicana</i>
	<i>L. major</i>	<i>L. amazonensis</i>
	<i>L. aetiopica</i>	<i>L. brasiliensis</i>
	<i>L. infantum</i>	<i>L. panamensis</i> <i>L. guyennensis</i> <i>L. peruviana</i> Others
Mucosal leishmaniasis	<i>L. aetiopica</i>	<i>L. brasiliensis</i> <i>L. guyennensis</i> <i>L. panamensis</i>
Visceral leishmaniasis	<i>L. donovani</i> <i>L. infantum</i> <i>L. archibaldi?</i>	<i>L. chagasi</i> <sup>a</sup>
Diffuse cutaneous leishmaniasis	<i>L. aetiopica</i>	<i>L. amazonensis</i> <i>L. pifanoi</i>

<sup>a</sup> May be the same as *L. infantum*.

vaccine is regarded as the best control means for all forms of leishmaniasis.

Antigenic cross-reactivity among *Leishmania* is so high that sera of patients cannot be used to identify the causative species; hence, it is hoped that with a single vaccine, it might be possible to protect against different *Leishmania* species. Some experimental and epidemiological data support this notion [13,14], but exception is also seen in experimental leishmaniasis [15]. Several reviews have been published on experimental vaccines against leishmaniasis [16–20]. Here we emphasize those in development and in clinical trials.

## II. IMMUNOLOGY OF LEISHMANIASIS

Acquired resistance to leishmaniasis is mediated by T cells. T-cell-deficient mice rapidly succumb after infection with most species of *Leishmania*, and adoptive transfer of normal T cells confers resistance to the animals. Moreover, as mentioned before, patients with AIDS are highly susceptible to leishmaniasis either as a result of concurrent infection, or as a reactivation of older subclinical infection [4]. Among the T cells, CD4<sup>+</sup> are crucial for resistance whereas CD8<sup>+</sup> T cells seem to participate more in the memory events of the immune response than as effector cells involved in parasite elimination. These conclusions were reached from a series of experiments using mice genetically engineered to lack either the class I or class II major histocompatibility complex (MHC) molecules, or in mice lacking CD4 or CD8 cells. In addition, the spectrum of susceptibility of different strains of mice to *L. major* infection has been extremely helpful for the understanding of the genetic control of the disease and the mechanism of protection or susceptibility mediated by different subsets of CD4<sup>+</sup> T cells [21–24]. Hence, the outcome of *L. major* infection in mice is under a multigene control system. Most of these genes do not map in the MHC systems of either humans or mice [25–27]. Resistant strains such as

C3H C57BL/6, CBA/J, or B10D2 normally develop a small lesion, which heals spontaneously within 4–6 weeks, whereas the BALB/c strain is so exquisitely susceptible that even a few metacyclic parasites will cause a full-blown lethal disease that cannot be treated with first-line drugs (antimonials). The BALB/c mice develop a progressive local lesion and a systemic, visceralized disease [28] with a pathology somewhat similar to human VL, including weight loss, hepatosplenomegaly, lymphadenopathy, hyperglobulinemia, anemia, leucopenia and thrombocytopenia, and, finally, death. In addition, this outcome is directly related to the typical Th2 response observed in these animals [29]. Mice of the resistant phenotype clearly develop a dominant Th1 phenotype of immune response to the parasite's antigens and interference with this response will make them susceptible [30,31].

In contrast to T cells, B cells are apparently important only during the early events involving the development of parasite-specific immune response. However, B cells themselves and the specific antibodies they produce are not involved in the host effector mechanisms against the parasites. When B-cell-deficient mice of the resistant phenotype were infected with either *L. mexicana* or *L. donovani*, they did not develop the disease [32–34].

In humans, circumstantial observations that show a direct correlation between Th1 response and resistance are primarily applicable to CL. A predominance of IFN- $\gamma$  producing cells has generally been found in healing cutaneous lesions whereas in chronic cutaneous or mucosal lesions, a mixture of type 1 and type 2 cytokines with a striking abundance of IL-4 mRNA has been consistently found [35,36]. In VL, however, no association with increased IL-4 and active disease could be found. Both splenic IFN- $\gamma$  mRNA and IL-4 mRNA are elevated during active disease, and decline significantly after cure. This same pattern of cytokine profile production occurs after antigenic stimulation of peripheral blood mononuclear cells (PBMCs) of patients with active disease and after cure [37]. However, a direct correlation between IL-10 production and active disease was reported in VL patients [38,39]. In conclusion, human studies similar to the murine observations point to a preferential association of Th1 cytokines with resistance against cutaneous leishmaniasis. Therefore, the design of a vaccine against CL should involve immunization protocols that generate primarily IFN- $\gamma$  and little or no IL-4 responses to the leishmanial vaccine components.

## III. ANIMAL MODELS FOR VACCINE STUDIES

Many *Leishmania* species infect mice, hamsters, and nonhuman primates. In addition, the natural hosts of some parasites [i.e., *Psammomys* (the wild rodent for *L. major*) and dogs (for *L. infantum*)] have been used as laboratory animals. These models have been very important in studying the parasite biology, natural history, and, particularly, the immunology of leishmaniasis as mentioned above. However, none of these animal models has been validated for vaccine studies for human diseases. Although a few investigators have used the resistant strains, the BALB/c and *L. major*

infection have been most extensively used for vaccine studies. It is thought that if a vaccine can protect BALB/c mice, then it should also protect humans. Laboratory animals are usually challenged by cultured promastigotes without the components of sandflies, which have a profound impact on the fate of the infection [40]. Sometimes amastigotes are injected intravenously when promastigote injection intradermally does not produce rapid or uniform infection (i.e., in dogs), or infection with *L. donovani* in mice and hamsters. Skin-associated immune responses are crucial for protection against all forms of leishmaniasis as the port of entry is skin. Hence, a vaccine may protect against an intravenous injection of amastigotes but has no impact against natural disease [41]. To promote infection, promastigotes isolated from infected sandflies just prior to injection of dogs [42], or exudates of salivary glands of sandflies mixed with culture promastigotes have been used in mice [40] and monkeys [43]. Belkaid et al. [44] have developed a model by which infected sandflies deliver the parasite to the ears of mice. This is the most natural mode of delivering the challenge organism; however, it is not easily quantifiable.

#### IV. TARGET ANTIGENS FOR VACCINE DEVELOPMENT

The life cycle of the parasite is relatively simple. *Leishmania* exists in two principal forms: promastigote, the flagellated form in the invertebrate host that can be grown in cell-free tissue culture media, and amastigote, the round intracellular form in the vertebrate's macrophages. There is some differential antigen expression in these two forms and most vaccine candidates are selected to be present at least in the amastigotes, although their presence in promastigotes as well is an added advantage. The promastigotes also undergo antigenic changes in the process of maturation from procyclic (noninfective attached to the wall of the midgut of sandflies) to infective metacyclic form (released to the foregut for delivery during blood meal). This maturation also occurs in culture for most *Leishmania*. These antigens, essentially lipophosphoglycans of the promastigote surface, are considered as possible antigens for transmission-blocking vaccines as are components of sandfly guts [45–49]. Specific antibodies to these antigens transferred to the sandfly during the blood meal could, in principle, prevent the normal maturation of the parasite within the vector.

Another intriguing target for vaccine development against leishmaniasis is the sandfly saliva. Recent observations in mouse models point to a protective effect of the phlebotomine's saliva components against challenge with *L. major*. The mechanism of this protection has not yet been completely elucidated. However, it has been suggested that the immunization of mice with the saliva of *Phlebotomus papatasi* induces a strong delayed-type hypersensitivity (DTH) to the saliva components. When parasites are delivered with salivary gland excretions during a blood meal, a local delayed-type hypersensitivity reaction, which could mediate parasites killing, is induced [50,51]. That a DTH to unrelated antigens at the site of infection could enhance healing was shown long ago [52]. The inclusion of sandfly

components that may induce hypersensitivity in a vaccine given to normal individuals who are exposed to bites of sandflies (mostly uninfected) may not be without risks. Further studies are needed to validate this approach.

#### V. VACCINES IN USE

There is no current prophylactic vaccine available for general use against leishmaniasis. "Leishmanization," an ancient preventive practice, is still used in high-risk populations in Uzbekistan. This consists of inoculating live virulent *L. major* to produce a self-healing lesion at a covered part of the body. This lesion will induce a protective response against natural infection, with multiple lesions on the face and other exposed parts of the body. Resistance to reinfection following recovery from CL was known to be very high when the natural history of the disease was described more than 500 years ago [53]. In its initial practice, pus from an active lesion was used for inoculation. Later, when the parasite was grown in vitro, axenically grown *L. major* was used for inoculation [54,55].

Presently, in Uzbekistan, a mixture of dead and live *L. major* is given, which usually produces a lesion of 1–2 cm in diameter that lasts 3–4 months and heals spontaneously. The Israeli group also used leishmanization in the 1960s and 1970s on over 5000 high-risk individuals [56]. It was noted that the "take" rate of the vaccine dropped precipitously (from 85% to 15%) over the years using the same organism, which was repeatedly subcultured [57]. To overcome this, Greenblatt et al. [58] developed a simple method to produce stabilates by freezing the parasite, which preserved its virulence for long periods. Nevertheless, the program was discontinued due to unwanted side effects, including allergic response in preexposed individuals, long duration of active lesion, and lack of immunity in the "nontake" individuals [59]. Leishmanization was practiced in large scale primarily in soldiers as the last resort in Iran during the Iran–Iraq war in the 1980s [60], following a trial in civilians [59] that showed over 98% efficacy. The leishmanization program was stopped after the war mainly due to the prolonged duration of lesions and the appearance of a few nonhealing cases, which were very difficult to treat. At present, stabilates have been prepared under the guidelines of good manufacturing practices (GMP) and leishmanization is being used in hyperendemic foci following vaccination with killed *Leishmania* vaccines as a live challenge for the evaluation of the efficacy of the killed vaccines (Khamesipour et al., personal communication).

Although antigen selection studies have led to the identification of several candidate molecules and most (but not all) have been produced as recombinant proteins (see "Second-Generation Vaccines" below), none has been taken into clinical development yet. This is primarily because the market for a leishmaniasis vaccine is conceived to be very limited and only of local importance within the endemic regions. Most laboratories do not have the resources required for preclinical and clinical development and the large pharmaceutical industries are not interested because of small markets. The best solution is to promote a vaccine-produc-

ing facility in a developing country (where leishmaniasis is of public health importance) to good manufacturing practices standards and to seek local governments' support for purchasing and distribution. Philanthropic support for the transfer of technology and production under GMP conditions is needed as most donor agencies for medical research are not interested in development. Hence, the generous grant of the Bill and Melinda Gates Foundation has allowed one such candidate vaccine (a trifusion of leishmanial antigens with a novel adjuvant) to enter clinical development with the view of transferring the production to an endemic country to assure low cost and sustainability, should the vaccine prove to be efficacious.

## **VI. FIRST-GENERATION VACCINES (KILLED LEISHMANIA WITH OR WITHOUT ADJUVANTS)**

Whole killed parasites, if given by appropriate route, and adjuvants can protect many experimental animals and hence have been used as a gold standard to evaluate different vaccine candidates. Because most *Leishmania* species can easily be grown in cell-free cultures, killed parasites have been tried as a vaccine much in the same way as early bacterial vaccines. The history of vaccine trials using killed *Leishmania* goes back to the 1920s and 1930s first for immunotherapy and then in the 1940s for prophylaxis (reviewed by Genaro et al. [61]). More recently, Mayrink et al. in Brazil, following the earlier studies of Pessoa [62] and Convit et al. using bacille Calmette–Guérin (BCG) as an adjuvant in Venezuela, initiated vaccine trials with killed *Leishmania* in prophylactic trials as well as therapeutical trials (see below).

## **VII. NEW WORLD (MULTIPLE STRAINS)**

The initial vaccine of Mayrink et al. [63,64] consisted of five different *Leishmania*, and several trials were conducted [65]. Three injections were given intramuscularly 1 week apart to volunteers with a negative leishmania skin test (LST) (also called a Montenegro skin test). The antigen is a low-concentration (5–10 µg) phenol-killed parasite. Vaccination induced LST conversion (>5 mm induration after 48–72 hr) in 35–70% of volunteers in different trials ranging from 480 to 2500 volunteers in each trial. The vaccine was well tolerated, acute adverse reactions were rare (mild pain), and long-time follow-up showed no untoward responses, including the presence of autoantibodies. Collectively, the trials showed the safety of this approach and revealed that skin test conversion is a powerful tool in field studies to monitor the responsiveness of the population. Antunes et al. [65] demonstrated that LST converters have a lower incidence of disease, which has been repeatedly seen in subsequent trials (ALM trial, see Sec.IX). A three-species autoclave-killed vaccine was produced in the laboratory of Armijos et al. [66] and the safety, immunogenicity, and efficacy of two injections against cutaneous leishmaniasis were tested in rural Ecuadorian children in a randomized, BCG-controlled, double-blinded study. Live BCG was used

as adjuvant. Within the 1-year follow-up, the incidence of CL was significantly reduced in the vaccine group compared with the control group (2.1% vs. 7.6%,  $P < 0.003$ ). The protective efficacy of the vaccine was 72.9% (95% confidence interval = 36.1–88.5%). This is the only trial in which a significant difference was observed between killed *Leishmania* + BCG vs. BCG alone.

## **VIII. NEW WORLD (SINGLE STRAIN)**

### **A. Brazil**

A single-strain *L. amazonensis* vaccine was produced by Biobras after a careful comparison of different strains [61]. This vaccine was tested in a dose-escalating trial for safety and skin test conversion [67], and further trials were conducted to analyze the immune responses [68–71]. The vaccine induced primarily a Th1-type response with demonstrable IFN- $\gamma$  but mostly from CD8 $^{+}$  cells—a pattern associated with the healing process in mice [72] and humans [73]. This vaccine was shown to be effective (96% cure) as an adjunct to low-dose treatment with antimonials (15% cure) and is the first human antiparasitic vaccine (therapeutic) to be registered. It is of interest, although so far only for a single case, that this vaccine was effective against mucocutaneous leishmaniasis in a patient concomitantly suffering from AIDS [74].

### **B. Colombia**

Mayrink et al.'s vaccine was formulated by Biobras at higher concentrations for use in combination with BCG, which is given intradermally. This formulation was compared for safety and immunogenicity with the intramuscular formulation in a double-blind, randomized, placebo-controlled trial in Medellin, Colombia [75]. Because of the side effects of BCG (active lesion for about 3 weeks), volunteers refused to receive the third injection; hence, a comparative study could not be completed. Nevertheless, the three injections of Mayrink et al.'s vaccine were shown to be well accepted with minor side effects. There were 86% and 90% LST conversion on day 80 postvaccination and a year later, respectively; there was no antibody production to the vaccine antigens; and the cytokine pattern was that of a Th1 response. Based on this, an efficacy trial has been started in a high-risk population and the results are expected in 2004.

### **C. Venezuela**

Convit et al. were the first to use BCG as an adjuvant and autoclaved *Leishmania* as the immunogen for immunoprophylaxis as well as immunotherapy [76,77]. Without the addition of antimonials, three injections of the vaccine (autoclaved *L. mexicana* + BCG) given a month apart can cure about 90% of CL patients (slightly below drug treatment), but at a much lower cost and with no serious side effects. In contrast, drug treatment (60 injections) produced 18% serious (cardiopathy and renal toxicity) and 16% moderate adverse reactions. Although drug treatment reached

over 90% cure in a shorter time, immunotherapy (three injections) is far more applicable and cost-effective than drug treatment. The BCG treatment alone cured about 40% during the same period. Historical controls without treatment usually take much longer to heal. This treatment is now being given initially, and if patients do not respond to three injections, they will be treated with chemotherapy [78].

#### IX. OLD WORLD (KILLED *L. MAJOR* + BACILLE CALMETTE-GUÉRIN)

Following the establishment of a seed bank from the *L. major*, which was used in the mass leishmanization program (see above), the Razi Institute in Iran produced different formulations of killed parasites, which were tested in randomized, double-blind, and controlled (RDBC) trials with single and multiple injections for safety, dose finding, and immunogenicity [79]. Finally, autoclaved *L. major* (ALM) produced similarly to Convit's method was chosen for efficacy trials at a dose of 1 mg per injection. This preparation has been used for all further trials of ALM + BCG in single or multiple injections against homologous or heterologous parasites [80–82]. All studies were double-blind and randomized, and BCG was used as control. Bacille Calmette-Guérin, rather than a placebo, was used to assure blindness even though BCG clearly converts some individuals (5–15%) from LST<sup>-</sup> to LST<sup>+</sup> (>5 mm), has a nonspecific immunopotentiation, and has antigenic cross-reactivity with *Leishmania*. The results of three efficacy trials of ALM + BCG are shown in Table 2. These consist of a single injection against zoonotic CL [80], a single injection against (heterologous) ACL [81], and two injections against VL [82]. In contrast to the trial of Armijos et al. [66], in none of these trials with ALM + BCG vs. BCG was there a significant difference between the two groups. However, individually

and collectively, these trials produced interesting findings as indicated below:

- (1) In all the trials, the vaccine produced more skin test conversion than BCG alone as expected, but BCG alone also produced LST conversion in 3.2–7.9% of individuals when tested 40–80 days post-injection and as high as 35% after a year.
- (2) In all the trials, the LST-converted individuals had a reduced incidence of disease. This was significant for the homologous trial and the trial with two injections against VL, but although the same trend was seen, the difference was not significant ( $P < 0.6$ ). These findings confirm the earlier studies with the vaccine of Antunes et al. [65].
- (3) The rate of skin test conversion in the volunteers living in the nonendemic regions was significantly higher than that in the endemic regions. This indicates that immunogenicity studies must be conducted in the endemic foci prior to deciding on the dose for formulation in efficacy trials. The reason for this is not clear; however, the LST-negative individuals living in an endemic focus may be genetically "nonresponders," whereas those in the nonendemic focus would be mixed.
- (4) Bacille Calmette-Guérin alone induces LST conversion and may protect a small proportion of volunteers for a short period of time. Bacille Calmette-Guérin is known to have cross-reactive antigens with *Leishmania* and to stimulate the cellular immune response nonspecifically for a limited period of time. Hence, the use of BCG as control in these trials may have obliterated the true protective value of the vaccine.
- (5) The vaccine is not sufficiently immunogenic as presented and stronger adjuvants should be used to enhance its immunogenicity.

**Table 2** Summary of Three Field Efficacy Trials with ALM + BCG

Trial	Vaccine	Disease	Groups	% LST	Incidence per 2 years	Other outcomes
1	ALM + BCG	ZCL <sup>a</sup>	BCG	7.9 (80)	18.5	35% ↓ incidence in LST <sup>a</sup> ( $P < 0.05$ ) ↓ severity in vaccinated children ( $P < 0.04$ )
	Single injection	2453 <sup>b</sup>	ALM + BCG	36.2 (80)	18.0	
2	ALM + BCG	ACL <sup>c</sup>	BCG	3.2 (80)	3.3	Boys protected greater than girls ( $P < 0.01$ )
	Single injection	3637 <sup>b</sup>	ALM + BCG	16.5 (80)	2.8	
3	ALM + BCG	VL <sup>d</sup>	BCG	7 (42)	12.7	43% ↓ incidence in LST conversion ( $P < 0.003$ )
	Double injection	2306 <sup>b</sup>	ALM + BCG	30 (42)	7.2

## X. NEW FORMULATION OF AUTOCLAVED L. MAJOR+BACILLE CALMETTE-GUÉRIN

To increase immunogenicity, the Razi Serum and Vaccine Research Institute, Iran, added alum to the vaccine. Single injections of Alum-ALM plus IL-12 or BCG were shown to protect against CL (caused by *L. amazonensis* [83]) and against VL (after a lethal dose of *L. donovani*) in nonhuman primates [84]. Preliminary safety and immunogenicity human trials with this vaccine are ongoing in Sudan and Iran (Khalil et al., in preparation; Khamesipour et al., personal communication).

## XI. ANTI-LEISHMANIA SUBUNIT VACCINE COMPOSED OF RECOMBINANT PROTEINS

Several investigators, including us, have, over the past decade, searched for gene-encoding leishmanial proteins that could induce protection against cutaneous and visceral leishmaniasis in several experimental models of the disease. Table 3 contains many of the recombinant proteins that have been described and obtained using a variety of lucidly planned cloning strategies [85–99]. However, soon after the great success in producing these recombinant molecules, it became evident that a critical step to successfully deliver them to induce the right type of immune response against leishmaniasis was missing (i.e., the induction of a strong

antigen-specific Th1 response in the absence of a Th2 response). Most of the adjuvants used in these initial experiments, including adjuvants licensed for human use such as alum, and adjuvants used in animal experimentation were not selective, or they stimulated primarily a Th2-type of response. Several different strategies, including IL-12, live vectors, naked DNA, oligonucleotides (CpG sequences), etc., have been tested, aiming to circumvent this impasse. These alternative means of antigen delivery are discussed in detail in Chapters 20–34.

IL-12 injected subcutaneously with leishmanial soluble antigens (SLAs) induces a strong anti-SLA Th1 response and no detectable Th2 response to this antigen. Importantly, this protocol of immunization confers excellent protection in BALB/c mice challenged with *L. major* [100]. Therefore, the presence of IL-12 in the milieu of the antigen stimulation of the T cells by the antigen-presenting cells (APCs) provides the necessary signal that causes the responding antigen-specific T cells to differentiate to a Th1 phenotype [101]. IL-12 has been successfully used as a Th1 adjuvant for a variety of antigens in both the murine and in the nonhuman primate models of several infectious diseases including leishmaniasis [83,98,100,102,103]. One of the drawbacks of IL-12 is the fact that its adjuvant effect is essentially restricted to the modulation of the immune response to the Th1 phenotype (i.e., there is no depot effect and, consequently, the amplitude of the immune response is not augmented as it is for conventional adjuvants). Moreover, in contrast with

**Table 3** Leishmanial Recombinant Proteins Tested as Vaccine Candidates

<sup>d</sup> Combination of TSA + LmSTI1.

conventional adjuvants and with DNA immunization, it seems that the immunological memory to the immunizing antigen is not stimulated appropriately when IL-12 is used as adjuvant. Thus, vaccination of BALB/c mice with the leishmanial antigen LACK mixed with IL-12 as an adjuvant resulted in short-term protection against challenge with *L. major*. In contrast, vaccination with LACK–DNA induced long-term protection. In addition, these studies suggested that the short-term nature of protection could not be overcome by creating a depot condition after immunization with LACK plus IL-12. Thus, mice immunized with a mixture of LACK + IL-12 + alum (added as a component of the vaccine to create the depot effect) developed a strong Th1 response to LACK, but short-term protection could not be overcome by the generation of depot [104,105]. These results question the utility of IL-12 for general use in vaccine development. Moreover, at the present time, the manufacture of IL-12 in large scale is difficult and expensive, imposing serious logistical restrictions to its use in mass vaccination of humans.

Although DNA vaccines are still in relatively early stages of development, they have been shown experimentally to induce excellent protection against several intracellular pathogens including *Leishmania*. Recent studies have demonstrated that DNA encoding the leishmanial proteins LACK, LmSTI1, and thiol-specific antioxidant (TSA) could effectively immunize susceptible BALB/c mice against *L. major* by inducing CD4<sup>+</sup> and CTL responses [104–106]. DNA immunization may provide an effective way to deliver leishmanial vaccines. However, DNA vectors currently available are less effective in stimulating appropriate human immune responses and still require validation and safety studies.

CpG ODN alone has been shown to induce a state of partial resistance in BALB/c mice up to 5 weeks against challenge with *L. major* [107]. If the CpG ODN is injected in conjunction with leishmanial soluble antigen, significant protection is obtained in these animals, which is maintained for as long as 6 months. In these experiments, the immunostimulatory properties of the CpG ODN were associated with the production of IL-12 and the emergence of strong Th1 response to SLA [108,109]. However, further studies are required to optimize CpG ODN as an adjuvant for humans.

## XII. VACCINE DEVELOPMENT WITH THE RECOMBINANT ANTIGENS TSA, LMSTI1, AND LEIF

Based on protection seen in mice and nonhuman primates [98], we have selected three leishmanial antigens to be included as a single protein in a recombinant vaccine. The vaccine will be developed both for prophylaxis as well as therapy for different forms of leishmaniasis.

### A. Thiol-Specific Antioxidant

A novel protein of *L. major* with sequence homology to eukaryotic thiol-specific antioxidant was discovered in experiments performed to characterize the immune responses elicited by *L. major* promastigote culture filtrate

proteins (CFPs). To identify the immunogenic components of the promastigote CFP, serum samples from CFP-vaccinated BALB/c mice, prior to challenge with *L. major*, were used to screen an *L. major* cDNA expression library. Southern blot hybridization analyses indicate that there are multiple copies of the *TSA* gene in all species of *Leishmania* that were analyzed (*L. tropica*, *L. donovani*, *L. infantum*, *L. chagasi*, *L. amazonensis*, *L. braziliensis*, and *L. guyanensis*). Northern blot analyses indicated that the *TSA* gene is constitutively expressed in *L. major* promastigotes and amastigotes. Immunization of BALB/c mice with recombinant TSA protein resulted in the development of strong cellular immune responses and conferred protective immune responses against infection with *L. major* when the protein was combined with IL-12 [97,98].

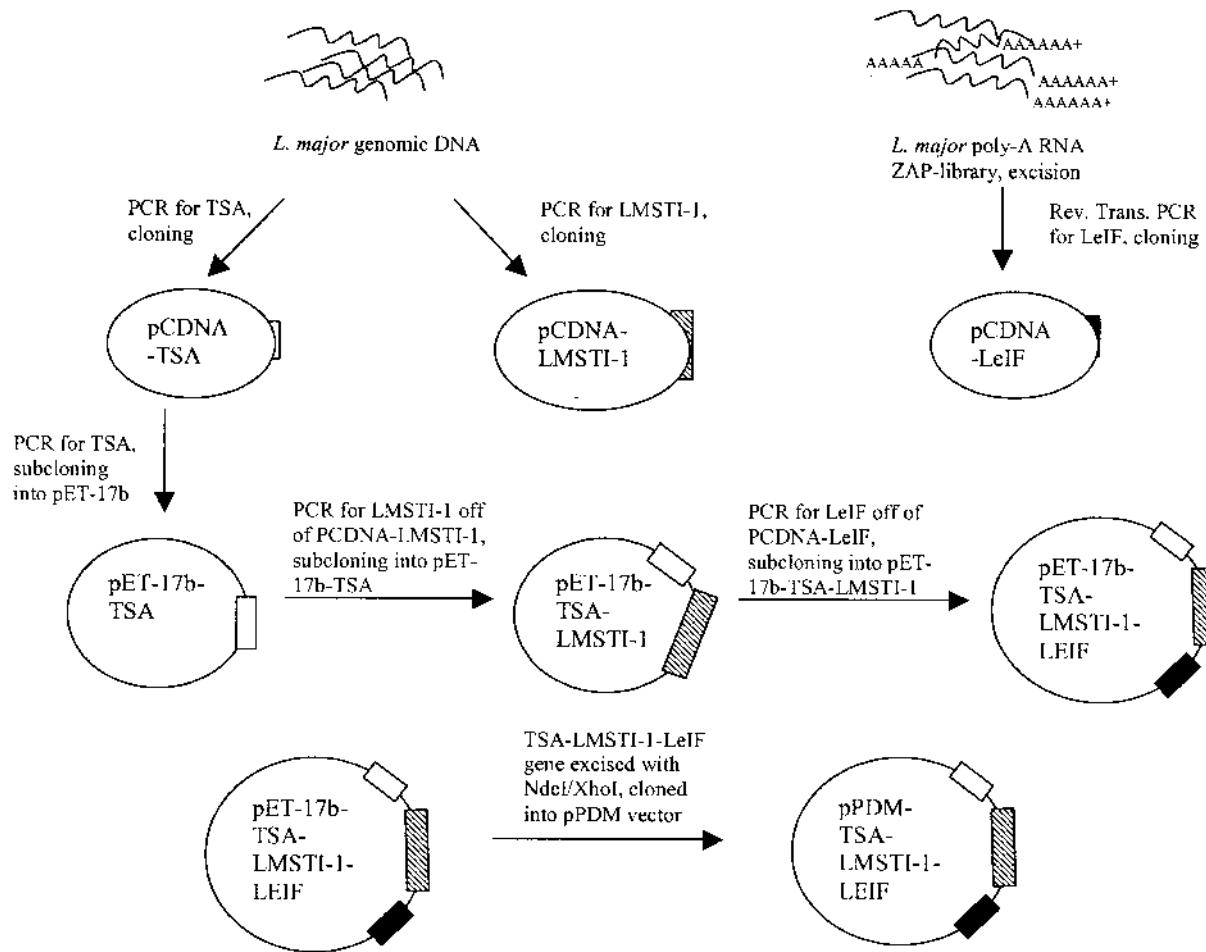

### B. LmSTI1

The screening of an *L. major* amastigote cDNA library with sera from *L. major*-infected BALB/c mice identified one clone with strong homology with eukaryotic Stress-Inducible Protein-1, designated as LmSTI1. LmSTI1 contains six copies of the tetratricopeptide consensus motif that is common to stress-inducible proteins. Recombinant LmSTI1 protein plus IL-12 elicited a mixed cellular response that was skewed toward a Th1 phenotype and protected susceptible BALB/c mice [98,110].

### C. Leishmania Elongation and Initiation Factor

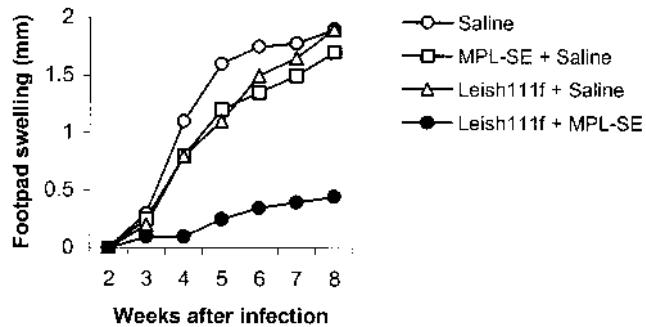

*Leishmania* elongation and initiation factor (LeIF) was identified by expression cloning using sera from a patient with mucosal leishmaniasis to screen a *L. braziliensis* genomic library. Immunoreactive antigens were purified and analyzed in patient T-cell assays for the ability to stimulate proliferative responses and preferential Th1 cytokine production. Several cDNAs were identified, one of which was LeIF, a *L. braziliensis* homologue of the eukaryotic initiation factor 4A, selected because this unique molecule has two important properties: (a) it is a powerful stimulator of the innate immune system for the production of IL-12, IL-18, and IFN- $\gamma$ , and therefore a Th1 inducer; and (b) because of its immunotherapeutic properties in mice infected with *L. major* [90,111,112].

Subsequent to the studies in which we showed that these individual antigens are protective against experimental leishmaniasis in both mice and monkeys, the three proteins LmSTI1, TSA, and LeIF were engineered as a single polyprotein (trifusion or Leish-111f) in tandem. The expression construct for Leish-111f protein was engineered in a multi-step process as shown in Figure 1. First, each gene was cloned into the pCDNA vector: TSA and LmSTI1 were amplified by polymerase chain reaction (PCR) from *L. major* Friedlin strain VI genomic DNA and cloned into the *Bam*H/*Eco*RI sites of the pCDNA vector. The gene for LeIF was amplified by PCR of an excised vector from a ZAP-cDNA library constructed with poly-A<sup>+</sup> RNA from *L. major* and cloned into the pCDNA vector. In the next phase, the fusion was built by first amplifying the individual genes off the pCDNA constructs and subcloning the *TSA* gene into

**Figure 1** Engineering of the expression construct Leish-111f. The engineering of the construct proceeded in three steps: (1) A cloning phase in which each of the coding sequences were cloned from *Leishmania major* Friedlin nucleic acids into pCDNA vectors; (2) a building phase in which the pCDNA vectors were used as templates for PCR to build the fusion construct in pET-17b; and (3) a subcloning step in which the final manufacturing construct (pPDM-TSA-LmSTI1-LeIF) was made.

pET-17b. Next, the gene for LmSTI1 was fused to TSA in pET-17b via a *Bam*H linker. Finally, the amplified gene for LeIF was fused to this construct with an *Eco*R linker. For manufacturing, a variant of pET-28, pPDM, was created by inserting a polylinker sequence from pET-17b into pET-28, resulting in an expression vector with an *Nde*I site in the polylinker and a kanamycin resistance marker. The coding sequence for the TSA-LmSTI1-LeIF fusion from pET-17b was excised by *Nde*I/*Xba*I restriction digestion and cloned into the pPDM vector. This DNA was then transformed into the HMS174 pLysS strain of *Escherichia coli* and used for testing, cell banking, and manufacture. The final construct is shown in Figure 1. This polypeptide (Leish-111f) was then tested in protection experiments in mice challenged with *L. major*. In addition, the adjuvant MPL-SE® was employed instead of IL-12. This adjuvant, a monophosphoryl lipid A derived from *Salmonella minnesota* plus the emulsifier Squalene, has been proven to be an excellent modulator of Th1 responses [113]. More importantly, this adjuvant is suitable

**Figure 2** Vaccination of BALB/c mice against *L. major* with Leish-111f. Mice (five per group) were immunized s.c., in the left footpad, twice (3 weeks apart) with 10 µg of Leish111 plus the adjuvant MPL-SE. Three weeks after the last immunization the mice were infected in the right footpad with 10<sup>5</sup> promastigote forms (metacyclics) of *L. major* and footpad swelling was measured weekly thereafter.

for human use. BALB/c mice immunized with Leish111f plus MPL-SE mounted a strong Th1 response to epitopes of the three individual proteins and, more importantly, they were totally protected against challenge with a high dose of virulent *L. major* ( $10^6$  metacyclic forms) (Figure 2). These highly promising results were the basis for selecting this construct for clinical development. Hence, Leish-111f has now been produced under conditions of GMP at large scale and an IND application has been submitted for conducting Phase 1 studies in the United States. Following safety evaluation and the identification of the optimal dose, clinical trials in endemic foci will commence. The transfer of technology and local production in a leishmaniasis endemic country will follow as soon as safety and protective efficacy are confirmed in clinical trials.

### XIII. CONCLUSION

During the past 4–5 years, several well-designed, double-blind, randomized trials have been conducted using various preparations of killed *Leishmania* (whole parasite) with or without BCG as adjuvant. With the exception of one report from Ecuador (72% protection), little or no efficacy was seen. A lower incidence of disease was seen in those who responded by converting from negative to positive DTH reaction (ranging from 15% to 35% in different trials with different doses). Alum has been added to increase immunogenicity and this formulation has been shown in preliminary trials to induce skin conversion in all recipients. It remains to be seen if the new formulation can induce significant protection against leishmaniasis. It should be noted, however, that the first-generation vaccines are crude antigens and it is difficult, if not impossible, to standardize them. The BCG used as adjuvant, although the most widely utilized vaccine in the world, is not standardized and various strains have different activities. Hence, even if the first-generation vaccines show efficacy, there will still be a need to develop a well-defined, safe, efficacious, and standardized vaccine.

The alternative, developing a second-generation sub-unit vaccine composed of recombinant antigens, is now moving from the laboratory bench to clinical trials. Over the past 5 years, several *Leishmania* recombinant proteins have been tested as vaccine candidates in mice and more recently in rhesus monkeys. A mixture of three leishmanial antigens, TSA, LmSTI1, and LeIF, engineered in tandem as a polyprotein named Leish111f and mixed with the adjuvant MPL-SE (Corixa Corporation, Seattle, WA), consistently induced protection in animals challenged with several *Leishmania* species. In view of these promising results, the first second-generation vaccine (Leish-111f plus MPL-SE) is being formulated under GMP for clinical development. This has become possible because of a generous grant from the Bill and Melinda Gates Foundation to the Infectious Disease Research Institute and the collaboration with Corixa Corporation. The vaccine will be tested both for its prophylactic efficacy as well as therapeutical efficacy. One condition of the grant is an assurance of the affordability of the vaccine, should it be shown to be efficacious. To this end, every effort is being made to transfer the technology of GMP production

to suitable vaccine manufacturing facilities in one of the leishmaniasis-afflicted countries to seek local government support for the reduction of cost.

Of the major human infectious diseases for which vaccines do not currently exist, leishmaniasis represents an opportunity for success. The induction of protective immunity appears to be exclusively T-cell-mediated, with a strong dependence on type 1 cytokines. Intensive work during the last two decades, made possible by molecular techniques, has completely changed the prospects for the development of a safe and effective vaccine for leishmaniasis. Of equal importance is the recent development of potent T-cell adjuvants, which have been shown to be safe and effective in both animal models and in clinical studies. The employment of such adjuvants will expedite the development of a range of new vaccines not possible a decade ago. Furthermore, the demonstration that both whole parasite and defined antigen vaccines can be used to treat incurable drug-resistant leishmaniasis not only provides strong support for the concept of a leishmaniasis vaccine, but indicates that the demonstration of therapeutical efficacy may speed up the development of candidate vaccines. Finally, leishmaniasis vaccine efforts are providing important insights into approaches for the development of safe and effective T-cell vaccines for a range of human diseases.

**Paul B. Bartley and Donald P. McManus**

*Queensland Institute of Medical Research, Brisbane, Queensland, Australia*

### I. INTRODUCTION

Schistosomiasis is a major helminth infection that, even at the beginning of the twenty-first century, still represents an important public health problem in many developing countries. As the second major parasitic disease in the world after malaria, schistosomiasis affects 200 million people, with 800 million at risk of infection. It is estimated that 20 million individuals suffer from severe consequences of this chronic and debilitating disease responsible for at least 500,000 deaths per year.

Infection is characterized by the presence of adult worms in the portal and mesenteric veins of humans and various mammalian species, as part of a complex migratory cycle initiated by cutaneous penetration of infective larvae (cercariae) shed by infected freshwater snails. The infective larvae transform into schistosomula in the skin of appropriate hosts and, over several weeks, develop into sexually mature, egg-laying worms. The adult worms can survive for up to 15 years in the definitive host. Female worm fecundity is characterized by the deposition in mucosae and tissues (in particular liver) of millions of eggs that are responsible for the pathology and disease associated with schistosomiasis.

In spite of undeniable chemotherapeutic progress and the existence of active molecules such as praziquantel (PZQ), there is a considerable spreading of schistosomiasis, particularly in West Africa. The construction of dams and the development of important irrigation schemes are often followed by impressive epidemic outbreaks, as for instance observed in the region of St Louis in Senegal. The massive Three Gorges Dam across the Yangtze River in Southern China, soon to be completed, is expected to significantly increase schistosomiasis transmission and introduce the disease into areas currently unaffected [1]. After some 20 years' experience, it is generally agreed that chemotherapy, although the mainstay of current control programs, does have significant limitations. In particular, mass treatment

does not prevent reinfection. This rapidly occurs in exposed populations in most endemic areas so that within a period of 6–8 months following chemotherapy, the prevalence returns to its baseline level. Efficient drug delivery requires a substantial infrastructure to regularly cover all parts of an endemic area. This makes chemotherapy an expensive and often impractical approach [2]. Although there is still no clear-cut evidence for the existence of PZQ-resistant schistosome strains, decreased susceptibility to the drug has been observed in several countries [3–5]. As a result, vaccine strategies represent an essential component for the future control of schistosomiasis.

Vaccination can be either targeted toward the prevention of infection or to the reduction of parasite fecundity. A reduction in worm numbers is the “gold standard” for anti-schistosome vaccine development but, as schistosome eggs are responsible for both pathology and transmission, a vaccine targeted on parasite fecundity and egg viability also appears entirely relevant. This review considers aspects of antischistosome protective immunity that are important in the context of vaccine development. The current status in the development of vaccines against the African (*Schistosoma mansoni* and *Schistosoma haematobium*) and Asian (*Schistosoma japonicum*) schistosomes is then discussed, as are new approaches that may improve on the efficacy of available vaccines and aid in the identification of new targets for immune attack. Earlier comprehensive reviews of the area are available [6–8].

### II. EFFECTOR MECHANISMS AND CLINICAL EXPRESSION OF IMMUNITY

Research developed on *S. mansoni* and *S. japonicum* for over 20 years has led to the identification of in vitro mechanisms of protective immunity against infection or reinfection in ani-

mal models and in humans. The most significant contributions of these studies have been the demonstration *in vivo* of the protective role of IgE [9] and eosinophils [10]. In humans, epidemiological correlations supporting these experimental observations and arising from several different studies in various parts of the world strongly suggest that IgE may be one of the key components of protective immunity [11,12].

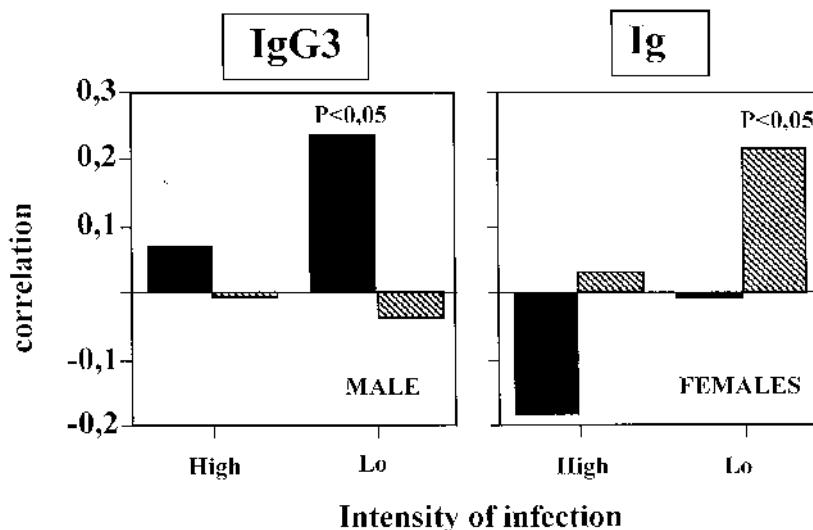

Together with IgE, high levels of IgG4 are produced during helminthic infection. Preliminary evidence was first reported of a significant correlation between susceptibility to reinfection of *S. mansoni* in humans and increased production of IgG4 to defined schistosome antigens [13]. In fact, in subsequent studies, elevated production of IgG4 and IgG2 antibodies was consistently associated with increased susceptibility to reinfection [14]. From these studies, it was concluded that immunity to reinfection was more closely related to the IgE/IgG4 balance than to the absolute level of each isotype. Similar findings have been obtained with *S. haematobium* and *S. japonicum* infections [8,12].

Contrasting effects of IgE and IgG4 could not be dissociated in the analysis indicating that these isotypes were probably antagonizing each other in terms of protection. Although both IgE and IgG4 responses initially depend on IL4 and IL13 production, it has recently been shown that the production of IgG4 antibodies is regulated in an antigen-specific context by IL10 and IFN- $\gamma$  produced by Th0 cells [15]. This supports the view that IgE and IgG4 can be dissociated in spite of their reported dependence on IL4. The putative role of IL10 in the preferential induction of an IgG4 response should be placed in the broader perspective of the general properties of this cytokine. Indeed, it is now well established that IL10 prevents antigen presenting cell (APC)-dependent IgE synthesis and IgE-dependent cytokine

release from host cells causes activation of eosinophils as well as IL5 release [16].

The evidence that IL10 has an inhibitory function toward several essential effector arms of the immune response should prompt further studies on its production profile and biological activity in human schistosomiasis. The clinical expression of immunity to schistosome infection is obviously not simply determined by the mere balance between IgE and IgG4 antibodies. It cannot exclude the participation of additional mechanisms observed in experimental models. The evidence for additional protective mechanisms operating in man has been provided by the recently observed relationship between IgA responses to the protective antigen Sm28GST and acquired resistance. Initial studies in the rat first indicated a potential protective role for IgA antibodies produced after vaccination with Sm28GST, as well as the synergistic association of IgA and IgE antibodies in rat eosinophil-dependent cytotoxicity [17]. A significant association between IgA antibodies to Sm28GST and the age-dependent decrease in egg excretion in infected humans was demonstrated [18]. The potential protective role of IgA antibodies in human schistosomiasis has now been supported by a series of convergent correlation studies in several parts of the word including *S. haematobium* and *S. japonicum* infection (see below). Within the limits of our current knowledge, the effector function of IgA antibodies appears to be associated with a decrease in female worm fecundity and egg viability [19].

Confirming initial observations made in Kenyan populations [17], recent studies in Senegal have shown a significant association between the IgA response to Sm28GST and a decrease in egg excretion, whereas neutralization of glutathione S-transferase (GST) enzymatic activity by antibodies

**Figure 1** Association of specific isotype response in males and females with Sm28GST enzymatic inhibition. Kendall's test was used to evaluate individual correlation of the presence of specific IgG3 and IgA in male ( $n = 76$ ) and female ( $n = 79$ ) volunteers with the neutralizing activity of the serum. Each population was divided into two levels of infection intensity (high and low) according to the geometric mean for both sexes and the WHO Technical Report Series, no. 830. The value of correlation coefficient  $r$  and the significance are indicated. (From Ref. 22.)

appeared closely related with inhibition of female worm fecundity [20]. Again, IgA does not appear to be the only isotype with such neutralizing properties, considering that IgG antibodies have also demonstrated this activity in cattle (*S. mattheei*), primates (*S. haematobium*) [21], and humans [20]. In the latter case, IgG3 to Sh28GST, especially in male populations, seemed to be correlated with the age-dependent decrease in egg output in *S. haematobium* infection [22]. Indeed, before any treatment, specific IgG3 response was predominant in the male population with low intensity of infection, and was associated with maximal glutathione *S*-transferase (GST) inhibition (Figure 1). In contrast, the neutralizing activity of serum samples from women with a low intensity of infection was correlated with high specific IgA response especially directed toward a peptide constitutive to the GST enzyme site (see Figure 2).

The potential role of IgA in immunity to schistosomes and, in particular, its antifecundity effect has led, over the past 3 years, to the development of novel strategies of mucosal immunization. Multiple vectors (synthetic or recombinant live vectors) have been used in the mouse model and have now established for the first time the feasibility of inducing a protective response associated with IgA production against a systemic parasitic disease [23,24]. This will probably lead to second-generation vaccines as soon as the optimal delivery conditions have been defined. Another question arising from these observations concerns the regulation of the IgA response in the general framework of antischistosome immunity. Although our current knowledge of the regulation of the IgA response (notably secretory IgA production) in man remains fragmentary, there are convincing pieces of evidence suggesting that both Th1 and Th2 cytokines are involved. There is also evidence that IL10 and TGF- $\beta$  positively regulate IgA production. It has been

postulated that Th3 cells which produce high amounts of TGF- $\beta$  significantly participate in IgA regulation [22]. This suggests that the overall cytokine pattern expressed in the context of human schistosomiasis might result from a complexity ranging from a simple (Th1/Th2) to a more sophisticated (Th0/Th3) model. Indeed, a continuously changing cytokine profile according to the different developmental stages, together with a continuum of different combinatory of cytokines, is the most likely scenario.

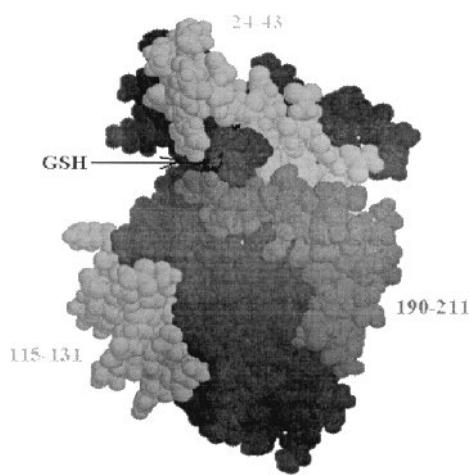

Although the existence of highly complex networks of regulation does not allow any attempt at oversimplification, by and large, it is still the case that clinical expression of protective immunity to schistosomes in human is largely associated with a Th2 profile of immune response, among which distinct mechanisms (either IgE- or IgA-dependent) might be implicated in the control of infection or of egg-induced pathology.

### III. FROM CONCEPTS TO VACCINE DEVELOPMENT—*S. MANSONI*

Based on these immunological studies, the identification and the molecular cloning [25] in the laboratory in Lille of a target antigen (Sm28GST) of the effector response has made it possible in the last 10 years to develop numerous approaches regarding its vaccine potential. At present, of six *S. mansoni* vaccine candidates (Table 1) that have been selected by the World Health Organization (WHO) for further development [6], the 28-kDa glutathione *S*-transferase (Sm28GST) is unquestionably the best-characterized and most promising molecule, and it has already entered into Phase II Clinical trials [6].

Identified as an enzyme, this molecule, initially cloned from a cDNA library from *S. mansoni* [25], has been crystallized [26], making the elucidation of its three-dimensional structure possible (Figure 2). The gene encoding for Sm28GST has been fully sequenced, leading to a series of studies concerning the control of protein expression [27]. Vaccination experiments performed with the recombinant protein [expressed in *Saccharomyces cerevisiae*, in various experimental models (rodents, primates, and cattle)] have demonstrated not only a partial but significant protective effect of the molecule against schistosome infection (reduction of 40–60% of the worm burden); they also provide evidence for a very significant inhibitory effect on female worm fecundity and egg viability [6]. It has been further shown that the inhibition of fecundity and of egg viability is associated with the inhibition of the enzymatic activity of the GST expressed in the N (24–43)- and C (190–211)-terminal regions of the molecule [28]. Research undertaken to identify the immune mechanisms induced by vaccination and implied in the inhibition of parasite fecundity led to the original demonstration of the potential role played by IgA antibodies in animal models [28]. In infected human populations, schistosome antifecundity immunity is associated with IgA and IgG3 responses together with neutralizing antibodies [20].

The extension of these observations to various animal models and to several schistosome species was made possible thanks to the molecular cloning in the laboratory in Lille of

**Figure 2** 3-D structure of the *Schistosoma mansoni* 28-kDa glutathione *S*-transferase. The enzymatic site of the GST implicates the N (24–43)- and C (190–211)-terminal regions of the protein. Specific antibody response against these regions inhibits the enzymatic activity and induces a significant inhibitory effect on the female worm fecundity and egg viability. (From Ref. 28. Image kindly provided by M. Hervé.)

**Table 1** *Schistosoma mansoni* Vaccine Candidates

Antigen and reference	Short form	Size (kDa)	Stage expressed	Particular property	Claimed protection <sup>a</sup> (%)			Legal status	Place of antigen development
					Mouse	Rat	Other

<sup>a</sup> Reduction in worm burdens.

the genes encoding 28 GST from the other schistosome species *S. haematobium*, *S. japonicum*, and *Schistosoma bovis* [29]. It is noteworthy that the C-terminal regions of the various schistosome GSTs, apart from that of *S. japonicum*, exhibit a remarkable degree of conservation and they are very closely homologous.

Preclinical studies performed in primates by homologous and heterologous immunization [30], as well as in cattle, have confirmed the remarkable antiparasite fecundity or anti-egg effect achieved by vaccination—reaching 75–85% in primates and 94% in young calves [31]. Although no cross-protection against challenge could be induced by heterologous immunization (*S. mansoni* vs. *S. haematobium*), a dramatic reduction in egg production and viability has been achieved, entirely consistent with the predictive comparison of the molecular structure of the various GSTs. This effect correlated in all cases with the induction of antibodies capable of neutralizing GST after vaccination, leading to the concept of a cross-species-specific antifecundity vaccine [6].

It is particularly noteworthy that a significant antiworm fecundity effect has now been observed in experiments performed with GSTs of all schistosome species (including *S. japonicum*, see below) by homologous immunization, leading to a wider view of the function of these molecules in schistosomes. In this context, the recent demonstration in the laboratory in Lille that schistosomes release significant amounts of prostaglandin D2 (PGD2), which regulates various stages of the immune response, and the demonstration that PGD2 synthase is an entire homolog of 28 GST [32] reinforces our views regarding the key role played by this enzyme in schistosome biology [33] and its relevance as a vaccine target.

#### IV. FROM CONCEPTS TO CLINICAL TRIALS

All these results have encouraged the initiation of Phase I human trials to evaluate the safety and immunogenicity of the schistosome GST vaccine. Although most of the research of the team in Lille has been primarily based on the model of *S. mansoni* infection, we have decided to concentrate in this initial project on *S. haematobium* GST (Sh28GST), the rationale being based on the following considerations.

1. It has been established that resistance to *S. haematobium* is strongly associated with immune mediated inhibition of parasite fecundity.
2. The methods of quantitative evaluation of eggs in urine through filtration procedures are reliable and easier to handle than stool examinations.
3. Urinary schistosomiasis provides a unique opportunity to follow by noninvasive methods (bladder and urinary tract ultrasound tomography) the evolution of inflammatory lesions associated with infection.
4. It is now well established from various surveys that in adolescents there is a rapid normalization of these indicators following chemotherapy and a rapid reappearance following reinfection. In addition, the existence of a demonstrated synergy between the

immune response and praziquantel treatment provides a unique opportunity to evaluate, under strict ethical conditions, the efficacy of the vaccine in association with chemotherapy compared with chemotherapy alone.

It should also be emphasized that preclinical studies in primates have clearly shown that vaccination performed either with Sm28 or Sh28GST leads to an identical decrease in egg excretion and egg viability after *S. haematobium* challenge.

Sh28GST has been produced under GMP conditions by our industrial partner (Pharos, Eurogentec, Belgium) and named *BILHVAX*. Phase I clinical trials were initiated in September 1998 and performed in Lille at the Center for Clinical Investigation. The main objective of this study, which involved 24 healthy volunteers (Caucasian males), was the evaluation of the safety of Sh28GST immunization and as a secondary objective the evaluation of its immunogenicity.

Consistent with toxicity testing performed in rats, rabbits, and dogs, where no systemic or local toxicity was observed and no cross-reactivity with rat and human GST was detected, no adverse reactions either local or systemic were observed in human volunteers. No cross-reactivity with the human GST(Pi), was detected in spite of high titers of specific antibody produced. The evaluation of immunogenicity led to noteworthy results. Following three injections of 100 µg of Bilhvax in alum hydroxide, a strong immune response was elicited in all immunized individuals. Specific IgG response was significantly induced after the first administration in 6 out of 8 vaccinated adults, the mean IgG titer strongly increased after the second infection, and all vaccinated adults showed positive responses.

Analysis of isotypic profiles indicated that the IgG1 response was predominant; low IgG2 and IgA responses were observed whereas, strikingly, the IgG3 response was high in 7 out of 8 adults. During the Phase Ib trial performed in Saint Louis, Senegal, specific antibody responses observed in healthy children after vaccination (two injections of 100 µg of Bilhvax) showed a similar profile compared to vaccinated adults and a high specific IgG3 response was observed in 10 out of 12 vaccinated children. The most striking feature of the antibody response was the production of high titers of neutralizing antibodies. In the Phase Ia study, all vaccinated adults demonstrated significant titers of neutralizing antibodies, which were strongly boosted after the third injection, reaching a concentration of 100-fold over the IC<sub>50</sub> usually observed in infected patients. It was evident that these antibodies were able to neutralize not only the recombinant, but also the native GST enzymatic activity. During Phase Ib, as observed in adults, two injections of Sh28GST induced a high titer of neutralizing antibodies in all vaccinated children.

As anticipated, no production of Th1 cytokines was observed in Phase Ia or Phase Ib. In contrast, there was a prominent production of IL-5 and IL13, again strongly boosted after the third injection in all vaccinated individuals. Identical cytokine profiles were observed in vaccinated children during Phase Ib, but the production of IL-5 and IL13 was higher, and a significant production of IL2 and IL10 was observed. The follow-up of vaccinated individuals, during

the 4-month period after the first shot, indicated that Bilhvax induced a high and lasting specific immune response associated with a Th2-type profile generally regarded as associated with protective immunity in human schistosomiasis [34].

It is also particularly noteworthy that the major features of the immune response induced by vaccination in humans are perfectly consistent with the concepts that our Lille group had derived from our studies of experimental models. In particular, if the close association between neutralizing antibodies and the inhibition of parasite fecundity already observed in experimental models and in human infected populations can be regarded, based on these results, as a surrogate marker of vaccine efficacy, then we have undoubtedly moved a significant step toward the feasibility of a clinical vaccine against one of the major human parasitic disease [35].

## V. VACCINES AGAINST *S. JAPONICUM*— BASIC CONSIDERATIONS

Schistosomiasis japonica is endemic in Southern China and the Philippines [36]. As stressed earlier, the control of schistosomiasis requires an integrated approach involving large-scale population-based chemotherapy in addition to environmental and behavioral modification [37]. Further, population movements [1] and the construction of dams already referred to, have contributed to the spread of schistosomiasis into new areas. As with the African schistosomes, there is therefore an important role for a vaccine to provide long-term prevention against Asian schistosomiasis. Unlike *S. mansoni* or *S. haematobium*, mammals other than humans (such as dogs, bovines, and pigs) can act as definitive hosts for *S. japonicum*. Zoonotic transmission adds to the complexity of control programs, but may provide opportunities for novel approaches in vaccine development to prevent human disease. When available for wide-scale use, it is envisaged that the vaccine would be applied in the first instance, at least in China, in water buffalo reservoir hosts (to impact on human transmission), and then, perhaps, if required, clinically (to prevent or reduce disease).

Recent progress has provided the basic framework for the development of an effective vaccine against this complex parasite. Schistosomulum lifecycle stage antigens are likely to be major vaccine candidate targets of protective immune responses. As with the *S. mansoni* mouse model, vaccination with radiation-attenuated cercariae induces significant levels of resistance to *S. japonicum* challenge in mice, rats, rabbits, sheep, and bovines [8]. Worm burden reduction ranges from 40% to >85%—with less protection evident in mice than rabbits or larger animals. Like *S. mansoni*, the initial protection is conferred by Th1 cellular immunity with lymphoid proliferation in regional and mediastinal lymph nodes. Subsequent vaccination (at least in mice) did not appear to confer additional protection. Appropriately timed passive transfer of sera from vaccinated mice can also confer protection. This protection is antibody-mediated, with predominantly IgG (less so by IgM) antibodies acting on the lung schistosomula stage. IgE depletion did not influence protection in these studies. Some later studies suggest that both Th1 and Th2 responses may contribute to protection [8].

Human immunity to *S. japonicum* has been predominantly assessed by reinfection and immune-correlative studies. As in *S. mansoni* and *S. haematobium*, acquired immunity to *S. japonicum* develops with age [8,12]. Like the African schistosomes, a high IgG4/IgE ratio to adult worm antigen (AWA) and soluble egg antigen (SEA) correlates susceptibility to reinfection, whereas IgE excess correlates with resistance to reinfection [38]. Further, peripheral blood mononuclear cells taken from resistant individuals in China produce significantly greater amounts of IL-10 in response to parasite extracts and recombinant antigens in vitro [39]. Preliminary field studies from the Philippines suggest that IgE antibodies to a 22.6-kDa tegument-associated antigen (Sj22.6) are associated with resistance to reinfection [8]. It should be stressed that, whereas much of our understanding of the effector mechanisms and clinical expression of immunity against *S. japonicum* has been extrapolated from the extensive studies on *S. mansoni* and *S. haematobium*, this may prove not to be the case, so different are the African and Asian schistosomes.

## VI. VACCINES AGAINST *S. JAPONICUM*— CURRENT STRATEGIES

While offering, in some cases, high levels of protection, the irradiated cercarial vaccine is impractical, cumbersome, and impossible to standardize. Additionally, the protection conferred is species- and often strain-specific. Therefore considerable efforts have been made aimed at the identification of relevant schistosome antigens that may be involved in inducing protective immune responses, with a view to developing either a recombinant protein, synthetic peptide, or DNA vaccine [8]. As emphasized earlier, coordinated laboratory and field research have identified a set of well-defined *S. mansoni* molecules with protective potential with the *S. mansoni* and *S. haematobium* 28-kDa GSTs being the best characterized and most studied of the candidate vaccine antigens. Several of these molecules are also recognized as major vaccine targets against *S. japonicum* (Table 2). One leading candidate is paramyosin.

Paramyosin is a 97-kDa myofibrillar protein with a coiled-coil structure and is exclusively found in invertebrates. It is expressed on the surface tegument of lung-stage schistosomula and may function as a receptor for Fc [40]. Native and recombinant paramyosin confer significant protection (approximately 35% decreased worm burden and 45% decreased liver egg burden) against *S. japonicum* in mice and buffaloes [41]. There is greater than 95% homology between the paramyosin genes of *S. japonicum* (Chinese and Philippine strains), *S. haematobium*, and *S. mansoni* [41]. This may facilitate development of a “consensus” molecule as a vaccine against all three human pathogens should efficacy be improved. Currently, mathematical modeling of the likely benefits of rec-Sj-97 at its current level of efficacy as an antifecundity vaccine suggest it would prove a useful adjunct to existing control programs [1,42].

A calcium-activated neutral proteinase (calpain) may be another “consensus molecule” vaccine. It has been identified in *S. mansoni* and *S. japonicum*, and has been localized to the

**Table 2** *Schistosoma Japonicum* Vaccine Candidates

Antigen <sup>a</sup>	Short form	Size (kDa)	Stage expressed	Biological function(s)	Claimed protection <sup>b</sup> (%)	
					Mouse	Other
Paramyosin (native)	Sj97	97	Somula Adult	Contractile protein + others	27–86	31–48 (sheep/cattle)
Paramyosin (recombinant)	recSj97	97	Somula Adult	Contractile protein + others	20–60	7–60 (buffalo/pigs/sheep)
Triose phosphate Isomerase (native)	TPI	28	All stages	Enzyme	21–24

<sup>a</sup> All in public domain.<sup>b</sup> Reduction in worm burdens. Significant egg reduction also recorded with the majority of candidates. (See Refs. 8,41 and 45.)

extracellular domain [43]. The protein is recognized by sera from infected patients. Vaccination results in approximately 40% reduction in worm and egg burdens in mouse models of *S. mansoni* and *S. japonicum* infection. The *S. mansoni* and *S. japonicum* 22.6-kDa (Sm22.6 and Sj22.6) tegument-associated antigens may also be useful vaccine targets. While the function of this family of proteins remains unknown, they are expressed near the surface of lung-stage schistosomula [44], and specific IgE and IgA antibodies appear associated with resistance to reinfection in human studies [8]. Mouse studies of bacterially expressed and purified recombinant Sj22.6 have demonstrated specific IgG and IgE production but no protection [44]. Also, vaccination with *Escherichia coli* and baculovirus-expressed recombinant *S. japonicum* aspartic protease—cathepsin D—generated high levels of specific antibodies but only a limited level of protection [45].

More encouraging results have been obtained with recombinant 26-kDa GST of *S. japonicum*, which induces a pronounced antifecundity effect, as well as a low but significant level of protection in terms of reduced worm burden. The molecule is capable of stimulating antifecundity immunity in mice (up to 59% decrease in liver eggs) [46] and pigs (53.5% decrease in liver eggs) [47], following challenge infection with *S. japonicum*. Similar vaccination experiments have been carried out on water buffaloes (*Bos taurus*), the major reservoir for transmission of schistosomiasis japonica in China, using purified reSjc26GST in order to investigate its vaccine potential [48]. Anti-Sjc26GST antibodies were produced in the immunized buffaloes and, following challenge with *S. japonicum* cercariae, a small but significant reduction in worm numbers was evident in vaccinated subjects when compared with control animals. The typical antifecundity effect was manifest, characterized by a significant decrease in fecal egg output and eggs deposited in host tissues with those in the liver and intestine being reduced by

about 50%. In addition to the antifecundity effect, reSjc26GST reduced by nearly 40% the egg-hatching capacity of *S. japonicum* eggs into viable miracidia.

In summary, all of the proteins mentioned above have shown some promise as candidate vaccines although they generally produce modest reductions in worm and egg burdens. It is important, therefore, to explore alternative vaccination strategies to improve vaccine efficacy, and to identify new target antigens.

## VII. VACCINATION AGAINST SCHISTOSOMES—DNA VACCINES

DNA vaccination offers many potential advantages including cost-effective production, thermal stability and the ability to induce a wide variety of immune responses—including induction of cytotoxic T-lymphocytes (CTLs) [49,50]. In addition to schistosomiasis, DNA vaccination is being explored for a wide variety of parasite, including helminthic infections [49,51]. Large reductions in parasite burdens have been demonstrated in animal models of some of these infections namely: *Taenia crassiceps* [52], *Fasciola hepatica* [53], and *Onchocerca volvulus* [54]. A prime-boost strategy of DNA vaccination followed by recombinant modified vaccinia virus Ankara (MVA) encoding pre-erythrocytic stage antigens has induced sterilizing immunity to malaria [55,56]. Similar prime-boost strategies have conferred protection against influenza [55] and swine fever [57]. A DNA prime-protein boost strategy using the *Plasmodium falciparum* 175-kDa erythrocyte binding protein induces a significant reduction in parasitaemia in *Aotus* monkeys [58]. Prime-boost vaccination along similar lines may prove valuable against schistosomiasis.

**Table 3** Some DNA Vaccines Tested in Mice Against *Schistosoma* spp.

Organism	Vector	cDNA	Method	Specific immune response	Worm burden reduction (%)	Egg burden reduction (%)
<i>S. japonicum</i>	VR1020 (Vical Inc., USA)	22-kDa Tegument antigen	Gene gun	Yes	Nil	Nil
<i>S. japonicum</i>	VR1020 (Vical Inc., USA)	Paramyosin	IMI—Quadriceps	Yes	Nil	Nil
<i>S. japonicum</i>	PcDNA1/Amp	Paramyosin	IMI— <i>Tibialis anterior</i>	Yes	35–40	50–80
<i>S. mansoni</i>	pNI	28 kDa GST	IMI—IL-18 plasmid adjuvant	Yes	23	28
<i>S. mansoni</i>	pcDNA1.1	Sm23 surface protein	IMI—IL-12 or IL-4 plasmid adjuvant	Yes	20–44	Not evaluated
<i>S. japonicum</i>	VR1020 (Vical Inc., USA)	Sj62, Sj28, Sj23 and Sj14-3-3	IMI—Cocktail vaccination ± IL-12 plasmid adjuvant	Yes	40	Not evaluated
<i>S. japonicum</i>	VR1020 (Vical Inc., USA)	62 kDa myosin	IMI—Naked DNA or liposomal	Yes	Nil	Nil

Indeed, there has already been considerable interest in the development of a DNA-based vaccine against schistosomiasis (Table 3). The modulation of immune responses possible with DNA vaccination renders this as an attractive prospect, given what is known about human and animal immunity to schistosomes. DNA vaccines tested to date have included plasmid DNA of *S. japonicum* paramyosin [59,60] and 62-kDa myosin [61], *S. japonicum* 22-kDa [62] and 23-kDa [63] tegument-associated antigens, *S. japonicum* 28-kDa GST [64], *S. mansoni* 28-kDa GST [65–68], *S. mansoni* 23-kDa integral membrane protein (Sm23) [69], and *S. mansoni* calpain [70].

Unlike vaccination with native or recombinant protein [41,71], DNA vaccination with paramyosin has yielded conflicting results. Early studies demonstrated specific antibody production without protection [59]. However, another group [60] recently demonstrated a 35–40% reduction in worm burden and 50–80% reduction in visceral egg burdens following intramuscular DNA vaccination into the *tibialis anterior* muscle of a different inbred mouse strain. The authors concluded that the differences in mouse strain and site of injection could account for the contrasting results. It is well described that intramuscular immunization (IMI) of DNA vaccines into the *tibialis anterior* induces significantly greater immune responses than IMI into the quadriceps muscle in mice [50]. DNA prime-protein boost with paramyosin is an attractive prospect.

DNA vaccination with either the 22- or 23-kDa *S. japonicum* tegument-associated antigens [62,63] has induced high titers of specific murine antibodies without protection. This is despite manipulation of the route of administration and fusion of the antigen cDNA to an Ig κ-chain secretory leader sequence [62]. Equally, DNA vaccination with a 62-kDa fragment of *S. japonicum* myosin did not induce protection in several strains of mice despite cationic lipid adjuvant and additional CpG motifs [61].

DNA vaccine plasmids encoding Sm28GST have also been the subject of much interest [65–68]. These vaccines

induce specific antibody responses which are boosted by challenge infection [66]. These antibody responses can mediate antibody-dependent cytotoxicity against schistosomulae [66] and also assist in immune-mediated killing of injured adult worms [68]. When coadministered with an IL-18-encoding plasmid, profound Th1 stimulation occurred with a 28% reduction in worm burden [67]. In general, however, Sm28GST DNA vaccines appear to evoke less protection than the recombinant protein.

DNA vaccines containing cDNAs from two other *S. mansoni* surface-associated proteins (calpain and Sm23) have undergone initial protection trials with promising results [69,70]. The Sm23pcDNA vaccine elicited a 21–44% reduction in worm burden in mice [69]. Protection was not enhanced by the addition of plasmids encoding either IL-12 or IL-4 to influence the immune response toward Th1 or Th2, respectively. A DNA plasmid encoding the large calpain subunit (p80) conferred a 60% reduction in worm burden [70]. Interestingly, the 5'UTR of p80 needed to be included in the DNA vaccine for this protection to be achieved. Vaccination of mice with “cocktail” DNA vaccines is another potentially promising avenue. A recent report demonstrated modest reduction of worm and egg burdens with a cocktail of DNA plasmids encoding four *S. japonicum* tegument-associated peptide antigens [72]. The recent assembly of multiple defined and different epitopes of *S. mansoni* into a variety of covalent structures, including a DNA plasmid vaccine encoding different epitopes in tandem, failed to protect mice from subsequent challenge infection [73].

### VIII. VACCINATION AGAINST SCHISTOSOMES—NEW ANTIGEN DISCOVERY

Secreted or transmembrane proteins are likely to encounter the host immune system and are, therefore, potential vaccine

candidates. This portion of the schistosome proteome is poorly characterized. Only 30 of the ~15,000 schistosome DNA expressed sequence tags (EST) in public databases, are known to possess coding sequence for signal peptides. Signal peptides are positioned at the N-terminus of secreted protein precursors. They initiate export of the precursor proteins across the endoplasmic reticulum. The ratio of known proteins with predicted signal peptides to ESTs is far greater in other parasites (e.g., *Brugia malayi*). It is therefore rational to identify additional schistosome cDNAs that encode proteins with functional signal peptides and assess their efficacy as vaccine candidates—in addition to determining their biological function. This approach is very much in its infancy. An alkaline-phosphatase signal sequence trap method [74] has been used to isolate sequences encoding secreted and transmembrane proteins from *S. mansoni* adult worm cDNA [75]. Among the 18 clones identified and sequenced to date, two encode novel tetraspanin-like proteins, five sequences have no known homologs, and several others are homologous to known *S. mansoni* ESTs. There is a likelihood of discovering a group of important secreted and surface schistosome proteins, potentially involved in central roles in the schistosome host–mammal relationship. In addition to the determination of their biological functions and interactions, some proteins may also be interesting vaccine candidates.

B-cell antigenic determinants appear to be dependent on the conformational integrity of the molecule in question. Conformational epitopes may be important in generating protective immunity against parasites. One example is the recent determination that the protection conferred against experimental cystic hydatid disease by the EG95 vaccine, a recombinant oncospherical protein, relies on conformational integrity rather than linear epitopes [76]. Indeed, the absence of tertiary structure and therefore conformational epitopes in the recombinant Sj22.6 vaccine is one possible explanation for the apparent lack of protection associated with this molecule [44]. Clearly, further evaluation of synthetic protein vaccines may need to take conformational epitopes into consideration. Likewise, improved efficacy of antischistosome vaccines may require more powerful adjuvants than those currently available for clinical use. In this respect, the recent demonstration that Lewis-type carbohydrate Lacto-N-fucopentose III (LNFPIII) found on *S. mansoni* egg antigens is a potent inducer of a Th2-type response and can also act as an adjuvant by inducing antibody against coupled protein antigen (human serum albumin) [77] suggests this molecule might prove useful for future development as an adjuvant for application with schistosome vaccines.

## IX. CONCLUDING COMMENTS

Taking the breadth of consolidated, international efforts to generate antischistosome vaccines, there is considerable optimism that these endeavors will prove successful [8,78]. Indeed, the promising preclinical trials with the Sh28GST vaccine followed by very encouraging Phase Ia and 1b human trials auger well for Phase II and Phase III efficacy trials underway or planned for the future. In addition, re-

markable recent progress in schistosome gene discovery [79,80] may lead to the identification of additional vaccine candidate molecules. When developed and employed, anti-schistosome vaccines will not be a panacea. They need to be regarded as one component, albeit a very important one, of integrated schistosomiasis control programs that complement existing strategies including chemotherapy and health education.

## Vaccines Against *Entamoeba histolytica*

Christopher D. Huston\* and William A. Petri, Jr.

University of Virginia School of Medicine, Charlottesville, Virginia, U.S.A.

### I. INTRODUCTION

Amebic colitis and liver abscess are due to infection with the enteric protozoan parasite, *Entamoeba histolytica*. This parasite has recently been separated using modern diagnostic techniques from the nonpathogenic parasite *E. dispar*, which is more common and identical in appearance to *E. histolytica* [2]. The World Health Organization (WHO) estimates that approximately 50 million people worldwide suffer from invasive amebic infection each year, with a resultant 40,000–100,000 deaths annually [1]. Infection with *E. histolytica* occurs worldwide, but people living in Central and South America, Africa, and India suffer from the bulk of the morbidity and mortality [2,3]. Carefully conducted serological studies in Mexico, where amebiasis is endemic, demonstrated antibody to *E. histolytica* in 8.4% of the population [4]. In the urban slum of Fortaleza, Brazil, 25% of the people tested carried antibody to *E. histolytica*; the prevalence of antiamebic antibodies in children aged 6–14 years was 40% [5]. A prospective study of preschool children in a slum of Dhaka Bangladesh demonstrated new *E. histolytica* infection in 39% of children over a 1-year period of observation, with 10% of the children having an *E. histolytica* infection associated with diarrhea and 3% with dysentery [6].

Recent advances include not only the reclassification of *E. histolytica* from *E. dispar* but also the identification of several amebic proteins associated with virulence, which are potential vaccine candidates [7–10]. More is also becoming known about the human immune response to amebic infection, and about the feasibility of a vaccine. This chapter summarizes the current knowledge of how *E. histolytica* causes invasive disease, the role of the host innate and acquired immune responses to limiting amebic infection, and recent progress in the development of a vaccine for amebiasis.

### II. PATHOGENESIS

It is generally accepted that *E. histolytica* invades tissues and causes clinical disease through a well-defined sequence of events that starts with the ingestion of the infectious cyst form of the parasite from fecally contaminated food or water [11–14]. Excystation of the amebic trophozoites occurs in the intestinal lumen. The trophozoites adhere to the colonic mucus and epithelial cells through the binding of a parasite galactose and N-acetyl-D-galactosamine (Gal/GalNac)-inhibitable lectin with host Gal/GalNac-containing glycoconjugates [7,15]. Secretion of proteolytic enzymes by the parasite may aid the disruption of the intestinal mucus and epithelial barrier, and may facilitate tissue penetration [8]. The trophozoite kills host epithelial and immune cells at points of invasion, causing the characteristic flask-shaped colonic ulcers for which it is known. Finally, *E. histolytica* resists the host's immune response and survives to cause prolonged extraintestinal infection such as amebic liver abscesses.

### III. ADHERENCE

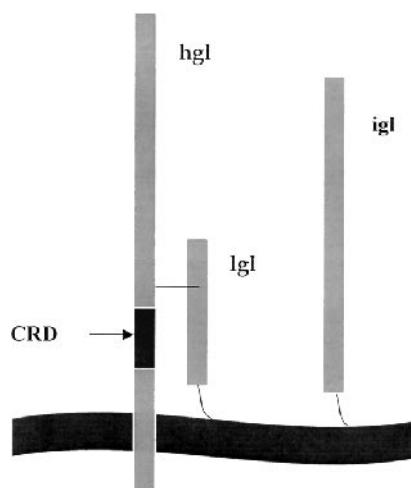

The adherence of *E. histolytica* trophozoites in vivo to the colonic mucosal surface occurs prior to tissue penetration or cytotoxicity [12–14]. The adherence of the parasite to the host is mediated by a parasite lectin that binds to N-acetyl-D-galactosamine and D-galactose (Gal/GalNAc) (reviewed in Ref. 7) [15,16]. The blockade of amebic Gal/GalNAc lectin activity with millimolar concentrations of Gal or GalNAc prevents the contact-dependent cytotoxicity for which the organism is named [16]. Additionally, Chinese hamster ovary (CHO) cell glycosylation-deficient mutants lacking terminal Gal/GalNAc residues on N-linked and O-linked sugars are nearly totally resistant to amebic adherence and cytolytic activity [17,18]. Importantly, the Gal/GalNAc lectin also mediates adherence to human neutrophils, colonic mucins, and epithelial cells—the in vivo targets of *E. histolytica* [7,19]. The disruption of the lectin (via inducible expression in the parasite of a dominant-negative mutant of

\* Current affiliation: University of Vermont College of Medicine, Burlington, Vermont, U.S.A.

the lectin) inhibits amebic abscess formation in an animal model [20].

The Gal/GalNAc lectin is composed of a 260-kDa heterodimer of disulfide-linked heavy (170 kDa) and light (35/31 kDa) subunits, which is noncovalently associated with an intermediate subunit of 150 kDa (Figure 1) [15,20–26]. The 170-kDa subunit contains a carboxyl-terminal cytoplasmic and transmembrane domain adjacent to a cysteine-rich extracellular domain [23,24]. Five distinct genes (termed *hgl1*–*hgl5*) encoding the lectin's heavy subunit have been identified and at least partially sequenced in strain HM1: IMSS, and simultaneous expression of three different heavy subunit genes has been demonstrated in cultures of trophozoites [25]. At least 89% sequence homology exists within this gene family, and the number and location of every cysteine residue are conserved [22,23,25]. The carbohydrate recognition domain (CRD) is located within the cysteine-rich domain of the heavy subunit [26,27]. A peptide encompassing cysteine-rich region amino acids 895–998 expressed in *Escherichia coli* has been shown to bind to Gal/GalNAc in vitro [26].

The function of the light and intermediate subunits of the Gal/GalNAc lectin remains unclear. Six to seven gene loci and at least three unique genes coding for the light subunit exist and are simultaneously expressed [25]. Interference with the overall production of light subunit via antisense production results in a reduction in heterodimeric lectin and a decrease in cytotoxicity [28]. The intermediate subunit is encoded by two genes, which share 81% amino acid sequence

**Figure 1** Gal/GalNAc adherence lectin of *E. histolytica*. The Gal/GalNAc lectin mediates parasite adherence to and killing of host cells. It is present on the plasma membrane of the ameba and is composed of three subunits. The integral membrane heavy subunit (hgl) has a short cytoplasmic tail implicated in intracellular signaling. The CRD is located within hgl. Hgl is disulfide-bonded to a lipid-anchored light subunit (lgl). Finally, the lipid-anchored intermediate subunit (igl) is noncovalently associated with the hgl-lgl heterodimer. The functions of lgl and igl in adherence and killing are unknown.

identity and are in turn members of a much larger family of amebic genes containing CXXC and CXC motifs [22].

#### IV. INVASION

In most human infections, the host remains asymptomatic [6,30,31]; alternatively, the trophozoite may penetrate the colonic mucus and epithelial barrier in a first step toward invasive disease. Penetration of the lamina propria can occur in the absence of local inflammation [12,13]. A discussion of parasite mechanisms of invasion can logically be divided into the roles of amebic proteinases and contact-dependent cytotoxicity [32].

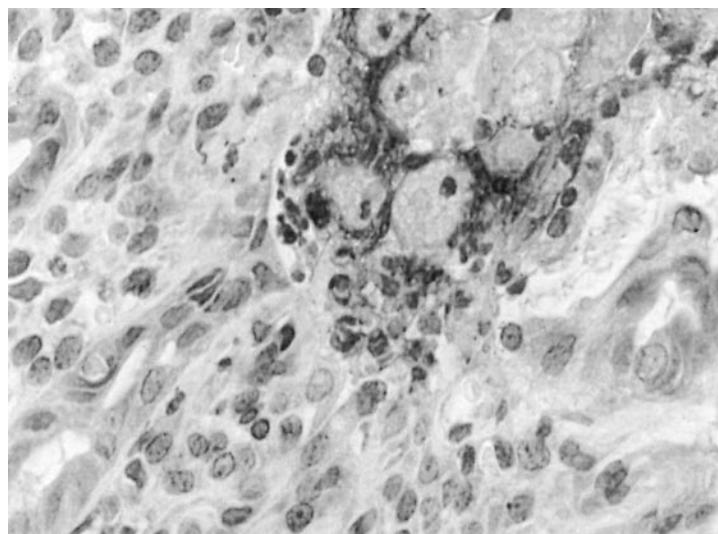

Two classes of amebic proteinases believed to play a role in pathogenesis have been isolated: thiol (cysteine) proteinases, which are secreted as well as located on the amebic cell surface, and a surface-bound metallocollagenase (reviewed in Ref. 8). Several investigators have independently purified amebic cysteine proteinases and have confirmed their ability to degrade relevant tissue proteins in vitro including type I collagen and the anchoring proteins fibronectin and laminin [33–35]. The cysteine proteinases also degrade IgA, IgG, and the complement anaphylatoxins C3a and C5a [36–39].

A total of six distinct *E. histolytica* genes (termed *EhCP1*–*EhCP6*) encoding typical precursors of cysteine proteinases have been identified and partially sequenced [40]. Cysteine proteinase activity in lysates from various *E. histolytica* isolates can be almost completely attributed to the expression of three of these genes: *EhCP1*, *EhCP2*, and *EhCP5*. *E. dispar* carries genes homologous to four of the six genes carried by *E. histolytica* (termed *EdCP2*, *EdCP3*, *EdCP4*, and *EdCP6*), but appears to lack genes similar to *EhCP1* and *EhCP5* [40]. In *E. dispar*, the most abundant RNA encoding a cysteine proteinase corresponds to the *EdCP3* gene, which contributes very little to *E. histolytica*'s proteinase activity [41]. Differences in the genes encoding cysteine proteinases and in their expression could partially explain the differences in pathogenicity between *E. histolytica* and *E. dispar*.

The release of the cysteine proteinases by *E. histolytica* is spontaneous [42], and the in vitro ability of trophozoites to degrade collagen correlates with virulence [43,44]. Amebic cysteine proteinases with the ability to activate interleukin-1 $\beta$  have also been implicated in intestinal inflammation [45]. The inhibition of cysteine proteinases of *E. histolytica* by the use of irreversible chemical inhibitors or antisense RNA results in a reduction or elimination of the ability of the amebae to form liver abscesses in animal models following intrahepatic injection of virulent trophozoites, supporting the role of cysteine proteinases in pathogenicity [46,47].

#### V. CYTOLYTIC ACTIVITY

The cause of the remarkable cytolytic activity for which *E. histolytica* is named has been the subject of intense investigation (Figure 2). Moments after the trophozoite contacts the host via the Gal/GalNAc lectin, host cells undergo membrane blebbing and loss of cytoplasmic granules and membrane integrity followed by cell death within 5–15 min

**Figure 2** Parasite-induced apoptosis of host cells at the site of colonic invasion. C3H/HeJ mice were infected intracecally with *E. histolytica* trophozoites. Twenty-four days after infection, cecal tissues were examined for apoptosis with the terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick-end labeling (TUNEL) stain. Apoptotic cells labeled brown by the TUNEL stain can be seen in contact with and within amebic trophozoites (arrows) (b, original magnification  $\times 600$ ). (Reprinted from Ref. 54.)

[16]. The parasite's ability to form abscesses is impaired in amebae rendered defective in cytotoxicity, either by inducible expression of a dominant negative mutant of the Gal/GalNAc lectin, or by expression of antisense RNA to the Gal/GalNAc lectin [20,28]. Therefore, *E. histolytica* cytotoxicity appears crucial to the ability of the parasite to cause disease.

Studies using cinemicrography show that blebbing and cell death of CHO cell monolayers occur only upon direct contact between amebae and their target cell [32]. The calcium channel blockers, verapamil and bepridil, significantly inhibit amebic cytotoxicity, as do the calcium chelator, ethylenediaminetetraacetate (EDTA), and the putative blocker of intracellular calcium flux, 8-(*N,N*-diethylamino)octyl-3,4,5-trimethoxybenzoate (TMB-8) [48,49]. As determined by studies utilizing the fluorescent calcium probe Fura-2 AM, the target cell's intracellular calcium concentration rises irreversibly and approximately 300-fold within 30 sec of contact with a trophozoite. The addition of D-galactose completely blocks both this calcium flux [50] and cytolysis [16,32]. Because abutment of trophozoites and target cells via centrifugation in the presence of galactose was not adequate to promote killing, the Gal/GalNAc lectin appears to participate actively in the cytolytic process rather than simply bringing host cells and amebae together [16]. Upon the incubation of CHO cells with purified Gal/GalNAc lectin at sublethal concentrations, a reversible rise in intracellular calcium concentration of magnitude and speed comparable to that observed with whole amebae occurs [51]. Minimal chromium release from CHO cells incubated with affinity-purified lectin, however, suggests that the lectin alone is not sufficient to induce cytotoxicity [51].

The ultimate cause of target cell lysis induced by *E. histolytica* may involve both programmed cell death and necrosis. Compaction of nuclear chromatin, cytoplasmic

condensation, and membrane blebbing, as well as DNA fragmentation characteristic of apoptotic cell death have been observed in a murine myeloid cell line killed by *E. histolytica* [52]. In contrast, other investigators have observed changes consistent with necrosis, including cytoplasmic swelling, and compromised membrane integrity [53]. The killing of the Jurkat human T lymphocyte cell line occurred via apoptosis, as judged by DNA fragmentation and caspase 3 activation. This killing was inhibited by galactose. Classical upstream caspases seemed not to be involved, as caspase 8-deficient cells, resistant to killing by FasL, were readily killed by *E. histolytica* [54]. Caspase 8-deficient cells treated with a caspase 9 inhibitor (Ac-LEHD-fmk) (at a level sufficient to inhibit apoptosis via etoposide) were readily killed as well. In contrast, the caspase 3 inhibitor, Ac-DEVD-CHO, at 100  $\mu$ M (sufficient to block killing via actinomycin D) blocked *E. histolytica* killing, as measured both by DNA fragmentation and  $^{51}\text{Cr}$  release, indicating that it was necessary both for the apoptotic death phenotype and for necrosis to occur [54]. The blockade of caspases has been shown to block amebic liver abscess formation in mice [55]. The mechanism by which the parasite activates caspase 3 to initiate cell death is unknown [54].

Several laboratories have reported the isolation of amebic pore-forming proteins similar in function to the pore-forming proteins of the immune system [56–60]. A 5-kDa polypeptide with pore-forming activity in liposomes, which may be a major effector molecule mediating *E. histolytica*'s ability to kill endocytosed bacteria, has been described [58]. The amoebapore (reviewed in Ref. 9) is a 77-amino-acid polypeptide. Computer-aided analysis of secondary structure predicts four adjacent  $\alpha$ -helices with tertiary structure maintained by three disulfide bonds [60]. Synthetic peptides based on the amino acid sequence of the

amoebapore possess cytolytic activity against bacteria and eukaryotic cells, and antisense RNA inhibition of amoebapore synthesis decreases amebic cytotoxicity [61,62].

## VI. SERUM RESISTANCE

Invasion of the colon and hematogenous spread to the liver result in the continuous exposure of the extracellular trophozoite to the human complement system. The complement system is one of the first barriers to infection in nonimmune individuals; circumvention of this defense is central to the pathogenesis of amebiasis. Trophozoites activate the classical and alternative complement pathways in the absence of antiamebic antibodies. The incubation of trophozoites in normal human sera results in the depletion of human complement, as measured by CH50 and C5b-9 hemolytic assays and C3 and C4 depletion [63]. The amebic 56-kDa cysteine proteinase cleaves C3 at a site one amino acid distal to that of the human C3 convertase, and may be the route by which the complement is activated [64,65]. Depletion of complement in hamsters by cobra venom factor treatment increases both the frequency and the severity of amebic liver abscess, providing evidence of the protective role of the complement system in amebiasis [66].

*E. histolytica* freshly isolated from patients with invasive amebiasis and laboratory strains passed through animals activate the alternative complement pathway but are resistant to C5b-9 complexes deposited on the membrane surface [63–65]. On the other hand, amebae cultured from the stool of asymptomatically infected individuals or virulent amebae attenuated by axenic (in the absence of associated bacteria) culture activate the alternative complement pathway and are killed by C5b-9 [63–65].

The killing of amebae is mediated by the terminal complement components, and the direct lysis of sensitive, but not resistant, *E. histolytica* has been demonstrated with purified complement components C5b-9 [65]. Resistance to terminal complement attack in *E. histolytica* could be due to an amebic cell surface protein with C5b-9-inhibitory activity, or to endocytosis or shedding of the C5b-9 complex. Rapid membrane repair via shedding or endocytosis of the membrane-inserted C5b-9 complex has been postulated to confer C5b-9 resistance to several different cells, including nucleated mammalian cells and the metacyclic (infective promastigote) stage of *Leishmania major*. However, the shedding or release of C9 from the membrane does not appear to be the explanation for C5b-9 resistance in *E. histolytica*, as C9 binding is higher in resistant than sensitive amebae.

Braga et al. produced monoclonal antibodies against serum-resistant amebae and identified an antibody that increased *E. histolytica* lysis by human sera and by purified human complement components C5b-9. It was a surprise that the antigen recognized by the antibody was the 170-kDa lectin subunit [67]. The inhibition of complement resistance by the anti-170 kDa mAb was shown to be specific to mAb-recognizing epitopes 6 and 7. An examination of the sequence of the 170-kDa subunit showed limited identity with CD59, a human inhibitor of C5b-9 assembly, and the purified lectin was recognized by anti-CD59 anti-

bodies. The lectin bound to purified human C8 and C9, and blocked assembly in the amebic membrane of the complement membrane attack complex at the steps of C8 and C9 insertion.

The lectin gene family therefore appears to participate not only in adherence and host cell killing, but also in the evasion of the complement system of defense via a remarkable mimicry of human CD59. Gal/GalNAc inhibition of lectin activity had only a minor effect on C5b-9 resistance of trophozoites, suggesting that the lectin and complement regulatory domains of the lectin are distinct.

## VII. THE INNATE AND ACQUIRED IMMUNE RESPONSE TO AMEBIASIS

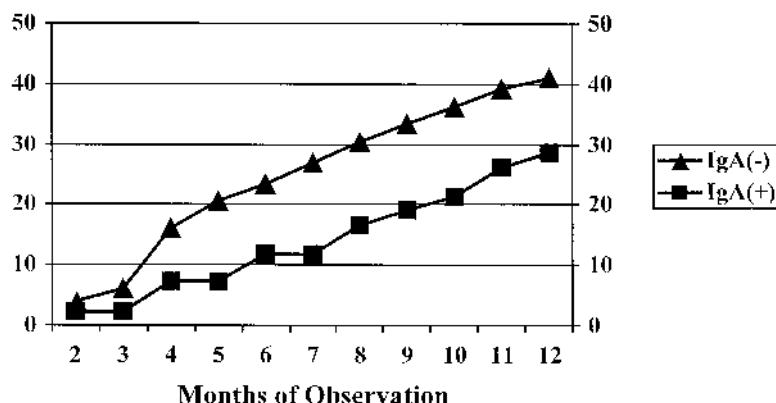

Although the precise roles and importance of humoral and cellular responses in immunity remain to be determined, protective immunity is likely to involve elements of both. Immunization of animals with several *E. histolytica* antigens provides protection from an intrahepatic challenge with *E. histolytica* [68]. These antigens include serine-rich and cysteine-rich proteins and the Gal/GalNAc adherence lectin.

Antibodies appear to play a role in immunization-mediated protection, as evidenced from studies using a severe combined immunodeficient (SCID) mouse model of amebic liver abscess. The passive transfer to SCID mice of antibodies against whole *E. histolytica* proteins, serine-rich proteins, or cysteine-rich domains of the galactose lectin resulted in a faster resolution of amebic liver abscess [26, 69–71].

Proinflammatory cytokines also appear to be important for protective immunity. Lymphocytes from patients recovered from invasive amebic disease proliferate in response to amebic antigens, have amebicidal activity, and produce interleukin-2 and interferon gamma (IFN- $\gamma$ ) [72,73]. Macrophages and neutrophils activated by IFN- $\gamma$  and tumor necrosis factor alpha (TNF- $\alpha$ ) are endowed with the capability of killing *E. histolytica* trophozoites, whereas in the absence of activation, these immune effector cells were killed by the amebae [72,73]. Proinflammatory cytokine production in response to *E. histolytica* infection may, in part, be an innate immune response: the purified Gal/GalNAc lectin promotes the production of IL-12 and TNF- $\alpha$  production by macrophages [74,75]. In murine macrophages, TNF- $\alpha$  was shown to play a central role in activating macrophages for nitric oxide-dependent cytotoxicity against *E. histolytica* [76]. Mice with targeted disruption ("knockout") of either IFN- $\gamma$  or inducible nitric oxide synthase had more severe amebiasis, providing in vivo evidence of the importance of proinflammatory cytokines in protection [76].

## VIII. ACQUIRED IMMUNITY IN HUMANS

Until recently, little was known about the existence or nature of acquired immunity. The development of invasive amebiasis in some *E. histolytica*-colonized individuals and documented second infections led many to conclude that acquired immunity was nonexistent or, at best, incomplete [77–80]. There was little in the way of clinical research to contradict

**Figure 3** Cumulative percentage of *E. histolytica* infection in children with or without mucosal lectin-specific IgA at the time of enrollment. The two groups are statistically significantly different at 5 months ( $P = 0.03$ ) and 7 months ( $P = 0.04$ ). (Reprinted from Ref. 6.)

this conclusion. Confounding the problem was the fact that most researchers failed to distinguish the invasive parasite *E. histolytica* from the noninvasive but identical in appearance parasite *E. dispar*, making their work difficult to interpret.

The existence of acquired immunity to amebiasis was discovered in a prospective observational study of amebiasis in preschool children in Dhaka, Bangladesh. Immunity was linked to a mucosal antiadherence lectin IgA response. The association of mucosal antilectin IgA with protection was demonstrated three ways. First, in a cross-sectional analysis, *E. histolytica* colonization was absent in all 64 children with stool antilectin IgA. Second, children with stool antilectin IgA acquired fewer new *E. histolytica* infections over a prospective period of observation [3/42 IgA (+) vs. 47/227 IgA (-);  $P = 0.03$ ] (Figure 3). Finally, the appearance of a stool IgA antilectin response coincided with the resolution of infection. Mucosal antilectin IgA is therefore an indicator of

immune protection and may prove effective as a surrogate marker of vaccine efficacy [6].

## IX. VACCINE CANDIDATES

Although whole *E. histolytica* proteins elicit a protective immune response indicating that an effective antiamebic vaccine is possible, vaccines using native antigens are expensive and impractical to produce. This has driven an aggressive search for antigens that might form the basis of a cheap, recombinant vaccine (reviewed in Refs. 10 and 68). Candidate proteins (see Table 1) that have been developed have mostly been cell surface or secreted. Among these are amebic proteins implicated in pathogenesis, including the Gal/Gal-Nac lectin, the cysteine proteinases, and the amoebapore. The use of cDNA libraries has resulted in the isolation of two

**Table 1** Known Characteristics of Current Antiamebic Vaccine Candidates

Amebic protein	Putative function	Surface expression?	Conserved?	Immunogenic?	Protective in animal models?
Amoebapore	Cytolytic activity	Yes, secreted	Yes	Unknown	Unknown
Cysteine proteinase	Tissue penetration/ degrades IgA, IgG, C3a, and C5a	Yes, secreted	Yes	Yes	Unknown
Gal/GalNac lectin	Adherence/ complement resistance	Yes	Yes	Yes	Yes
SREHP	Possible role in adherence	Yes	No	Yes	Yes
29-kDa cysteine-rich antigen	Thiol-dependent peroxidase	Controversial, probably yes	Yes	In liver abscess only	Yes

Source: Ref. 68.

additional candidates: the serine-rich *E. histolytica* protein (SREHP) and the 29-kDa cysteine-rich *E. histolytica* antigen [81,82].

## X. PARENTERAL VACCINES

The Gal/GalNac lectin plays an essential role in adherence and cytotoxicity, as well as in resistance to serum complement. In addition, the lectin's cysteine-rich extracellular domain is highly conserved [83,84]. The 170-kDa heavy subunit is the predominant amebic protein recognized by immune sera of individuals cured of invasive amoebiasis from geographically diverse areas including the United States, Mexico, Africa, India, and Jordan [83,84]. More than 90% of sera from individuals with amebic liver abscess or asymptomatic colonization with *E. histolytica* contain antilectin antibodies [83–85]. Furthermore, as mentioned above, acquired immunity in humans is associated with the production of mucosal IgA against the lectin.

In one study, 100% of gerbils immunized with purified native Gal/GalNac lectin in complete Freund's adjuvant developed high-titer serum antibodies to the heavy subunit. Immune sera completely blocked amebic adherence to CHO cells at 1/10 dilutions, and 67% of gerbils were completely protected from liver abscess following intrahepatic injection of trophozoites. Surprisingly, the remaining animals developed larger abscesses [86]. Antibodies to different epitopes on the lectin's 170-kDa heavy subunit variably enhance or inhibit amebic adherence to CHO cells and to human colonic mucin, but no differences in the development of antilectin antibodies or their adherence-inhibitory properties were observed in the immunized gerbils [86].

Parenteral immunization with two different recombinant peptides based on the cysteine-rich extracellular portion of the lectin's heavy subunit has been protective in the gerbil model of amebic liver abscess. In one study, immunization of gerbils with the recombinant LC3 region and Titermax adjuvant elicited a high-titer serum IgG response capable of inhibiting amebic adherence to CHO cells. There was a 71% reduction in the number of animals with liver abscesses following immunization with the native lectin; abscesses in the immunized gerbils that developed them were no larger than in controls [87]. Similarly, Lotter et al. immunized gerbils with several recombinant peptides based on the carboxyl-terminal portion of the lectin's cysteine-rich extracellular domain. Immunization with a 115-amino-acid peptide (termed 170CR2) completely prevented abscess development in 62.5% of animals, and the remaining animals in this study developed significantly smaller abscesses than unimmunized controls. Antibody production to a 25-amino-acid sequence within 170CR2 correlated strongly with the development of protective immunity. Successful passive immunization of SCID mice with rabbit serum raised against the peptide reconfirmed the importance of humoral immunity in the prevention of amebic liver abscess [88].

Stanley et al. [81] identified the SREHP by screening cDNA libraries. This protein contains multiple-tandem dodecapeptide repeats reminiscent of the repetitive circum-

sporozoite antigens of malarial species. Indirect immunofluorescent staining localizes the native SREHP to the cell surface and to focal areas within the cytoplasm [89]. Different *E. histolytica* isolates have different numbers of dodecapeptide repeats encoded within their SREHP genes [90]. Western blots for the presence of anti-SREHP antibodies in patients from diverse geographical regions with acute invasive amoebiasis were positive in 82%. Seropositivity ranged from 65% in Durban, South Africa to 91% in Mexico City [91]. Differences in the observed rates of anti-SREHP antibody production may have been due to differences in the timing of serum sampling during the course of acute illness. They also raise the possibility that local populations have differing abilities to produce anti-SREHP antibodies, or that differences in the number of SREHP repeats in different *E. histolytica* isolates affect immunogenicity [91].

Zhang et al. tested the ability of recombinant SREHP to elicit a protective immune response against amebic liver abscess in gerbils. Gerbils were immunized either subcutaneously in a single shot, or intraperitoneally in a series of three shots with a recombinant SREHP/maltose-binding protein (MBP) fusion protein combined with complete Freund's adjuvant. Immunization completely prevented amebic liver abscess following intrahepatic challenge in 64% of gerbils immunized intraperitoneally and 100% of gerbils immunized with a single subcutaneous shot. All of the immunized animals developed delayed-type hypersensitivity reactions [92]. African green monkeys immunized with three doses of the SREHP/MBP fusion protein developed serum antiamebic antibodies 10 days after the first booster. Unfortunately, the control monkeys in this trial did not develop liver abscesses following intrahepatic challenge, so vaccine efficacy could not be assessed [93].

Screening of cDNA libraries also identified the 29-kDa cysteine-rich *E. histolytica* antigen, another immunogenic protein that may be suitable for inclusion in a vaccine [82]. The 29-kDa antigen appears to be a thiol-dependent peroxidase because it possesses hydrogen peroxide-removing capacity in the presence of reducing agents such as thioredoxin [97,98]. It may, therefore, protect *E. histolytica* from oxidative attack by activated neutrophils and macrophages. The location of the 29-kDa antigen within the ameba remains controversial. Immunofluorescent staining of formalin-fixed cells with monoclonal antibodies shows the protein within both the nucleus and the cytoplasm [97,98]. An enzyme-linked immunosorbent assay (ELISA) using purified native and recombinant 29-kDa proteins demonstrated the presence of anti-29-kDa antibodies in 79% of people with amebic liver abscess, but failed to show significant antibody production in patients suffering from amebic colitis and in asymptomatic carriers [98]. Intraperitoneal immunization of gerbils with a recombinant fusion protein based on the 29-kDa protein and Titermax adjuvant elicited production of antigen-specific IgG and was partially protective (54% vaccine efficacy) against amebic liver abscess following intrahepatic challenge with virulent trophozoites [99].

The cysteine proteinases and the amoebapore are additional amebic proteins associated with virulence that must be considered. Each has yet to be evaluated as a potential vaccine component. Numerous studies document the central

role of amebic cysteine proteinases in the penetration of host tissues and in the evasion of host defenses via the degradation of IgA, IgG, C3a, and C5a. Patients with amebic liver abscess, moreover, develop antibodies to histolysain (*EhCP2*), and the use of protease inhibitors in SCID mice reduces the size of liver abscesses following intrahepatic injection of trophozoites. The recombinant amoebapore's cytotoxicity toward eukaryotic cells prohibits its use in a vaccine. The identification of antigenic regions within this peptide, however, should yield other possible vaccinogens.

## XI. ORAL VACCINES

Two major oral vaccine strategies have been used: the incorporation of amebic antigens into attenuated bacterial strains, and the creation of fusion proteins composed of amebic antigens and cholera toxin or its subunits. An effective oral vaccine against *E. histolytica* could have several advantages over parenteral preparations. A direct stimulation of the gut-associated lymphoid tissue (GALT) might stimulate the production of secretory IgA more effectively than parenteral immunization, and prevent both colonization and invasive disease. By establishing a limited invasive infection in the host, moreover, an oral vaccine carried by an attenuated bacterial strain might provide more prolonged immunity than parenteral vaccines based on the same antigens. Combination vaccines providing protection against multiple organisms may also be possible. For example, immunization with attenuated *Salmonella typhi* strains engineered to express amebic antigens might protect against both amebiasis and typhoid fever. Finally, the lower cost and ease of administering an oral vaccine would increase acceptance in developing nations.

An oral attenuated vaccine for typhoid fever is currently in use in humans. Foreign antigens expressed in attenuated *Salmonella* species can effectively stimulate both cell-mediated immunity and production of secretory IgA. Oral immunization of mice and gerbils with an attenuated strain of *S. typhimurium* that expresses the SREHP/MBP fusion protein at high levels resulted in the production of secretory IgA and serum IgG. Anti-lipopolysaccharide (LPS) antibodies also developed in both sham-immunized and immunized animals, suggesting that the amebic antigen did not impair the immune response to the *Salmonella* infection. A vaccine protective against both, therefore, might be possible. Following intrahepatic injection with amebic trophozoites, 100% of control gerbils and only 22% of immunized gerbils developed abscesses in this study [100]. In another study, oral immunization of gerbils with *S. dublin* expressing a fragment of the Gal/GalNAc lectin resulted in significant reduction in mean abscess weight, but no significant difference in the number of animals developing abscesses. No serum antiamebic antibody production was observed in this study, suggesting that the observed protection may have been cell-mediated [101]. The plasmid carrying the lectin fragment, however, was somewhat unstable in vitro; higher or more prolonged expression of the antigen may have resulted in antibody production and in greater vaccine efficacy [101].

Cholera toxin has two subunits, a 28-kDa A subunit with ADP-ribosylating activity and an 11.5-kDa B or binding subunit. The A subunit contains A1, the active toxin domain, and A2, which noncovalently links subunit A to five B subunits. A pentamer of B subunits binds the intestinal epithelium. Whole cholera toxin stimulates the production of serum IgG and secretory IgA when orally administered, and also stimulates immunity to coadministered antigens [102]. In humans, the B subunit retains some of whole cholera toxin's oral adjuvant properties. Parenteral immunization of rats with native Gal/GalNAc lectin in complete Freund's adjuvant followed by intra-Peyer's patch injection of lectin with cholera toxin's B subunit stimulates the production of antilectin secretory IgA [103]. Oral immunization of mice with the recombinant LC3 portion of the lectin and whole cholera toxin induced the production of secretory IgA capable of inhibiting the adherence of amebic trophozoites to CHO cells. Interestingly, there was a negative correlation between intestinal IgA production, and serum IgA and IgG titers in this study [104]. High-dose oral immunization with streptococcal antigens by other investigators has resulted similarly in a strong mucosal immune response with no systemic antibody production, whereas lower doses led both to mucosal and systemic antibody production [105].

A potential limitation of strategies combining recombinant peptides with cholera toxin's B subunit is that large, attached molecules might prevent the pentamerization of the B subunit and reduce its adjuvant properties by changing its ability to bind to intestinal epithelium. The coupling of antigens to the B subunit via A2 to create holotoxin-like molecules could potentially increase their immunogenicity as well as facilitate the use of larger recombinant antigens. A holotoxin-like molecule containing the SREHP fused to the A2 domain of cholera toxin (SREHP-H) has been created. Oral immunization of mice with SREHP-H coexpressed with the cholera toxin B subunit in *E. coli* resulted in the production of mucosal IgA and serum IgG antiamebic antibodies [106].

## XII. CONCLUSIONS AND AREAS FOR FURTHER INVESTIGATION

The identification of acquired immunity to amebiasis in humans lends tremendous credence to the development of a vaccine against *E. histolytica*. Many obstacles to the production of a vaccine have fallen by the wayside in the last decade. Effective immunity in humans is now known to be associated with a mucosal IgA response against the Gal/GalNAc lectin, one of several well-characterized virulence factors of the parasite. A mouse model of amebic colitis has been developed and allows for the first-time identification of protective immune responses at the mucosal surface where infection occurs. Well-characterized cohorts of children with *E. histolytica* infection have been described. The extremely high rates of new *E. histolytica* infection in these children should enable the testing of vaccine efficacy using small numbers of patients. Although much progress has been made, the burden of disease due to amebiasis throughout

the tropical and subtropical world makes vaccine development an urgent task.

### I. INTRODUCTION

Human hookworm infection is a soil-transmitted intestinal helminthiasis caused by either *Necator americanus* or *Ancylostoma duodenale* [1]. In a few focal areas, intestinal infections with the canine hookworms *Ancylostoma ceylanicum* and *Ancylostoma caninum* occur as a consequence of zoonotic transmission [2]. Hookworms are one of the most ubiquitous infectious agents of humankind; some estimates suggest that as many 1.2 billion people are infected worldwide [3]. The infection is found wherever rural poverty intersects with a tropical or subtropical climate and adequate moisture. In the Western Hemisphere, hookworm is common in the rural areas of Central America and the tropical regions of South America, including Brazil and Venezuela. In Asia, hookworm is highly endemic in China, Southeast Asia, and the Indian subcontinent. Hookworm is common throughout sub-Saharan Africa and Egypt. *N. americanus* is the predominant species worldwide, except in some northerly latitudes of China and India, Argentina and Paraguay, and in Egypt, where *A. duodenale* is focally endemic [1]. Mixed infections with both major hookworm species are common. Human infections with *A. ceylanicum* and *A. caninum* have been sporadically reported from Asia and Australia, respectively.

Hookworms injure their human host by causing intestinal blood loss, leading to iron deficiency and protein malnutrition [1,4,5]. As these processes are typically insidious and chronic and do not usually result in death, until recently hookworms were often overlooked as significant causes of morbidity. For instance, hookworms were not placed on the World Health Organization's (WHO) priority list for its Tropical Disease Research (TDR) program during the 1980s. Instead, hookworm was recognized for its devastating effects by its victims living in the rural tropics or by small numbers of biomedical researchers and public health practitioners, such as Norman Stoll of the Rockefeller Foundation and Institute, who labeled hookworm "the great infection of mankind" [6]. Public health interest in hookworm was re-

newed in the 1990s when new quantitative estimates of disease burden based on disability adjusted life years (DALYs) revealed its global impact [7]. As shown in Table 1, soil-transmitted helminthiases, which include hookworm, ascariasis, and trichuriasis, are the most significant parasitic infections of humans with the exception of malaria. The disease burden caused by hookworm alone exceeds three tropical infectious diseases under investigation in the WHO-TDR program, namely African trypanosomiasis, Chagas disease, and leprosy. Hookworm outranks dengue fever. However, even these DALY measurements probably underestimate the true disease burden impact of hookworm. Iron-deficiency anemia is one of the leading causes of morbidity in the developing world, possibly exceeding the impact of HIV/AIDS (Table 1). New data on the epidemiology of iron deficiency anemia in East Africa and elsewhere points to the important contribution of hookworms to this condition [4,5,8].

Some of the most accurate data on the prevalence and intensity of hookworm comes from China, where the Ministry of Health conducted fecal examinations on almost 1.5 million people as part of their nationwide survey of intestinal parasites between 1988 and 1992 [9]. An estimated 194 million cases of hookworm occur in a belt across South China that extends from the eastern coast to the western provinces of Sichuan and Yunnan (Table 2a). Subsequent data obtained after 1997 reveal that hookworm remains highly endemic wherever rural poverty occurs [10–16] (Table 2b). In addition to its health impact, hookworm may also affect regional economic development in China [16].

### II. RATIONALE FOR VACCINATION

Hookworm remains highly endemic in the developing countries of the tropics and subtropics despite the widespread availability for almost two decades of relatively safe and inexpensive benzimidazole anthelmintic drugs, such as mebendazole or albendazole. The failure to control hookworm with benzimidazoles is largely a reflection of the high rates of

reinfection following treatment. Studies sponsored by WHO in a highly endemic region of East Africa, for instance, revealed that hookworm returns to its original pretreatment level within 4–12 months following deworming with mebendazole [17]. Similar results have been reported from Papua New Guinea [18]. The high rates of reinfection are indicative of inadequate host natural immunity to hookworm, which leads to the observation that experience with the infection does not confer resistance [19], except in selected individuals who somehow acquire parasite-specific IgE responses [20,21]. The absence of natural immunity has been confirmed in volunteer infections with *N. americanus* [22].

**Table 2a** China's Helminth Infections Based on the Nationwide Parasite Survey<sup>a</sup>

Helminth infection	Estimated number of cases
Ascariasis (large roundworm infection)	531 million
Trichuriasis (whipworm infection)	212 million
Hookworm infection ( <i>Necatoriasis</i> and <i>Ancylostomiasis</i> )	194 million
Clonorchiasis (oriental liver fluke infection)	4 million
Fasciolopsisiasis (intestinal fluke infection)	2 million
Taeniasis (pork and beef tapeworm infection)	1 million
Schistosomiasis (blood fluke infection)	1 million

<sup>a</sup> Numbers derived from data obtained during China's nationwide parasite survey of 1,477,742 individuals between 1988 and 1992 [9]. Modified from Ref. 16.

The inability to mount natural immunity to hookworm means that effective control with benzimidazoles in a given population would require frequent deworming treatments on, at least, a semiannual basis. The ability to provide the infrastructure required for regular deworming for the rural poor is often not sustainable. One solution under investigation is to implement a practice of providing regular benzimidazole anthelmintic treatments in the schools [23]. School-based deworming programs were rationalized based on the observation that *Ascaris* and *Trichuris* infections exhibit their highest prevalence and intensity among school-age children between the ages of 5 and 14 years [23]. However, this is unlikely to be a feasible control strategy for hookworm. In many areas, hookworm infections exhibit epidemiologic patterns that are distinct from infections with *Ascaris* and *Trichuris* [24]. Although hookworm has an important impact on childhood growth and cognitive development [25,26], in much of the developing world, the highest prevalence and intensity of hookworm infections occur among young and middle aged adults [27–29]. This accounts for the observation that an estimated 44 million pregnant women are infected with hookworm [29]. Hookworm during pregnancy is a major contributor to iron deficiency anemia

**Table 2b** Prevalence of Human Hookworm Infection in Selected Provinces 1997–1998

<sup>a</sup> From Ref. 7, Annex Table 9.d, p. 553.

of pregnancy [8,29], and is associated with a number of adverse fetal outcomes. As shown in Table 2c, hookworm is a major cause of disease burden in women of child-bearing age in China, where it exceeds Japanese encephalitis, malaria, and tetanus as significant causes of infectious disease morbidity. Further epidemiologic investigations of hookworm in China and Southeast Asia have also identified the elderly as an important population that suffers from heavy hookworm infections [14–16,30]. In rural Hainan, where the overall hookworm prevalence exceeds 50%, age alone accounts for 27% of the variance attributed to hookworm [15]. Hookworm is now emerging as an important geriatric infection among a rapidly expanding population of elderly in the developing world [16].

In addition to the inability of school-based deworming programs to control hookworm, there are also new concerns about the emergence of antihelminthic drug resistance. Outright failure of mebendazole has been reported from Mali [31], with other anecdotal reports of failure from China. Benzimidazole resistance occurs as a consequence of point mutations in nematode tubulin genes, which can lead to widespread resistance among parasite populations. Among the nematode parasites of livestock, for instance, high rates of benzimidazole drug resistance now occur in South Africa, Australia, New Zealand, and South America [32]. These concerns have led to the need to consider alternative or complementary approaches to control that rely on vaccination [33].

### III. VACCINE PERFORMANCE CHARACTERISTICS

Because no human vaccine against a parasitic helminth vaccine currently exists, the desired attributes and efficacy of an effective antihookworm vaccine are difficult to define and predict. Hookworms, like most other human parasitic helminths, do not replicate in their host. For that reason, there is frequently a disparity between hookworm infection and hookworm disease. Clinical disease resulting from hookworms usually only occurs with moderate and heavy infections. The degree of iron deficiency and protein malnu-

trition resulting from hookworms depends on the following: (1) numbers of hookworms, (2) hookworm species (*A. duodenale* causes greater blood loss than *N. americanus*), and (3) dietary iron and protein intake and host reserves.

From experience with live larval vaccines (see below), it is almost certain that sterilizing immunity that provides 100% hookworm burden reductions will not be achieved by vaccination. Fortunately, sterile immunity is not a prerequisite for a nematode vaccine and, in fact, may prove detrimental in the long term [34]. Computer modeling of veterinary antinematode vaccines for sheep and cattle based on population dynamics demonstrate that adequate control can be achieved with vaccine efficacy well below 100%, and possibly, as low as 60% worm burden reduction [35]. However, these models are heavily biased to limit helminth egg deposition on modest-sized grazing pastures, which would then lead to the interruption of nematode transmission [34]. For that reason, reductions in parasite egg fecundity are considered as important, or even more important for domestic animal veterinary vaccines than worm burden reductions. This situation would not be applicable to human helminthiases. Instead, the goals of successful antihookworm vaccination include targets aimed at reducing intestinal blood loss and hookworm disease. This could either be accomplished by reducing the number of third-stage infective larvae that reach the intestine or by impairing the ability of surviving adult hookworms to feed at the attachment site in the intestinal mucosa and submucosa.

A two-tiered strategy that attempts to target both third-stage infective larvae (L3) as well as adult hookworms is analogous to some antimalarial vaccine strategies that target both sporozoites and asexual blood stages of *Plasmodium* spp. It is likely that an optimal antihookworm vaccine will therefore include a cocktail of antigens derived from both L3 and adult worms. As will be detailed below, an effective vaccination strategy will likely become one that elicits a strong T-helper type 2 (Th2) response with high levels of parasite antigen-specific IgE.

In summary, the optimal hookworm vaccine will be one that blocks the establishment, development, fecundity, and survival of the adult parasites in the human intestine [36]. The major parasitological parameters are outlined below.

**Reduced worm burden.** As noted above, reduced worm burden is a critical component of successful vaccinations. Decreased numbers of hookworms in the human intestine could either result from diminished numbers of larval hookworms that enter the intestine (decreased establishment), or from increased mortality of adult hookworms at the site of their intestinal attachment [37]. The former might be achieved by employing larval-specific antigens as immunogens, while the latter might result from selecting adult-specific antigens. In the case of *A. duodenale* infections, acquired immunity could also reduce worm burden by forcing the infective larval stages to arrest their development in the musculature or other tissues.

**Worm size.** Parasite stunting has been ascribed to the effects of an antihelminthic immune response. A reduced length might be attributable to inhibited growth, a selective expulsion of large worms, or shrinkage of worms during infection [37]. It is anticipated that vaccinations conducted

with adult worm-derived secreted proteins might have this effect, as well as cross-reacting antigens shared between L3 and adult hookworms [38].

*Altered worm morphology.* Reduced size of the nematode vulval flap has been described from nematodes recovered from vaccinated ruminants. This effect has not yet been described for hookworm vaccinations [37].

*Altered habitat selection.* Recently, vaccinations with *Escherichia coli* expressed recombinant proteins that encode adult hookworm-specific proteinase inhibitors and enzymes were found to alter the habitat selection of adult hookworms in the canine small intestine [39]. Dogs with high levels of antihookworm antibodies were shown to exit their classical habitat in the small intestine and migrate past the ileocecal valve into the colon. It is uncertain whether adult hookworms have the ability to survive for long periods in the colon, or whether this observation reflects a transition-phase of the adult hookworms before they are expelled per rectum [39].

*Fecal egg counts.* This is the only parasitological parameter that can be regularly obtained from the same animal during infection [37]. Reduced fecal egg count in immune animals can either be the result of reduced numbers of female worms or reduced egg production per female worms. Fecal egg counts do not strictly reflect the fecundity of the parasite population, although there is typically a good correlation between fecal egg counts and number of eggs in utero [37].

*Hematologic parameters.* For reasons outlined below, it is likely that successful vaccination will require induction of Th2 responses, including the induction of prominent antigen-specific IgE responses and eosinophilia. This is discussed under the section on “Mechanism of Protection.” An important hematologic parameter will be the reductions in intestinal blood loss as manifested by host circulating hemoglobin concentration, hematocrit, and ferritin concentration.

#### IV. FEASIBILITY OF ANTIHOOKWORM VACCINATIONS

No human clinical trials with an antinematode vaccine have ever been conducted. Instead, proof-of-concept that it is possible to vaccinate against hookworms is based on over 70 years of experience with laboratory animal models of infection [33,40]. The two major lines of evidence for the feasibility of an antihookworm vaccine are: (1) the success of vaccinating against canine infections with the dog hookworm *A. caninum*, using either trickle doses of living L3 or L3 attenuated by ionizing radiation, and (2) the success of vaccinating ruminants with chemically defined antigens against the blood-feeding nematode *Haemonchus contortus*.

##### A. Protection with Live Nematode Larval Vaccines

It is possible to immunize laboratory animals against infection by using killed L3. However, achieving this goal requires heroic efforts with large numbers of larvae and multiple injections. For instance, rats were successfully vaccinated against *Strongyloides ratti* by administering a total 16,000 killed L3 in 13 subcutaneous injections at intervals of 3 days

[34,41]. The vaccination series can be completed in a more efficient and timely manner by substituting living larvae. This was best shown by using vaccinated and challenged with *A. caninum* L3. Studies conducted at the Johns Hopkins School of Hygiene and Public Health during the 1930s and 1940s revealed that protective immunity could be obtained by administration of repeated doses of live *A. caninum* L3 over a period of several weeks [42–47]. These studies were recently reviewed and summarized [40]. Vaccine immunity could be stimulated by either subcutaneous or oral injections of L3. Specific immunity was not absolute but instead was demonstrable by diminished intensity of infection. Resistance induced by graded doses of larvae was manifested by reduction in worm burden, delayed development of worms, reduced size of the worms developing and lower fecundity [40]. These observations led to the development of a commercial canine hookworm vaccine that relied on *A. caninum* L3 attenuated by exposure to x-rays and other forms of ionizing radiation [38,48,49]. The advantage of using irradiated larvae was that larger numbers of L3 could be administered over a much shorter period of time. This practice allowed L3 to be manufactured into a product of potential commercial utility. Single and double vaccination schedules with x-irradiated larvae protected vaccinated pups against the establishment of potentially severe challenge infections by reducing worm burdens 37% and 90%, respectively [38,48]. The vaccine was marketed in Florida in 1973 and then the eastern United States in 1974 [48]. Ultimately, the vaccine failed as a commercial product because of high production costs (to harvest L3 from canine feces), some respiratory side effects (some irradiated L3 still migrated into the lung and even reached the intestine), short shelf life (dead and dying L3 were not effective immunogens), and an absence of sterilizing immunity, which sometimes resulted in the appearance of hookworm eggs in the feces. This last observation led both pet owner and veterinarian to erroneously conclude that the vaccine had failed [48].

Despite the commercial failure of live L3 vaccines, these early experiments led to the important observation that the protective antigens might not present in sufficient quantity in extracts of dead parasites but might be actively secreted by the living parasites [50]. The first experiments pointing to the importance of larval secreted products were conducted at the University of Chicago during the 1930s by Sarles and Taliaferro [51,52], who found that when L3 of the rodent nematode *Nippostrongylus brasiliensis* are maintained in serum from immunized rats, precipitates form at the L3 amphid, oral opening, and excretory pore; similar precipitates were detected histologically around the orifices of L3 in the skin and lungs of immune rats. These precipitates did not appear to damage the worm directly, but may have blocked a secretion, such as an enzyme required for survival in the host [34]. Subsequently, it was shown that sera from children with low hookworm burdens, despite repeated endemic *N. americanus* L3 exposure, also forms immune precipitates around hookworm L3 [53,54]. Because rats and guinea pigs could be successfully protected by vaccination with L3 secreted products [55,56], it was anticipated that humans could also be protected by *N. americanus* L3 secreted proteins. This situation is analogous to the development of antimalaria

vaccines in which irradiated sporozoites and their corresponding circumsporozoite antigens elicit high levels of protection [57].

The absence of sufficient quantities of available hookworm L3 secreted proteins blocked progress in developing hookworm vaccines. For that reason, the major hookworm L3 secreted antigens were produced in bacteria by genetic engineering [58–60]. Mice immunized with recombinant L3 hookworm antigens acquired parasite-specific antibody and Th2-dependent immunity that blocked larval migration and entry into the lungs [61–63]. A homolog of the major secreted hookworm L3 antigens were subsequently shown to protect guinea pigs against challenge with L3 of the sheep stomach-worm *H. contortus* [56].

### B. Protection with Purified Nematode Antigens

Because animal and human hookworms are not usually available in sufficient quantities for antigen purification, there are very few reported vaccine trials with isolated hookworm proteins. Instead, most antinematode vaccine development programs are focused on trichostrongyle nematodes, which parasitize the alimentary tract and lungs of ruminants. Cattle and sheep infections with *Trichostrongylus colubriformis* and *H. contortus* are major veterinary problems in subtropical and temperate climates, particularly South Africa, South America, Australia, New Zealand, and the Southeastern United States. High rates of benzimidazole drug resistance have encouraged some veterinary pharmaceutical companies to embark on vaccine development programs [32]. A major advantage of selecting *T. colubriformis* and *H. contortus* is the relatively abundant quantities of parasite material available for purifying antigens. In some cases, millions of L3 and thousands of adult worms can be recovered from a single ruminant infection.

For comparison with hookworm, vaccine trials against infections with *H. contortus*, the “stomach worm” or “wire-worm” from the abomasums of sheep, goats, and cattle, are particularly instructive. The hookworms and *H. contortus* each belong to different families within the order Strongylida of the phylum Nematoda [64] (Table 3). Like hookworm disease, the principal clinical feature of haemonchiasis is anemia, which occurs when the adult and fourth-stage larvae ingest blood and leave mucosal wounds that hemorrhage [64]. The average blood loss has been calculated at 0.05 ml blood per parasite per day and blood first appears in the feces 6–12 days postinfection.

Two major classes of antigens from trichostrongyles offer promise as vaccine targets: (1) secreted molecules that are essential for parasite survival, and (2) biochemically extracted molecules from the parasite alimentary canal and other parasite organs [34].

*Secreted parasite molecules.* This category includes molecules released by the parasite during in vitro culture; in the parasite literature, fluids containing these molecules are typically referred to as excretory–secretory (ES) products. ES products may be derived from the parasite surface, from specialized secretory glands, or as byproducts of parasite digestion [34]. Almost 70 years ago, Asa Chandler [65,66] first theorized that antibody directed against critical parasite

From Ref. 64.

secreted enzymes mediates a successful anthelmintic immune response. These antibodies may “prevent the worms from digesting and assimilating host proteins,” thereby creating an unfavorable environment for helminths living in the small intestine [39,65,66]. Thorson [67] subsequently provided proof of principle of the anti-ES enzyme hypothesis when he observed that serum obtained from dogs immunized against *A. caninum* contained antiprotease properties that could neutralize proteolytic enzyme activity from hookworm esophageal extracts. Abundant quantities of ES antigens are available from trichostrongyles. For instance, it was estimated that 25,000 *T. colubriformis* adults produce 1 mg protein/day [34,37].

To date, promising results were obtained by using purified or enriched preparations of a secreted cysteinyl protease from *H. contortus* [34] and an acetylcholinesterase (ACh) and superoxide dismutase from the trichostrongyle lungworm *Dictyocaulus viviparous* [68–70]. The corresponding enzymes have been identified from *Ancylostoma* and *Necator*. However, the most promising ES antigens belong to a family of adult and L3 cysteine-rich secretory proteins with homology to the *Ancylostoma* secreted proteins (ASPs) [58,59,71]. These include Hc24 and Hc15 isolated from *H. contortus* adult worm ES products and Hc40 from *H. contortus* L3 ES products (Table 4). Hc24 and Hc15 were discovered and selected based on their reactivity to serum obtained from sheep that were partly immune to primary and secondary infections [72]. Vaccination of sheep with Hc24 and Hc15 results in substantial reductions in fecal egg output and final worm burdens of 77% and 85%, respectively [73,74]. Similarly biochemical fractionation of *H. contortus* L3 ES products resulted in the isolation of Hc40 [56]. Vaccination of guinea pigs with either naturally purified Hc40 or Hc40 expressed in baculovirus provides a high level of protection (worm burden reduction) against *H. contortus* challenge of >80% and 45%, respectively [56].

*Biochemical fractionation of worms.* Another approach for isolating trichostrongyle natural products that effectively

function as vaccines is to progressively fractionate parasite extracts. The fractionation procedure is followed by vaccine testing of each fraction. Although extremely labor-intensive, at least two vaccine molecules have been successfully purified by this approach, including an ASP from *H. contortus* adults [75], and a tropomyosin homolog from *T. colubriformis* L3 [76].

To expedite biochemical fractionation, successful attempts have been made to narrow the search by isolating specific antigens from defined parasite organs that can serve as targets for antibody or immune effector cells. The trichostomyle target organ most successfully exploited for purposes of antigen discovery has been the nematode gut. This approach is based partly on proof-of-principle obtained in developing vaccines against gut antigens derived from the tick *Boophilus microplus*. The Bm86 antigen, an 89-kDa glycoprotein with an extracellular location on the digestive cells of the tick gut, has been shown to be function as an effective antitick vaccine for cattle. Bm86 is not ordinarily recognized by the host bovine immune system during tick infestation. However, forcing an immune response against Bm86 through vaccination results in the appearance of specific antibodies that can be ingested by the tick as it takes up a bloodmeal. In doing so, the antibody acts as a “Trojan horse” by targeting the tick gut and interfering with the tick’s ability to digest blood [77]. Although the *E. coli*-expressed recombinant protein is not as effective as the native Bm86 [78], recent success with Bm86 expressed in the methanol utilizing yeast *Pichia pastoris*, suggests that yeast-derived recombinant proteins might successfully reproduce the conformational epitopes of the Bm86 glycoprotein [79].

Based on this success, efforts in several laboratories have attempted to isolate antigens or enzymes that line the alimentary canal of trichostrongyle nematodes. Lambs have been successfully immunized with several different antigens extracted from the gut of adult *H. contortus*, including contortin, a helical polymeric structure [80]; H11, an integral membrane 110-kDa glycoprotein aminopeptidase [81–83]; H-gal-GP, a lectin-binding galactose-containing complex,

which is composed of galectin [84], cystatin [85,86], thrombospondin [87], a pepsinogen-like aspartic protease [88], and a metalloprotease (MTP) [34,89]; thiol sepharose binding proteins (TSBP) comprised of cathepsin B-like cysteinyl proteases [90] and GA1, a carbohydrate containing complex of two proteins of 46 and 52 kDa [91]. These gut-derived complexes of proteins have produced high levels of protection. To date, however, no protection has been obtained when these proteins are expressed in *E. coli* and tested as recombinant vaccines [92]. Presumably, *E. coli* expression vectors do not accurately reproduce the conformational epitopes of the native protein. The conformational dependence of these proteins is illustrated by studies in which protection with H11 is reduced when it is progressively denatured with SDS and dithiothreitol [81], suggesting that conformational epitopes are required for the full expression of protective immunity [34,92].

## V. CANDIDATE ADULT HOOKWORM ANTIGENS

### A. Adult Hookworm Secretory Antigens

Studies are in progress to isolate the major adult *A. caninum* secreted proteins. A partial listing of the predominant gene products are listed in Table 5.

#### 1. Single-Domain *Ancylostoma* Secreted Proteins (ASP-3, ASP-5, Platelet Inhibitor)

The ASPs are a family of cysteine-rich secretory proteins from adult and larval hookworms (Table 4). Ac-ASP-1 and Ac-ASP-2 from *A. caninum* are the two most abundant proteins released from infective third-stage larvae (L3) of *A. caninum* upon host stimulation, and were the first two members of the family that were cloned and expressed (see below). It was noted that the ASPs share consensus sequences in their C-termini with antigen 5, a major venom allergen from stinging insects of the order Hymenoptera, and its

mammalian evolutionary counterpart, a sperm-derived protein known as testes-specific protein [58,59]. No functions have yet been ascribed to the ASPs, antigen 5, or testes-specific protein. There are two classes of ASPs. Single-domain ASPs are monomeric structures that contain between 200 and 245 amino acids, and double-domain ASPs are heterodimorphic repeats of monomeric-like sequences. The major adult single-domain ASPs are composed of ASP-3, ASP-5, and a protein that was isolated as an inhibitor of platelet aggregation. The single-domain ASPs share conserved KLGCAV sequences.

*Rationale for vaccine selection.* The adult hookworm-derived, single-domain ASPs have significant amino-acid sequence homology to Hc24, the 24-kDa protective antigen secreted from adult *H. contortus* [73,74] (Table 4). Some homology is also apparent between Hc15 and the ASPs. As noted above, a cocktail vaccine comprised of Hc24 and Hc15 is highly protective in sheep [73,74,93]. The two adult *A. caninum* secreted single-domain ASPs, ASP-3 and ASP-5, exhibit 25% and 32% homology to Hc24, respectively. ASP-3 is the most abundant single-domain ASP isolated from adult *A. caninum* secretory products. Vaccine trials with ASP-2, which has 50% homology with Hc24, are in progress.

## 2. Double-Domain ASPs (ASP-4, ASP-6)

Double-domain ASPs are heterodimorphic repeats of the monomeric single-domain structures [33], and are composed of anywhere between 424 and 508 amino acids. Adult *A. caninum* hookworms secrete two different double-domain ASPs, Ac-ASP-4 and Ac-ASP-6.

*Rationale for vaccine selection.* In *H. contortus* vaccinations, adult parasite-derived double-domain ASPs were shown to be highly protective. Successive column fractionation of adult *H. contortus* worms resulted in a consistent

peak of protein that associated with vaccine protection in a guinea pig model [75]. Final purification resulted in the isolation of a single 45-kDa glycoprotein corresponding to a double-domain ASP.

## 3. Neutrophil Inhibitor Factor (NIF)

Ac-NIF from *A. caninum* is a 41-kDa glycoprotein that potently inhibits CD11/CD18 in vitro [94]. It blocks the adhesion of activated neutrophils to vascular endothelial cells. The mature protein is composed of 257 amino acids (with a 17-amino-acid secretory leader peptide), and has 10 cysteines and 7 potential N-linked glycosylation sites. Ac-NIF from *A. caninum* exhibits 43% amino acid sequence homology to Ac-ASP-3.

*Rationale for vaccine selection.* In hamsters, *Pichia*-expressed recombinant *A. ceylanicum* NIF reduces parasite fecundity when used as a vaccine (85.8% by day 21 postinfection) [95]. However, it does not reduce host worm burdens or hematocrit values. No comparable vaccine protection experiments have been conducted with *A. caninum*.

## 4. Tissue Inhibitor of Metalloproteinase (TMP)

Ac-TMP is the most abundant protein secreted by adult *A. caninum* hookworms [96]. A cDNA encoding a putative TMP was cloned from an *A. caninum* adult hookworm cDNA library by immunoscreening with antihookworm ES antiserum. Ac-TMP is encoded by a 480-bp mRNA with a predicted open reading frame (ORF) of 140 amino acids ( $M_w = 16,100$ ) that contains one potential N-linked glycosylation site, and an N-terminal C–X–C consensus sequence. The ORF is 33% identical and 50% similar to the N-terminal domain of human TIMP-2. Reverse transcription-polymerase chain reaction (RT-PCR) analysis indicates that

transcription is restricted to the adult stage. Ac-TMP can be successfully expressed in *E. coli* as a soluble product and purified.

**Rationale for vaccine selection.** In a canine model, vaccination with *E. coli* expressed recombinant Ac-TMP (precipitated with alum) resulted in 11% reduction in the number of adult hookworms recovered from the small intestine relative to alum-injected dogs [39]. There was a 500% increase noted in the number of adult hookworms recovered from the colon. No effects on hookworm fecal egg counts were observed.

### 5. Anticoagulant Peptide (AP)

Ac-AP is an 8-kDa factor Xa inhibitor released from the amphidial (cephalic) glands of adult *A. caninum* [97–100]. It belongs to a family of nematode anticoagulant peptides (NAPs), which also includes a factor VIIa/tissue factor inhibitor [100]. Ac-AP can be expressed as a soluble product in *E. coli* [98].

**Rationale for vaccine selection.** Ac-AP precipitates with calcium phosphate but not with alum [39]. Vaccination of dogs with a combination of alum and calcium phosphate-precipitated Ac-AP does not result in consistent host antigen-specific antibody responses [39]. However, in a single dog that exhibited prominent antibody responses, adult hookworms were found to significantly alter their habitat selection by migrating out of the small intestine (35% reduction of small intestinal hookworms) and into the colon (1083% increase).

### 6. Cysteinyl Proteases (CP-1)

Adult *A. caninum* hookworm secrete cathepsin-B-like proteases [101,102]. These might function as hemoglobinases. Modeling of one of these enzymes, Ac-CP-1 indicates that it preferentially cleaves Phe–Arg over Arg–Arg, thereby providing an explanation of why the enzyme contains cathepsin-L-like substrate specificity, although structurally it more closely resembles cathepsin B [103]. Ac-CP-1 exhibits 51% homology to the *H. contortus* cysteinyl protease HMCP4.

**Rationale for vaccine selection.** A cysteine protease enriched fraction from *H. contortus* that binds to thiols-Sepharose elicits 47% reduced worm burdens and 77% reduced egg excretion [92,104]. In *H. contortus*, the predominant CP appears to localize to the gut membrane [92], whereas it is a secreted amphidial antigen in hookworms. Cysteinyl proteases were also shown to function as effective antigens for some laboratory animal trematode infections.

### 7. Other Secreted Adult Antigens

Among the other secreted proteins described from hookworms are a broad spectrum Kunitz-type serine protease inhibitor from *A. ceylanicum* [105], glutathione S-transferases [106], a Cu/Zn superoxide dismutase [107,108], and a calreticulin-like molecule from *N. americanus* [109]. *Necator* calreticulin interacts with C1q and the cytoplasmic signaling domains of some integrins [109]. Of these, the superoxide dismutase (SOD) might hold the most promise as a vaccine antigen, based on reports of worm burden reduction with the

*Haemonchus* enzyme (David Knox, personal communication).

## B. Adult Hookworm Gut-Associated Antigens

As noted above, the gut-associated antigens of *H. contortus* are a potent vaccine that elicits high levels of protection. In particular, the H-gal-GP complex, composed of a metalloprotease(s), aspartic protease, cysteinyl protease, cystatin, thrombospondin, and galectin, results in 72% reduction in worm burdens and 93% reduction in fecal egg counts. However, the cDNAs encoding most of the components of H-gal-GP have been expressed in *E. coli* and, to date, none of these recombinant proteins have been reported to be protective [92]. For that reason, efforts are underway to express both the hookworm and *Haemonchus* components in *Pichia* (yeast) and insect cells.

### 1. Metalloendopeptidase (MEP)

Ac-MEP is encoded by a 2.8-kb mRNA with a predicted ORF of 870 amino acids ( $M_w = 99$  kDa) that contains four potential N-linked glycosylation sites and predicted zinc-binding domains (HexxH and EnxADxGG) [110]. These domains represent signature sequences of the neprilysin family of enzymes. RT-PCR indicates that the transcription of Ac-MEP occurs only in the adult stage. Experiments in which adult worms are probed with Ac-MEP-specific anti-serum localize this enzyme to the microvilli of the worm gastrointestinal tract. The function of Ac-MEP is unknown, although by its localization, it may be involved in the digestion of a blood meal. Culley et al. [111] recently showed that host eotaxin, a potent eosinophil chemoattractant that acts selectively through CCR2 expressed on eosinophils, basophils, mast cells, and Th2-type T cells is specifically cleaved by hookworm metalloproteases. Eotaxin also elicits rapid vesicular transport mediated release of preformed IL-4 from human eosinophils [112]. Therefore, Ac-MEP may have an important immunoregulatory function for the parasite.

**Rationale for vaccine selection.** In addition to its possible importance in modulating host Th-2 type effector immunity, Ac-MEP also exhibits strong amino acid sequence homology to Hc-MEP-1 and MEP-3 from *H. contortus*. The Hc-MEPs are prominent components of the H-gal-GP protective antigen complex against haemonchiasis. Hc-MEP-3, in particular appears to be an important component for protection (David Knox, personal communication).

### 2. Aspartic Proteases (APRs)

Two gut membrane-bound aspartic proteases have been cloned from *A. caninum*. Ac-APR-1 (also known as Ac-ASP in some literature) is a 422-cathepsin-D-like aspartic protease that exhibits 48.5% homology to human cathepsin D [113]. APR-1 also localizes to the microvillar brush border of the adult hookworm gastrointestinal tract (A. Williamson and A. Loukas, unpublished observation). A second, related aspartic protease (APR-2) with homology to pepsinogen from *H. contortus* [88] has also been cloned from adult *A. caninum* and *N. americanus* (A. Williamson and A. Loukas, unpublished observation).

*Rationale for vaccine selection.* Aspartic proteases from hookworms are key enzymes required for blood feeding [114,115]. Vaccination of dogs with alum-precipitated APR-1 followed by *A. caninum* larval challenge resulted in an 18% reduction in the number of hookworms in the small intestine relative to alum-injected dogs [39]. The APR-1 homolog of *H. contortus* is not considered to be a prominent component of the H-gal-GP complex (David Knox, personal communication). Instead, the major aspartic protease component of the complex is probably pepsinogen [92].

### 3. Other H-gal-GP Components

Homologs of the other predominant H-gal-GP components, namely cystatin [85], thrombospondin [87], and galectin [84], have not yet been cloned from hookworms, although expressed sequence tags (ESTs), encoding at least two distinct *A. caninum* cystatins, have been recovered from an EST database. If cloned, hookworm cystatin may be a particularly attractive component based on the observations that nematode cystatins inhibit host class II MHC-restricted antigen processing [116,117], and a cystatin homolog from the infective larval stages of *Onchocerca volvulus* (Ov7) elicits high levels of protection when formulated with alum and used as a vaccine in a mouse model [86]. Whereas the cysteinyl protease of *H. contortus* is a gut membrane-bound antigen, Ac-CP-1, the predominant hookworm cysteinyl protease, is secreted from amphidial glands, suggesting a potentially distinct role in the parasite's pathobiology.

## VI. CANDIDATE INFECTIVE LARVAL (L3) HOOKWORM ANTIGENS

### A. Larval Secretory Antigens

Secreted larval antigens are attractive hookworm vaccine candidates because they may provide the basis by which irradiated larval vaccines elicit protection. The *A. caninum* and *H. contortus* homologs of larval ASPs elicit high levels of protection in laboratory animal models [56,61–63]. Further rationale for targeting L3-secreted antigens is based on early studies with antibody from animals vaccinated with living L3, which resulted in immune precipitates at the openings of glandular ducts near the anterior end of the parasite. There are at least two major sites of secretion by infective hookworm larvae: amphidial glands and esophageal glands. Amphids are nematode organs of chemosensation; in parasitic L3, the amphids are modified to have elaborate glandular structures. The amphids are one of the only exposed organs in the environmental life history of the parasite prior to host entry. In contrast, the mouth and pharynx of L3 are sealed with an electron-dense plug while the L3 is in the soil. Therefore L3 are nonfeeding stages and believed to be developmentally arrested [118,119]. Upon host entry, the electron-dense plug is either dissolved or dislodged. This stimulates the L3 to resume feeding. Resumption of larval feeding is coupled to the resumption of development and associated with the transition to parasitism [119]. The observation that host antibody in animals rendered resistant by larval vaccination localizes to either the amphids or the oral

pore connected to the parasite esophagus, suggests that secretions originating from either of these two sources might be a rich source of protective antigens. Knox [34] has theorized that immune responses to these openings may block release of these molecules that are critical for parasite survival.

#### 1. ASP-1 and ASP-2

Ac-ASP-1 and Ac-ASP-2 are the most abundant proteins released in vitro by *A. caninum* hookworm L3 activated under host-stimulatory conditions and represent, double-domain (heterodimorphic repeat) and single-domain (monomeric form) ASPs, respectively [33,58,59]. *Ac-asp-1* cDNA encodes a 424-amino acid protein ( $M_w = 45,735$ ), including an 18-amino-acid secretory signal sequence. ASP-1 is released from the L3 amphidial glands. Similar to other ASPs, ASP-1 exhibits homology with a family of antigenic molecules from hymenoptera venoms, such as antigen 5 from the yellow jacket *Vespa squamosa*, and antigen 3 from the red imported fire ant, *Solenopsis invicta*. ASP-1 is released within 30 min after host-stimulated activation of the parasite, with the majority released by 4 hr. Complementary DNAs homologous to *Ac-asp-1* cDNA were cloned from the human hookworms *A. duodenale* and *N. americanus* [71]. Each of the predicted proteins exhibits characteristic heterodimorphic repeat structure. *Ad-asp-1* from *A. duodenale* L3 encodes a 424-amino-acid protein with a 19-amino-acid hydrophobic signal sequence. There are three potential N-linked glycosylation sites, none of which are present in Ac-ASP-1. The *Na-asp-1* cDNA from *N. americanus* also encodes a 424-amino-acid protein, but like Ac-ASP-1, it contains no potential N-linked glycosylation site. Surprisingly, the Na-ASP-1 sequence from *N. americanus* is more similar to the Ac-ASP-1 sequence than the sequence from the congeneric species *A. duodenale* (97% vs. 88% amino acid homology) [33,71]. Ac-ASP-2 is the second most abundant molecule released by activated *A. caninum*. The *Ac-asp-2* cDNA encodes a single-domain ASP of 219 amino acids ( $M_w = 23,954$ ), which also has homology to the hymenoptera venom antigens [59]. Of the ASP cDNAs cloned from *A. caninum*, it is of interest to note that the ORF encoded by *Ac-asp-1* most closely resembles Hc40 from *H. contortus* L3, while *Ac-asp-2* cDNA most closely resembles Hc24 from *H. contortus* adults (Table 4). ASP-1 is most likely derived from L3 amphids whereas ASP-2 is released through the oral opening from L3 esophageal/pharyngeal glands.

*Rationale for vaccine selection.* The rationale for targeting L3 amphidial or esophageal gland secretory products is outlined above. In addition, vaccine studies conducted with recombinant Ac-ASP-1 expressed in *E. coli*, indicate that this will function as a protective antigen in laboratory mice challenged with *A. caninum* L3 [61–63]. Because L3 do not develop to adult hookworms in mice [44,61], vaccine protection was measured by counting the number of L3 that enter the lungs after either oral or subcutaneous inoculation. These studies also confirmed that vaccine protection is antibody mediated and IgE-dependent [62]. Bm-VAL-1, an ASP from the filarial parasite *Brugia malayi* protects jirds against challenge infection [120]. Similarly, Hc40, an ASP

homolog from *H. contortus* L3 elicits high levels of protection in guinea pigs, either as the natural product (>80% protection) or as a baculovirus expressed recombinant protein (45% protection) after *H. contortus* challenge [56].

## 2. Astacin-Like Metalloprotease (MTP)

In addition to the ASPs, *A. caninum* L3 also release a zinc metalloprotease upon in vitro stimulation with host serum ultrafiltrate [121–123]. A cDNA encoding Ac-MTP was isolated by screening an *A. caninum* L3 cDNA expression library with serum from human patients that are putatively resistant to hookworm infection [123]. The protease is a member of the astacin family of metalloproteases, and is characterized by a conserved zinc binding region, HExx-HxxGFxHExxRxDRDm, and a “Met turn,” SxMHY. The domains of Ac-MTP-1 are typical of astacin family members, and include a signal peptide, a prosequence that is cleaved during protease activation, a highly conserved catalytic domain, and C-terminal EGF-like and CUB domains. RT-PCR from life cycle stages indicated the presence of *Ac-mtp* mRNA in both L3 and adult stages, but not in the egg, or L1/L2 stages. Western blots using a polyclonal antiserum against recombinant MTP-1 indicate that only infective larvae stimulated in vitro with host serum components secrete the metalloprotease.

*Rationale for vaccine selection.* The stage specificity and secretion of Ac-MTP during L3 activation suggests a critical function in the infective process. Possibly, the enzyme is used either in tissue invasion or molting. For that reason, together with its apparent immunoreactivity to patient serum [123], Ac-MTP is an attractive vaccine antigen candidate.

## 3. Acetylcholinesterase (ACh)

A 1851 cDNA encoding an ORF of 594 with predicted homology to nematode acetylcholinesterase has been cloned from *N. americanus*. By western blots using anti-Na-ACh-specific antiserum, ACh was secreted by both L3 and adult stages of *A. caninum*.

*Rationale for vaccine selection.* The observation that *Dictyocaulus* and *Trichostrongylus* protective immunity can be stimulated with purified ACh [68–70] suggests that this antigen is worth pursuing for vaccine development. *Necator* ACh is also immunogenic in humans [124]. The function of nematode ACh is unknown. However, an older body of literature also points to the importance of nematode ACh for parasite survival [125], while newer data indicates that ACh and related enzymes affect host immunity [126–128].

## 4. Transthyreitin (TTR)

Both larval and adult stages secrete proteins with homologies to *Caenorhabditis elegans* retinol binding proteins. The larval retinol binding protein is a 144-amino-acid polypeptide with homology to a protein known as transthyreitin. Its predicted  $M_w$  is 15,934 (with signal peptide). Its function is unknown, although it may serve to scavenge host retinol. A protein with partial homology to TTR from *O. volvulus* (Ov20) was shown to elicit partial protection.

## B. Larval Surface Proteins

Two cDNAs encoding *A. caninum* larval surface proteins have been cloned and expressed. Ac-103 is a homolog of Ov-103, a protective antigen from *O. volvulus*. A second protein was obtained by immunoscreening using antiserum from a rabbit immunized with live *A. caninum* L3. The protein has regions of predicted homology to von Willebrand factor.

## VII. MECHANISMS OF VACCINE PROTECTION

There are very few studies on the mechanisms by which recombinant nematode antigens protect against challenge infections. However, increasing evidence points to the importance of host IgE responses and Th2-type immunity for a successful vaccine outcome. Kooyman et al. [93] found that vaccine protection with the adult *H. contortus* secretory proteins Hc24 and Hc15 depends on the age of the cohort and that this correlates with the magnitude of host IgE responses. Vaccinated sheep, 9, 6, or 3 months of age, were protected for 83%, 77%, and –34%, respectively. The difference between these vaccinated groups significantly correlated with antigen-specific IgE responses. Increased eosinophilia and mucosal mast cells were also noted [93]. Mice vaccinated with Ac-ASP-1 elicit Th2 responses marked by high antigen-specific IgG1 and IgE [62]. This vaccine protection is abrogated when mice receive injections of antimouse IgE, or if vaccinations are conducted in mice deficient in host IL-4. In contrast, vaccine protection is unaffected in mice receiving antimouse IgG or if the vaccinations are conducted in mice deficient in gamma interferon (K. Ghosh, unpublished observations). Mice vaccinated with recombinant antigens derived from *O. volvulus* exhibit increased protection when the antigens are first formulated with alum (a Th2-inducing adjuvant) instead of Freund's complete adjuvant [86]. Human correlates of immunity to hookworm antigens have not been extensively investigated. However, in two preliminary unpublished studies, human IgE antibody to recombinant Ac-ASP-1 [129] and Ac-MEP was associated with lower fecal egg counts (J. Bethony, unpublished communication).

The importance of IgE in mediating antigen-specific vaccine protection may also partly explain why purified proteins elicit worm burden reductions and lowered fecundity when the corresponding recombinant *E. coli* proteins fail. Most investigators interpret this finding on the basis of conformational epitopes that are not preserved in the *E. coli* expressed product. Indeed, baculovirus-expressed Hc40 protects, whereas the *E. coli*-expressed Hc40 fails [56]. However, as an alternative explanation, Holland et al. [130] found that proteins secreted by parasitic nematodes act as natural adjuvants for Th2 responses, whereas comparable Th2 stimulating adjuvants are possibly missing in *E. coli* expressed proteins.

The mechanisms by which IgE results in worm burden reductions are unknown. IgE may promote eosinophil attachment to parasite surfaces and result in antibody-dependent cell mediated toxicity (ADCC). In the case of amphidial-derived proteins, cellular attachment at the

ampullal opening could interfere with parasite-secretory mechanisms or chemosensation. Alternatively, generation of relatively high levels of specific IgE may be important in mast cell mediated effector responses [37]. The observation that eosinophils released cytokines [112] has led to the suggestion that eosinophils may function as antigen presenting cells, particularly after IgE binding to Fc receptors. In this case, the appearance of IgE might possibly break tolerance to masked parasite antigens.

In contrast to vaccinations with single antigens, vaccinations using living L3 appear to operate by redundant pathways. For instance, anti-IgE has no effect on protective immunity against *S. stercoralis* L3 in mice [131], and IL-4 deficient mice vaccinated with *A. caninum* L3 are still protected against challenge infections. Vigorous cellular inflammatory responses to challenge L3 are seen after live L3 vaccinations [132–138], but cellular inflammation is typically absent during single antigen vaccinations.

## VIII. PRECLINICAL TESTING

Successful preclinical testing of recombinant hookworm antigens requires their appropriate soluble expression in a prokaryotic or eukaryotic vector and isolation by chromatographic methods, selection of an appropriate laboratory animal for vaccine testing, appropriate adjuvant formulation to elicit high levels of antigen-specific IgE, and selection of an optimal challenge route of infection.

### A. Protein Expression

Experience with recombinant *Haemonchus* antigens suggests that *E. coli*-expressed proteins will not be suitable for hookworm vaccinations. To date, no *E. coli*-expressed recombinant protein has been reported to offer protection against *H. contortus* challenge infection. The reason for this has been largely explained on the need to preserve conformational epitopes, which are not typically preserved in many *E. coli*-expressed antigens. Recently, baculovirus-expressed Hc40 (ASP homolog) was shown to exhibit significant protection [56], whereas baculovirus-expressed H11 did not [92]. There are no reports of vaccine studies with *Pichia*-expressed *Haemonchus* proteins, although *Pichia*-expressed NIF from *A. ceylanicum* was reported to elicit reduced fecundity among female *A. ceylanicum* hookworms in hamsters [95]. A distinct advantage of *Pichia* expression over insect cell expression are the lower costs and higher yields associated with the former, and therefore the possibility of developing *Pichia* recombinant proteins as low-cost, public sector vaccines. Recently, Na-ASP-1 from *N. americanus* was expressed in *Pichia*, and Ac-APR-1 from *A. caninum* was expressed in baculovirus. A number of platform technologies also offer potential promise for hookworm vaccine development.

### B. Laboratory Animals

*N. americanus* infections have been successfully established in nonhuman primates, such as the chimpanzee and patas

monkey [139]. However, the expense and support required for maintaining nonhuman primates and conducting pre-clinical trials precludes their use for routine vaccination studies. Although the dog, rabbit, and hamster have demonstrated some degree of susceptibility to infection with *N. americanus* [140–143], they do not yield reproducible and consistent numbers of adult hookworms in the small intestine and therefore are not considered reliable models for pre-clinical vaccine testing. *A. duodenale* has been successfully adapted to dogs [144], but steroids are usually required in order to ensure that large numbers of L3 successfully mature into adult hookworms. Mice can be employed to model L3 tissue migrations of a number of hookworm species [44, 61,62], but L3 seldom if ever mature to adult hookworms in mice.

Currently, the two laboratory animal systems that have been successfully used for vaccine development are: (1) hamster infections with *A. ceylanicum* [95,145] and (2) canine infections with *A. caninum* [146]. Of the two, only canine infections with *A. caninum* model a natural host-parasite relationship. For that reason, *A. caninum* infections in dogs most closely resemble *A. duodenale* human hookworm infections. Like *A. duodenale*, *A. caninum* L3 are both orally and percutaneously infective. The L3 of both species have the capacity to undergo developmental arrest and possibly undergo lactogenic transmission. Among the differences between canine and human hookworm infections is the observation that an age-related innate resistance develops in the former. This feature shortens the window period when a vaccine can be successfully studied. For vaccine studies, purpose-bred beagles are usually vaccinated with hookworm antigens formulated with adjuvant beginning at 8–10 weeks of age. Up to 2 months are often required in order to complete the immunizations series, followed by challenge infections. In nonvaccinated dogs, challenge doses of 400 L3 result in the establishment of 100–150 adult *A. caninum* hookworms in the gastrointestinal tract [146].

### C. Adjuvant Selection

The importance of antigen-specific IgE in mediating antigen-specific vaccine protection may require specific augmentation of host Th2 immune responses through new adjuvants. To date, alum and aluminum hydroxide (Alhydrogel™) have been the most reliable adjuvant for promoting this type of responses [61–63,86]. Although the Glaxo Smith Kline adjuvant SBAS2 promotes high levels of antibody, it does not elicit vigorous IgE responses (unpublished observations). The Lewis-type carbohydrate lacto-*N*-fucopentaose III (LNFP III) found on *Schistosoma mansoni* egg antigens was recently found to promote Th2-type immunity [147], and may become useful for parasite vaccinations. LNFP III may also find a role in DNA vaccinations, which have not yet successfully stimulated protective immunity against gastrointestinal helminths.

### D. Route of Immunization and Challenge

Both subcutaneous and intramuscular injections of antigens have elicited high levels of antihookworm immunoglobulin

in mice, hamsters, and dogs [61–63,145,146]. In mice, intraperitoneal injections are also effective in eliciting high titers of Th2 antibody [62]. Both oral and subcutaneous challenge doses of hookworm L3 have been used successfully in laboratory animals. Subcutaneous challenge is used commonly to substitute for skin penetration. The advantage of subcutaneous challenge in dogs is that high percentages of L3 successfully migrate into the lungs and gastrointestinal tract. Therefore it is possible to standardize the challenge dose with relative ease. This is in contrast to percutaneous challenges in which only a small percentage of the L3 successfully penetrate skin even in nonvaccinated controls [49]. Concerns have been raised, however, that subcutaneous challenge bypasses the skin, which is an important organ of immunity against hookworm [49]. Intradermal inoculation may therefore be a more preferable route of challenge.

## IX. HUMAN CLINICAL TRIALS

No human clinical trials have been conducted with recombinant hookworm vaccines. Successful preclinical testing will warrant the good manufacturing practices (GMP) manufacture of hookworm antigens suitable for immunogenicity testing in nonhuman primates followed by Phase 1 safety testing in the United States. Possible toxicities include the requirement to elicit IgE responses that could potentially cross-react to other antigens, including autoantigens in human tissue. For instance, the ASPs exhibit a small region of homology with testes-specific protein found in mammalian sperm [58,59]. These issues will require resolution prior to safety testing.

Because of the public-sector nature of a hookworm vaccine, it is not likely that GMP manufacture will be carried out by one of the traditional large pharmaceutical companies. Instead, its manufacturing may occur offshore, presumably in a country with a proven track record for producing high-quality vaccines, and presumably in a country with endemic hookworm. This list might include Brazil, Mexico, India, or China. Target age populations and appropriate dosing schedules for the vaccine may depend on the in-country epidemiology of hookworm. Studies in China and elsewhere suggest that women of child-bearing age might represent one such target population. To date, there is no evidence of significant geographic antigenic variation of the major hookworm-vaccine candidates under investigation [148].

The development of a hookworm vaccine has the potential to enormously impact on the health, education, and economic underdevelopment for the rural poor living in the tropics and subtropics. It would diminish the reliance on benzimidazole anthelmintics and, at the same time, lower hookworm burdens among at-risk populations including children, pregnant women, and the elderly.

## ACKNOWLEDGMENTS

These studies were supported by the Human Hookworm Vaccine Initiative of the Sabin Vaccine Institute and The

Bill and Melinda Gates Foundation, as well as grants from the NIAID, NIH (AI-32726 and AI-39461).

## Principles of Therapeutic Vaccination for Viral and Nonviral Malignancies

Drew M. Pardoll

*Johns Hopkins University School of Medicine, Baltimore, Maryland, U.S.A.*

### I. INTRODUCTION

In contrast to the success of many prophylactic vaccines, therapeutic vaccination for established chronic infections as well as cancer has yet to achieve widespread acceptance. To date, no therapeutic vaccine has been approved for general use in the United States, despite there being a number that have recently been tested in Phase III registration trials. The striking differences in success between immunoprophylaxis and immunotherapy are based on the fact that, in order to become successfully established within the host, either pathogens or cancer cells have developed mechanisms to avoid recognition and elimination by the immune system (Table 1). Potential mechanisms for immune invasion are best understood for tumors and viruses, which often use common strategies. Downmodulation of components of the antigen processing and presentation system to T cells represents one of the best defined mechanisms for both viruses and tumors [1–31]. Production of cytokines that inhibit or divert productive effector responses [32–35] as well as induction of antigen-specific tolerance through normal pathways of self-tolerance generation [36–46] represents additional mechanisms by which tumors and some viruses can avoid recognition by the immune system. However, these mechanisms of immune resistance do not represent absolute barriers. Most chronic viral infections involve expression of at least one viral gene which provides a target for immunotherapy. Although they are derived from “self,” all tumors express antigens recognizable by the immune system, either as unique antigens (the result of genetic alterations), tissue-specific antigens or upregulated self-antigens (Table 2) [47,48]. While most successful prophylactic vaccines protect through the induction of long-lived neutralizing antibody responses, successful immunotherapy of established cancer or pathogenic infections will likely depend to a larger extent upon diverse effector pathways regulated by both CD4 and CD8 T cells [49].

Despite the barriers to immunotherapy of chronic viral infection and cancer, the fundamental knowledge about the

molecular and cellular basis for immune regulation, particularly at the level of T-cell responses, provides a new arsenal of approaches to enhance antigen-specific responses in both these settings. In the case of cancer, immune responses to antigens can be induced through both engineering of the tumor cells themselves or by engineering responses against specific tumor antigens.

### II. THE LINK BETWEEN CHRONIC VIRAL INFECTION AND CANCER

Many of the strategies for development of immunotherapy are applicable to both cancer and chronic viral infections. The immunobiology of these two diseases has indeed intersected for a number of reasons. First, chronic viral infections are carried in the form of integrated or episomal proviruses within viable cells. Recognition and elimination of these virally infected cells appears to involve similar mechanisms to the recognition and elimination of tumor cells. In the case of viral infections, viral antigens expressed during the chronic carrier state represent ideal targets for antigen-specific immunotherapy. While the delineation of immunodominant antigens in tumors is a much more complex endeavor, chronic viral infection offers defined antigens to target with immunotherapy. The most significant link between immunotherapy efforts for viruses and cancer comes from the fact that some of the most common human cancers in immunocompetent individuals are induced by chronic viral infection and actually harbor proviral elements.

The most clear-cut link between viruses and human cancer is represented by human papillomavirus (HPV) infection, whose prooncogenic properties depend on the expression of the E6 and E7 antigens [50–53]. E6 binds and induces the degradation of the tumor suppressor gene p53 whereas E7 binds and induces the inactivation of the tumor suppressor gene, Rb. These events are not transforming but enhance the probability of transformation significantly by

**Table 1** Contrasting Features of Prophylactic Vaccines and Therapeutic Vaccines Indicate Significant Differences Between the Two

Prophylactic vaccines	Therapeutic vaccines
<ul style="list-style-type: none"> <li>• Typically infectious dz</li> <li>• Antibody mediated</li> <li>• Immune system is naive to vaccinating antigen—no tolerance or immune evasion</li> <li>• Antigens are known</li> </ul>	<ul style="list-style-type: none"> <li>• Typically cancer</li> <li>• T-cell responses key</li> <li>• Immune system has been exposed to vaccinating antigen—tolerance and/or immune evasion operative</li> <li>• Relevant antigens may not be known</li> </ul>

reducing genome integrity, thereby facilitating the accumulation of additional transforming mutations. Essentially all cervical cancer as well as anal cancer and a proportion of head and neck cancer arises from HPV-infected cells in the cervix, anus, and oral/laryngeal epithelium, respectively. Of the over 100 HPV types, only 8–10 predispose to cancer, with HPV-16 and HPV-18 being the most common. One of the most compelling arguments for the development of a therapeutic vaccine for premalignant HPV infection is that a majority of HPV infections are naturally eliminated by the immune system in immunocompetent individuals. Even late-stage premalignant HPV lesions (so-called CIN II or CIN III) resolve spontaneously in a significant proportion of women. The dramatic increase in HPV persistence in immunodeficient individuals confirms the central role of the immune system in viral elimination in immunocompetent women. It is thus possible that a relatively modest enhancement of the right type of immune response directed at E6 and/or E7 might tip the balance toward immune elimination of infected cells.

Hepatocellular carcinoma, a leading cancer killer worldwide, is associated with chronic hepatitis B or hepatitis C chronic virus infection in the majority of cases [54–57]. Chronic hepatitis is a precursor to cancer with both viruses. The etiologic link between these viruses and cancer is less clear than with HPV. Both viruses elicit potent immune responses during acute infection. While the acute hepatitis accompanying hepatitis B infection is relatively strong and results in viral clearance >90% of the time, the acute response to hepatitis C infection is generally mild (and asymptomatic) and clears the virus only about 20% of the time. While gene products of both viruses have been implicated in carcinogenesis, it is believed that the nonsterilizing inflammatory responses during the chronic phase of both these viruses may be the major contributor to cancer formation.

While Epstein–Barr virus is best known for its role in lymphomagenesis in immunodeficient patients, it also causes cancers such as Burkitts lymphoma, nasopharyngeal carcinoma, and Hodgkins disease in immunocompetent individuals [58–60]. Almost everybody is infected with EBV, whose transition from latency (generally in B cells) is rapidly perceived by the immune system such that EBV transformed cells are rapidly eliminated by a T-cell-dependent response. This is the classic example of successful immune surveillance. It is still unclear how EBV evades immune surveillance in cases of EBV-associated cancers in immunocompetent individuals, as they all express a subset of EBV antigens capable of recognition by T cells. The finding that the EBNA-1 antigen contains sequences that prevent its processing via the proteasome provides a hint at mechanisms of immune evasion [61], although other antigens such as LMP-2 appear to be perfectly recognizable. In any case, all of the chronic viral infections associated with premalignant states are good candidates for therapeutic vaccination.

### III. PRINCIPLES IN THE CANCER–IMMUNE SYSTEM INTERACTION UNDERLYING CANCER VACCINE STATEGIES

Successful immunotherapy of cancer will ultimately require understanding the natural relationship between the immune system and tumors as they transform, invade, and metastasize. There is evidence that immune responses against tumor antigens bear both similarities and differences to immune responses against “self” tissue antigens. That immunity to tumors would resemble immunity to normal tissues is not surprising as tumors are, of course, transformations of normal cells in which growth control has become deregulated. However, dissection of the molecular events of tumori-

**Table 2** Categories of Tumor Antigen<sup>a</sup>

- 3) Antigens selectively expressed in tumor >> normal tissue: MAGE1-3, BAGE, GAGE (“cancer-testes ag”), HER-2/neu
- 4) Viral antigens in virus associated malignancies: HPV (E6 and E7), EBV (EBNA-1, LMP-1, and 2), HBV, HCV

<sup>a</sup> The list of candidate tumor rejection antigens continues to grow. The most specific tumor antigens arise from mutations, however, these are usually unique to individual tumors. The other three categories (tissue specific antigens, tumor selective antigens, and viral antigens) are shared among many tumors.

ginesis together with the pathophysiology of cancer progression teaches us that there are significant features that distinguish cancer cells from their normal counterparts. Some of these differences significantly impact the nature of their interaction with the immune system. It is these distinctive features that may well represent the immunologic Achilles heel of cancer, capable of being exploited therapeutically.

Specifically, tumors differ fundamentally from their normal cell counterparts in antigenic composition and biologic behavior. The molecular hallmark of carcinogenesis is genetic instability [62]. Genetic instability in cancers is a consequence of deletion and/or mutational inactivation of genome guardians, such as p53 [63]. Indeed, many of the genetically defined familial cancer syndromes, such as hereditary nonpolyposis colon cancer and familiar breast cancer, are due to mutation in genes that mediate responses to DNA damage [64–69]. The genetic instability of cancer cells means that new antigens are constantly being generated in tumors as they develop and progress. This does not occur in normal, nontransformed tissues, which maintain a very stable antigenic profile. In addition to the thousands of mutational events that occur during tumorigenesis, hundreds of genes that are either inactive in the normal tissue of origin or expressed at relatively low levels are activated dramatically in cancers. While these epigenetic changes do not formally create tumor-specific neoantigens, they raise the concentration of encoded proteins many orders of magnitude, thereby dramatically affecting antigenicity.

While uncontrolled growth is certainly a common biological feature of all tumors, the major pathophysiologic characteristics of malignant cancer responsible for morbidity and mortality are the ability to invade across natural tissue barriers and to metastasize. Both of these characteristics, which are never seen with normal tissues or benign tumors, are associated with dramatic disruption of tissue architecture. One of the important consequences of tissue disruption, even when caused by noninfectious mechanisms, is the elaboration of pro-inflammatory signals. These signals, generally in the form of cytokines and chemokines, are central initiators of both innate and adaptive immune responses. Thus, unlike normal tissues, cancers are constantly confronted with inflammatory responses as they invade tissues and metastasize through the body. How they handle and modulate these responses dictates the interplay with the host immune system [70].

Despite a continuing interest in the concept of natural immune surveillance of cancer, there is an ample wealth of evidence that the normal immune response to tumor antigens is tolerance induction, rather than activation. In considering the concept of tolerance induction by tumors, it is critical to distinguish between induction of unresponsiveness through mechanism such as anergy or deletion vs. resistance mechanisms to recognition and killing of tumor cells by activated immunologic effectors. In contrast to tolerance induction, which implies a failure of immune surveillance, the presence of resistance mechanisms that cloak the tumor from recognition by T cells or inhibit the function of immune effectors implies that the tumor was either selected or has adapted to survive an environment in which immune surveillance is operative.

While there is a huge body of literature on tumor resistance mechanisms, virtually all of the evidence is circumstantial and does not prove that the observed alterations in antigen processing machinery or expression of immune inhibitory molecules is a response on the part of the tumor to activate antitumor immunity. Downregulation of the antigen processing machinery—particularly the MHC class I pathway—has been documented extensively in a large variety of tumors. In the human, downregulation of the MHC class I molecules has been observed in a diversity of tumor types, particularly breast cancer, prostate cancer, and lung cancer [1–18]. Downmodulation of MHC class I genes can result from multiple mechanisms affecting transcription [13,23,71]. Downregulation of TAP genes as well as components of the immunoproteasome such as LMP-2 and LMP-7 has likewise been documented in a number of tumor types [25–30]. In the majority of cases where the MHC class I processing machinery is downmodulated, it is usually rapidly upregulated by IFN- $\gamma$ , suggesting that the diminished expression is epigenetic in origin and reversible.

The other major mechanism for putative immune resistance by tumors is the expression of secreted or cell surface molecules that either kill or inhibit cellular components of the effector immune response. The most clear-cut example is TGF- $\beta$ , which is produced by many different tumors particularly of epithelial origin [32–35]. Relatively little evidence exists that expression of TGF- $\beta$  by tumors protects them from recognition and killing by effector components of the immune response once they have been successfully activated. It is in fact more likely that TGF- $\beta$  inhibits the generation of pro-inflammatory responses during tumor invasion and therefore inhibits the induction of immune responses at the outset. It is thus a more likely agent to participate in the induction of true immune tolerance (see below) rather than immune resistance. A more controversial effector of immune tolerance is FasL. After an initial spate of reports that many tumors express FasL and that FasL expression provides immunologic resistance with consequent enhanced *in vivo* tumor growth [72–77], subsequent reports have called these conclusions into serious question [78–80]. Difficulties in assessing the true levels of cell surface FasL expression by monoclonal antibodies have been a major technical problem. Thus expression of FasL by tumors is unlikely an important mechanism in resistance to recognition by effector components of the immune system.

In contrast to persistent uncertainties regarding tumor resistance mechanisms, experiments employing TCR transgenic mice have provided strong evidence for the capacity of tumor cells to induce tolerance to their antigens [36–45]. Tolerance appears to be operative predominately at the level of T cells; B-cell tolerance to tumors is less certain as there is ample evidence for the induction of antibody responses in animals bearing tumors as well as human patients with tumors. With the exception of antibodies against members of the epidermal growth factor receptor family, there is little evidence that the humoral response to tumors provides significant or relevant antitumor immunity. In contrast, numerous adoptive transfer studies have demonstrated the potent capacity of T cells to kill growing tumors, either directly through CTL activity or indirectly through multiple

CD4-dependent effector mechanisms [81,82]. It is thus likely that from the tumor's standpoint, induction of antigen-specific tolerance among T cells is of paramount importance for survival. Likewise, breaking tolerance to tumor antigens is absolutely critical if therapeutic vaccines are to have a significant clinical impact against cancer.

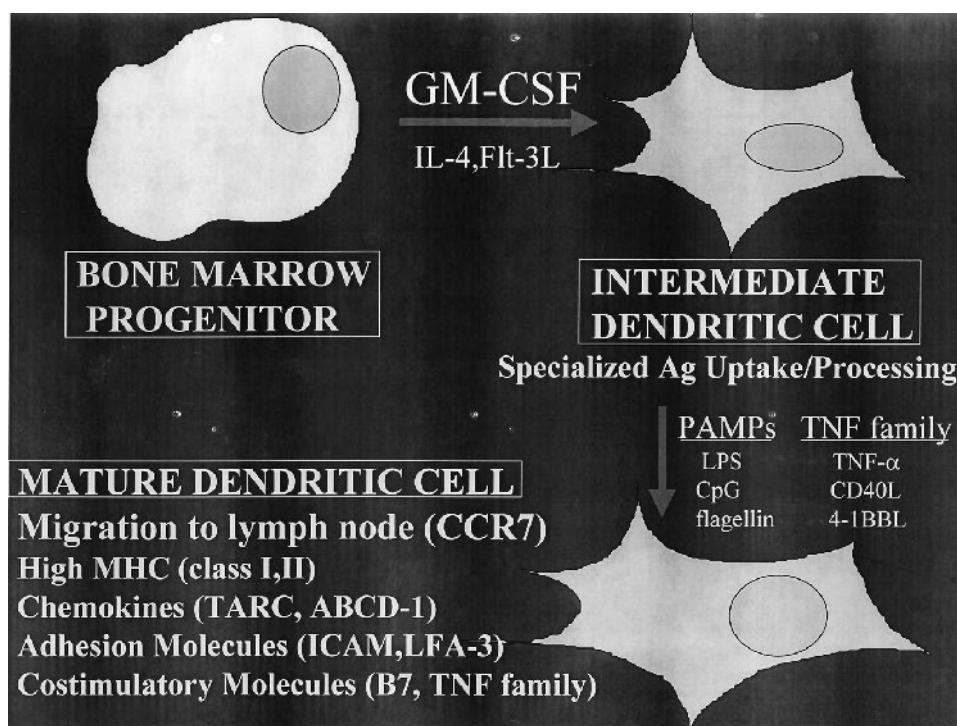

#### IV. CENTRAL ROLE OF THE DENDRITIC CELL AS A TARGET FOR THERAPEUTIC VACCINES

The most common theme among active immunotherapy strategies is enhancement or modulation of APC function. Indeed, presentation of antigen by APCs is the critical initial step in the initiation of adaptive immunity. The quantitative and qualitative characteristics of T-cell responses to antigen depend upon the signals they receive from the APC. Elucidation of the molecular events of APC proliferation, differentiation, and activation, together with the molecular definition of signals communicated between APCs to T cells, is transforming the design of therapeutic vaccines. Among the major bone marrow-derived APC subtypes (B cells, macrophages, and dendritic cells), the dendritic cell (DC) has emerged as the most potent APC type responsible for initiating immune responses (Figure 1). As virtually all phases of DC differentiation and function can be modulated by engineered vaccines, it is important to understand the molecular signals that regulate their role in the activation of T-cell-dependent immunity [83,84].

At sites of infection and inflammation, bone marrow-derived progenitor cells (either circulating or resident in the tissue) respond to both proliferative and differentiative

signals in order to develop into mature DCs. The cytokine GM-CSF is the most potent known mitogenic factor for DCs at both immature and mature stages. Other cytokines such as FLT-3L, IL-3, and IL-4 can also serve as mitogenic or comitogenic factors for DCs, particularly in conjunction with GM-CSF [85–89]. Initially, immature DCs pass through a stage of differentiation that is specialized for antigen uptake and processing but not for presentation to T cells. Antigen uptake occurs through both micropinocytosis ("drinking of fluid-phase antigens") and receptor-mediated endocytosis, dependent upon lectin-like membrane molecules such as CD36 and DEC-205 [90,91]. Once in endosomal compartments, antigens are digested into peptide, peptidoglycan, and glycolipid fragments which are shunted to lysosome-like compartments where they associate with MHC class II as well as class Ib molecules [92]. In addition to processing within vesicular compartments, antigens are also transferred out of endosomes and into the cytosol where they can undergo proteasome-dependent processing and TAP-dependent transport into the ER for association with MHC class I molecules [93].

Once they have ingested antigens at inflammatory sites in the tissue, immature DCs differentiate in response to a number of distinct "maturation" signals. While many diverse molecules induce DC maturation, most appear to signal DCs via binding to two classes of receptor—the toll-like receptors (TLR) and the TNF receptor (TNFR) family. Toll-like receptors are "pattern recognition receptors" (PRR) which bind common chemical moieties expressed by pathogens termed pathogen-associated molecular patterns (PAMPs) [94]. Lipopolysaccharide (LPS) is the prototypical PAMP and activates the maturation of DCs through binding

**Figure 1** Signals involved in the differentiation and maturation of dendritic cells.

to a TLR-4-containing complex. Other examples include zymosan which binds to TLR-2 and unmethylated CpG DNA sequences which bind to TLR-9. The TNFR family members deliver maturation signals in response to endogenously produced ligands. The two best characterized endogenous DC maturation factors are TNF- $\alpha$  itself and CD40L [95–97]. It is as yet unclear whether these different DC maturation signals result in distinct phenotypes of activated DCs. They all appear to have at least one signaling pathway in common, which is activation of NF- $\kappa$ B.

One of the first consequences of DC maturation is the expression of chemokine receptors such as CCR7 which cause migration from the peripheral tissues to the draining lymph nodes via afferent lymphatics [98]. Once in the draining lymph node, full maturation transforms DC function from antigen uptake and processing into antigen-presentation to T cells. This maturation phase involves the traffic of MHC class II molecules from MHC loading compartments onto the cell surface where they present peptides derived from antigens ingested during the immature tissue phase [99,100]. Presentation of MHC class II-restricted antigens to CD4 cells in the paracortical regions of the lymph node sets up a cross talk in which CD4 cells further activate DCs through CD40 as well as CD40-independent pathways [101–104]. These activated DCs are particularly potent in presenting antigens to and activating CD8 cells. Mature DCs also produce chemokines that selectively attract immature T cells to their surface. This function together with expression of high levels of adhesion molecules such as ICAM-1 can be dramatically observed through clustering of as many as 100 T cells onto the surface of a single dendritic cell [105].

In addition to provision of high densities of peptide-MHC complexes for T-cell stimulation (termed signal 1), DCs regulate T-cell activation and differentiation through provision of costimulatory signals in the form of soluble and membrane-bound ligands (collectively termed signal 2). The best characterized soluble signal delivered to T cells by DCs is the cytokine IL-12, which induces IFN- $\gamma$  production and promotes Th1 differentiation via a STAT-4-dependent pathway. The best characterized membrane-bound costimulatory ligands are represented by the B7 family. Activation of naïve T cells is critically dependent upon the engagement of the CD28 receptor by B7.1 and B7.2, the first two B7 family members to be discovered [106–109]. While essentially all APC types express B7.1 and B7.2 to varying degrees upon activation, mature DCs express higher levels of B7.2 than any other APC [96,110]. At least three other more recently discovered B7 family members—B7H1/PDL1, B7-DC/PDL2, and B7H3—are also expressed by DCs [111–115]. These B7 family members fail to bind CD28 (or its counter-regulatory partner CTLA-1), indicating that a complex family of costimulatory ligand-receptor pairs participate in the delivery of signals to naive T cells. These distinct B7 family members appear to induce different patterns of cytokine production by T cells.

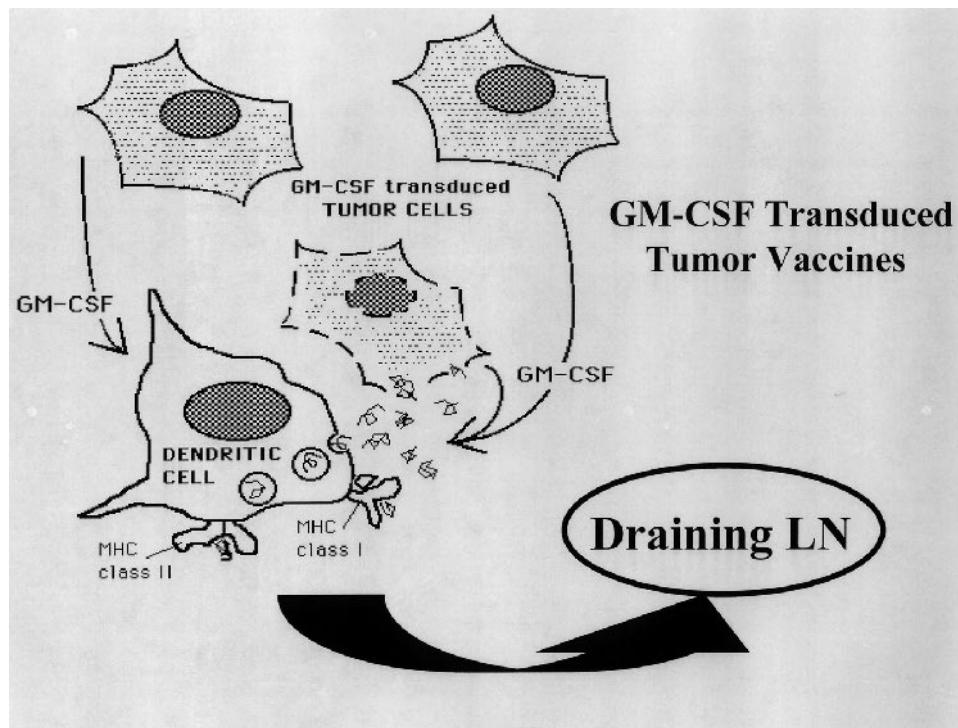

In addition to the B7 family members, other TNF family members expressed by DCs costimulate T cells. 4-1BBL and OX40-L represent examples of this category of costimulatory signals [116–118]. The ever-expanding panoply of costimulatory signals utilized by DCs to instruct T cells as to their pathway of differentiation and effector function defines

a high degree of complexity to the communications that occur between APC and T cell. Each of the molecular events involved in proliferation, antigen presentation, and costimulation represents potential targets that are being exploited in the design of immunotherapy approaches.

## V. GENETICALLY MODIFIED CELL-BASED TUMOR VACCINES THAT ENHANCE DENDRITIC CELL FUNCTION

The elucidation of specific molecules that induce DC proliferation and maturation has provided an important tool kit for the engineering of vaccines with enhanced therapeutic potency. The prototypical example has been the incorporation of GM-CSF into cell-based tumor vaccines (Figure 2). Prior to the discovery of GM-CSF transduced tumors as potent vaccines a large number of genetically modified tumor vaccines had been evaluated. Genes introduced into tumor cells included MHC genes, genes encoding foreign antigens (so-called xenogenization) [119–121], costimulatory genes [122–124], and cytokine genes [125–134]. A detailed comparison of the potency of tumor cell vaccines transduced with different cytokine and immunoregulatory genes demonstrated that GM-CSF-transduced cell vaccines produce the most potent systemic immunity against challenge with wild-type tumor. GM-CSF-transduced vaccines were further shown to cure animals of established micrometastatic tumors [135,136]. Biopsy analysis of the local vaccine sites of GM-CSF-transduced tumor vaccines demonstrates a strong infiltrate of mononuclear cells expressing markers characteristic of the DC lineage. Within a few days of vaccination, one can find increased numbers of mature DCs in the draining lymph node together with active T-cell proliferation in the paracortical regions. As GM-CSF is strictly a DC proliferation factor, it is unclear what stimuli induce DC maturation. The most likely maturation stimulus in GM-CSF-transduced vaccines comes from endogenous factors released by dying cells, such as heat shock proteins. Indeed, a recent report demonstrated that transduction of tumor cells with the hsp-70 gene, thereby significantly increasing the concentration of intracellular hsp-70, enhanced tumor cell immunogenicity [137]. In fact, co-transduction of tumor cells with the GM-CSF gene as well as certain hsp genes or simple heat shocking of GM-CSF-transduced tumor cell vaccines prior to vaccination results in enhancement of vaccine potency relative to the GM-CSF vaccines alone [138]. Another example of vaccine engineering using a combination of DC proliferative and maturation stimuli was provided by Colombo and colleagues. They found that vaccination with tumor cells co-transduced with GM-CSF and CD40L genes generated a dramatic increase in activated DCs at the vaccine site as well as enhanced vaccine potency [139].

The adjuvant effects of paracrine GM-CSF either in the form of transduced cells or incorporated into recombinant nucleic acid vaccines (see below) results in enhancement of diverse effector functions characterized by mixtures of both TH1 and TH2 components. In addition to CTL generation, documented TH1 effector pathways induced by paracrine GM-CSF vaccines include macrophage activation resulting in the production of both superoxides and nitric oxide as

**Figure 2** GM-CSF-transduced tumor vaccines.

tumoricidal effectors. TH2 effector pathways involve the activation of eosinophils at the site of tumor metastases. These mixed effector responses have been documented in clinical trials using GM-CSF-transduced vaccines in renal cell cancer, melanoma, and pancreatic cancer [81,140].

A number of early stage clinical trials using both autologous [141,142] and allogeneic [143] GM-CSF gene-transduced cell-based vaccines have demonstrated both immunization and occasional clinical responses in diverse cancer types, including renal cancer, prostate cancer, melanoma, and pancreatic cancer. While these results are promising, they must be viewed with caution, particularly because earlier generations of BCG-based cancer vaccines that showed promise in initial reports failed to demonstrate significant clinical benefit in larger multicenter randomized clinical trials [144–146]. Two principles form the basis for application of allogeneic genetically modified vaccines. First, tumor antigen discovery studies in human cancer—particularly melanoma—have demonstrated a significant proportion of recognized antigens to be shared [47,48]. Second, a number of murine studies have demonstrated that the critical pathway for processing of tumor antigens is crosspresentation by bone marrow-derived APCs [39,46,147,148]. Thus it is not necessary to match HLA alleles between patient and allogeneic vaccine lines. Indeed, a recent analysis of immune responses generated after vaccination with an allogeneic GM-CSF-transduced pancreatic vaccine definitively demonstrated the crosspriming pathway [143,149].

One of the major challenges in the development of autologous GM-CSF-transduced vaccines clinically is the

difficulty in achieving reproducibly high transduction and subsequent GM-CSF production with each individual tumor harvest.

Additionally, it is difficult to obtain or culture large numbers of tumor cells from many cancers. In cases where large numbers of tumor cells can be easily obtained (i.e., leukemias, lymphomas, multiple myeloma, and solid tumors where a large mass of relatively pure tumor can be obtained), Borrello et al. have developed a bystander cell approach that obviates the need for individualized transduction. They have demonstrated that simply admixing a GM-CSF-producing bystander cell with unmodified tumor cells produces a vaccine effect equivalent to direct tumor cell transduction [150]. Clinical trials using a human GM-CSF-expressing bystander cell are currently in progress in multiple myeloma, acute myelocytic leukemia, and colon cancer.

## VI. EX VIVO LOADED DENDRITIC CELL VACCINES

The ability to culture DCs ex vivo has led to a plethora of studies of ex vivo antigen-loaded DCs as tumor vaccines. Initially, it was demonstrated that loading of ex vivo cultured DCs with either MHC class I-restricted peptides or whole proteins followed by administration back into the animal led to the generation of immune responses against the loaded antigen [151,152]. Subsequently, significant antitumor responses were demonstrated after injection of DCs loaded with either tumor-derived peptides or tumor lysates

[153,154]. More recently, the advent of more efficient gene transfer vectors has led to approaches in which ex vivo cultured DCs are transduced with genes encoding relevant viral or tumor antigens [155–157]. A number of recombinant replication defective viruses have been used to transduce DCs. In addition, Gilboa and colleagues have demonstrated that purified RNA can be used to effectively transduce DCs with resultant presentation of encoded antigens [158]. This strategy offers the interesting possibility that DCs could be transduced with the entire amplified transcriptome of a tumor cell, even when only tiny amounts of tumor tissue are available.

Another approach aimed at providing DCs with a full complement of tumor antigens has been DC-tumor fusion vaccines [159]. The concept behind this approach is to fuse autologous tumor cells with dendritic cells, thereby allowing for the coexpression of all relevant tumor antigens together with all relevant DC molecules within the same cell. One of the major limitations to clinically translating an approach of this type is the efficiency with which fusion can be achieved between DCs and tumor cells in the absence of selection.

Elucidation of proliferative and maturation signals for DCs has led recently to approaches in which DCs are not only loaded with antigen but are transduced with genes encoding proliferation and maturation signals. This would result in autocrine DC stimulation in vivo after reinjection. In one study, DCs loaded with antigen were transduced with genes encoding GM-CSF and CD40L. These genetically modified DCs resulted in much more potent stimulation of antitumor immunity than immunization with DCs only loaded with antigen [160].

A major issue with regard to ex vivo loaded DC vaccines is the degree of maturation that is induced in vitro and its relevance to homing and function of loaded DCs after reinjection. Concern has been raised that full-blown maturation/activation of DCs ex vivo to a stage normally achieved once they are within paracortical regions of the lymph node will impair their ability to home to lymph nodes after reinjection. This has led to the suggestion that DCs should be loaded and reinfected in an immature state and allowed to mature in vivo. Such an approach has potential negative consequences as Steinman, Bardwaj, and colleagues have demonstrated that immunization of patients with antigen-loaded immature DCs can actually result in tolerance/suppression of antigen-specific responses as compared with activation induced by immunization with antigen-loaded DCs matured in vitro prior to injection [161,162].

There are currently active clinical development of ex vivo loaded DC vaccines so the therapeutic value of various

DC manipulations will hopefully be sorted out. At present, the paucity of direct comparative studies leaves open the question of which method of loading DCs ex vivo will be the most effective.

## VII. ANTIGEN-SPECIFIC VACCINES—TARGETING ANTIGEN TO MHC PROCESSING PATHWAYS OF DENDRITIC CELLS

A major advantage of cell-based vaccines is the diversity of expressed tumor antigens and the lack of necessity to know the immunorelevant tumor antigens for a given patient's cancer (Table 3). However, the continuing elucidation of specific immunodominant antigens at the molecular level (Table 2) allows for new generations of antigen-specific vaccines that previously were only possible in infectious diseases vaccines. The elucidation of specific receptors on DCs that are responsible for receptor-mediated endocytosis provides a strategy to modify antigens so that they can be more efficiently bound to these DC uptake receptors. Indeed, the antigen-GM-CSF fusion proteins represent a potential example of DC targeting as the GM-CSF component of the antigen not only stimulates DC proliferation but also may act to target the antigen into endosomal compartments once it binds the GM-CSF receptor. Linkage of GM-CSF to antigen in the form of recombinant protein, nucleic acid, and viral vaccines has been shown to significantly enhance immunization. In the case of protein vaccines, both preclinical and clinical trials have been done with idiotype vaccination for B-cell lymphomas. Levy and colleagues demonstrated that fusion proteins of idiotype with GM-CSF-enhanced vaccine potency to the greatest extent relative to fusion of idiotype proteins to other cytokines such as IL-2 [163]. In these fusion vaccines, GM-CSF may also enhance targeting of antigen to endosomal antigen processing compartments after binding to its receptor on DC progenitors. GM-CSF protein has also been mixed with idiotype vaccines in an attempt to recapitulate the paracrine physiology of cytokines. While simple mixture is simple and can add some immunization potency, the effect is not nearly as great as when GM-CSF is genetically or physically linked to the vaccinating antigen.

More direct antigen-targeting approaches have utilized fusion genes between antigen and immunoglobulin Fc regions to enhance Fc receptor-mediated antigen uptake by APCs [164,165]. Such an approach is likely to be more effective in targeting antigens to macrophages which have

<sup>a</sup> The two major categories of tumor vaccines are cell-based and antigen-specific. Cell-based vaccines use either autologous or allogeneic tumor cells as the source of antigen.

higher levels of FcR than do DCs. Approaches that modify antigens so that they can be selectively targeted to DC receptors such as CD36 and DEC-205 may ultimately provide more effective priming [166]. A recent study demonstrated that conjugation of antigens to anti-DEC-205 antibodies dramatically enhanced the targeting of antigen to DEC-205<sup>+</sup> DCs. Importantly, this maneuver alone failed to produce sustained antigen-specific immunity, owing to the failure to activate DCs *in vivo*. Addition of an activating anti-CD40 antibody to the DEC-205-antigen conjugate did produce sustained immunity, demonstrating the importance of combining MHC targeting and APC activation strategies.

Another interesting category of proteins that may target antigen effectively to DCs and furthermore into MHC processing pathways are the heat shock proteins. It is now well established that complexing of peptide antigens to certain heat shock proteins such as gp96, hsp-70, calreticulin, and hsp-110 enhances their immunogenicity significantly [167–169]. Heat shock proteins were first utilized as tumor vaccines by purifying them from tumor cells followed by immunization. Heat shock proteins isolated from tumors are naturally complexed with a whole array of tumor-associated peptides. Other approaches to link antigen to heat shock protein have included the production of recombinant fusion proteins in which antigenic peptides are linked to the heat shock protein as well as nucleic acid-based vaccines in which fusion genes between antigen and heat shock protein gene are incorporated [170,171]. In one direct comparative study using the HPV-E7 antigen as a model, it was demonstrated that nucleic acid vaccines encoding an E7-hsp70 fusion gene

were 30-fold more effective than the wild-type E7 gene in generating CD8 responses [171]. Immunogenic hsp's complexed with antigenic peptides have been shown to efficiently load the MHC class I processing pathway [172]. Although the intracellular pathway by which heat shock proteins effectively load MHC class I molecules with their associated peptides has not yet been elucidated, Srivastava and colleagues have identified CD91, the  $\alpha 2$  macroglobulin receptor, as an important receptor for multiple types of heat shock protein (gp96, hsp-70, hsp-90) [173]. Blockade of CD91 on antigen-presenting cells resulted in inhibition of hsp-mediated *in vitro* crosspresentation into MHC on MHC class I molecules. Ultimately, the immunogenicity of heat shock proteins has been proposed to result from their ability to activate APCs in addition to targeting antigens to MHC processing pathways. One report has suggested that hsp-70 can activate macrophages via CD14/TLR-4 (LPS receptor)-dependent and -independent pathways [174]. Heat shock proteins have also been reported to activate DCs although the receptors that mediate these putative activation functions have yet to be elucidated [175].

Another approach to enhance peptide-MHC ligand density on DCs is to enhance the targeting of antigens into the MHC processing pathways. Two approaches have been utilized to accomplish this goal. One approach has utilized the linkage of targeting signals onto the antigen that will more effectively target them into MHC processing compartments and pathways. Strategies for antigen targeting to the MHC class II processing pathway have utilized the invariant chain targeting signal and the endosomal/lysosomal target-

**Figure 3** Design of recombinant antigen-specific vaccines.

ing signal in the cytoplasmic tail of the LAMP-1 protein. In the case of the LAMP-1 sorting signal, fusion genes of the E7 antigen linked to the LAMP-1 sorting signal resulted in increased targeting E7 into the MHC class II processing pathway and resultant enhancement of presentation to E7-specific MHC class II-restricted CD4 T cells [176–178]. Incorporation of the LAMP targeting signal onto the E7 gene enhanced CD4 responses and ultimate antitumor potency of both recombinant vaccinia and recombinant nucleic acid vaccines.

A number of MHC class I targeting approaches have also resulted in enhanced immunization potency [179–181]. The antigen-hsp70 fusion genes described above represent such an example, selectively enhancing antigen-specific CD8 responses. Other validated targeting signals that enhance CD8 priming include calreticulin, VP22, and *Pseudomonas* exotoxin B. Another strategy for enhanced MHC class I processing has been the construction of “epitopes on a string.” This approach separates out individual epitopes from a given antigen and strings them together separated by linkers that encode basic amino acids that are good substrates for proteosome cleavage [182]. As a number of these strategies likely function via distinct mechanisms, maximal loading of MHC on APCs will likely be achieved through combining different targeting signals (Figure 3).

### VIII. EPITOPE MODIFICATION TO ENHANCE THE T-CELL RECEPTOR SIGNAL

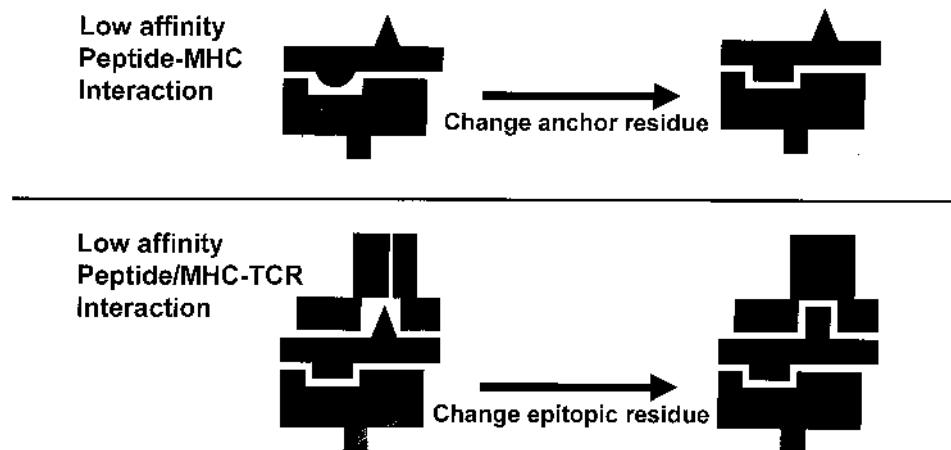

Just as with APC development and activation, the tremendous explosion in knowledge about T-cell development, antigen recognition and activation provides opportunities to engineer immunotherapies that directly modify T-cell responses. Because virtually all of the signals to T cells begin at the cell membrane, vaccines and other immunotherapies can be enhanced by inclusion of ligands that bind these cell membrane receptors. As will be discussed, the enhanced versatility of new vector systems allows for combinatorial construction of immunotherapies containing multiple elements that target multiple points in the pathway of T-cell activation.

In considering the immunogenicity of various antigenic formulations, it is commonly assumed that alterations in the immune response will depend strictly on the set of costimulatory signals (Signal-2) provided to T cells at the time of antigen recognition. However, it is now clear that both qualitative and quantitative characteristics of the peptide MHC interaction with TCR (Signal-1) are equally important in determining the outcome of T-cell responses. The two most well-defined parameters of TCR engagement are ligand density and TCR affinity. Multiple studies with altered peptide ligands have indicated that there is a relatively narrow range of TCR affinities that will produce optimal T-cell stimulation [183]. Lower affinity ligands result in partial agonist properties and ultimately in antagonist properties—under certain circumstances resulting in anergy induction. The favored model to explain these findings is a kinetic proofreading model which suggests that the TCR must be engaged by the peptide MHC complex for a long

enough time period to initiate the complete set of intracellular biochemical signaling events for T-cell activation. Engagement of the T-cell receptor for time periods less than that requisite for complete activation of signaling cascades results in incomplete activation. Suboptimal TCR engagement may ultimately deplete substrates or activate negative feedback pathways resulting in abortive T-cell stimulation and leading to a state of unresponsiveness. Even for high affinity ligands, it has been demonstrated that exposure of T cells to ligand densities below activation threshold can also result in induction of T-cell unresponsiveness. Evidence in favor of the kinetic proofreading model comes from the finding that exposure of T cells to altered peptide ligands with lower affinity for TCR results in partial phosphorylation of the zeta chain as well as other incomplete signaling events. A fundamental corollary of the hypothesis that tumors arising endogenously are capable of inducing tolerance among T cells specific for neoantigens is that the residual repertoire of tumor antigen-specific T cells will either be low affinity or specific for epitopes presented at low density. Similar mechanisms may be operative when viruses evade immune elimination and set up a chronic carrier state.

Analysis of T-cell responses specific for defined tumor antigens has indeed provided experimental evidence for this notion. The human tumor for which immunodominant antigens have been best characterized is melanoma. The majority of melanoma-specific T cells that have been grown in culture appear to recognize melanocyte-specific differentiation antigens such as MART-1/melan-A, GP100, and tyrosinase. As specific MHC class I and class II-restricted epitopes have been identified, a surprisingly large number appear to have extremely low affinities for their presenting MHC molecule, resulting in low-density peptide MHC complexes both on the tumor and on APCs loaded with the antigen. This low MHC affinity is generally associated with undesirable residues at critical anchor positions. In other cases, tumor peptides bind well to MHC molecules but available T cells display low affinities for the peptide-MHC complex [48]. T-cell responses to the immunodominant antigen of the murine CT26 colon tumor represent an example of this latter case [184]. This antigen, derived from an endogenous retroviral gp70 gene, is the target for roughly 90% of the total CD8 response in animals vaccinated with this tumor. The particular immunodominant epitope was shown to display a high affinity for its restricting MHC class I molecule. However, when the peptide-MHC affinity of the T-cell receptor expressed by T cells grown from vaccinated animals was measured, it was significantly lower than affinities measured for T cells specific for standard foreign antigens.

As tumor antigens continue to be identified, there will be important opportunities to modify epitopes so that they are presented to T cells in a fashion that provides the most effective transmission of signal 1 (Figure 4). For antigens that have poor MHC binding affinity, a number of groups have demonstrated that alteration of MHC anchor residues to more favorable amino acids can result in dramatic enhancement of MHC binding while nonetheless retaining the capacity for enhanced activation of T cells specific for the

**Figure 4** Peptide-MHC binding vs. peptide/MHC-TCR binding in immunogenicity of tumor antigens.

original wild-type epitope [185,186]. This results in a heteroclitic response in which vaccines containing the anchor-modified epitope can produce greater immune responses against the wild-type peptide *in vivo* as well as enhanced antitumor immunity. Epitope engineering can also generate enhanced immunity at the level of TCR affinity for peptide-MHC. Thus in the case of the low affinity response to the GP70-derived peptide described above, a single amino acid alteration was identified which did not affect MHC binding but increased the affinity of peptide-MHC for the T-cell receptor by threefold. Immunization with DCs loaded with this altered peptide resulted in a dramatic enhancement in the expansion of T cells *in vivo* specific for the original wild-type peptide and enhancement of systemic antitumor immunity [184].

The effect of T-cell affinity is not only manifest at the level of T-cell priming but also at the level of T-cell effector function. This concept was most effectively demonstrated by Greenberg and colleagues who were able to separate tyrosinase-specific T cells cloned from melanoma patients into high and low affinity populations based on their level of staining with peptide-MHC tetramers. Higher affinity T cells bind greater amounts of tyrosinase peptide-A2 tetramer at equilibrium than low affinity T cells. When analyzed on peptide-loaded targets (which express artificially high ligand densities) both high and low affinity T-cell clones lysed targets with relatively equivalent efficacy. However, only the high affinity T-cell clones were capable of lysing the original tumor cells *in vitro*. These findings have led to clinical trials in which T-cell clones are first selected based on levels of tetramer binding prior to expansion and reinfusion [187].

## IX. ENHANCEMENT OF COSTIMULATION IN THERAPEUTIC VACCINE DESIGN

As mentioned above, qualitative and quantitative elements of T-cell activation and differentiation are determined in large part by signals delivered by costimulatory molecules.

As the number of costimulatory molecules increase, a picture is emerging in which T-cell activation requires integration of a large number of different signals. The best characterized costimulatory signals fall into three families: the B7 family, the TNF family, and cytokines. Among these three categories of costimulatory molecules, the B7 family appears to be the only one with a unidirectional vector of signaling, namely, from APC to T cell. In contrast, different members of the TNF family and cytokine families provide multidirectional signaling, i.e., from APC to T cell, from T cell to APC, and T cell to T cell. Tremendous effort has been placed in engineering costimulatory molecules into vaccines and other immunotherapies in an attempt to enhance their activity. In the case of the B7 family members, virtually all of the focus thus far has been on B7.1 and B7.2. It will be interesting to see how the new B7 family members B7H1/PDL1, B7-DC/PDL2, and B7H3 [111–115] will fit into the armamentarium as they bind distinct receptors from B7.1 and B7.2 and have only partially overlapping biological activity.

There are three primary approaches that have been used to build B7.1/B7.2 into immunotherapeutic approaches. One involves the transduction of tumor cells with B7 genes in order to enhance their immunogenicity as vaccines [122–124]. The original concept behind introducing B7 genes into tumors came from the idea that tumors fail to stimulate immune responses against them under normal circumstances because they did not express costimulatory molecules. Therefore presentation of signal 1 (peptide/MHC) in the absence of costimulatory signals would result in either failure to effectively activate tumor-specific T cells or tolerance induction. Transduction of tumor cells with the genes encoding either B7.1 or B7.2 would reconstitute costimulation and therefore might activate antitumor immune responses through direct presentation. Indeed, multiple studies have confirmed that B7-transduced tumor cells are effectively rejected when high enough B7 levels are achieved. However, when the transduced tumor is poorly immunogenic (as is presumably the case in human tumors) transduction with B7 fails to induce systemic protective immunity although the B7-transduced cells themselves are rejected. As

described above, more detailed analysis of the mechanisms of both rejection and immune priming by B7-transduced tumors supports the emerging view that direct presentation by tumor cells to the immune system is a relatively minor pathway as compared with the indirect presentation pathway via bone marrow-derived APCs (crosspriming). Rejection of B7-transduced tumor cells involves a major NK-mediated component. Indeed, NK cells appear to recognize B7 as a target for activation and lysis. Bone marrow chimera studies demonstrated that after initial vaccination with B7-transduced tumors, the majority of T-cell priming came from bone marrow-derived APCs rather than from the B7-transduced tumor cells themselves. Once a primed population of T cells had been induced, then B7-transduced tumor cells could amplify those responses through direct presentation [188].

A more promising application of the B7 molecules to vaccine design has been the inclusion of B7 genes into recombinant nucleic acid and viral vaccine vectors for antigen-specific vaccination [189,190]. The basis for the inclusion of B7 genes into recombinant nucleic acid or viral vaccines comes from the idea that one of the methods by which these vaccines immunize is through direct transduction or infection of APCs. Theoretically, although professional APCs (i.e., dendritic cells) naturally express B7 molecules, the increased expression provided by B7 genes engineered into recombinant vaccines as well as altered patterns or ratios of expression of the different B7 family members could significantly modify the ultimate outcome of T-cell priming *in vivo*. A number of studies have demonstrated that incorporation of either B7.1 or B7.2 into DNA vaccines as well as recombinant vaccinia vaccines enhances the generation of CTL responses and in some cases antibody responses against the specific antigen expressed by the recombinant vaccine. Interestingly, while these studies have failed to corroborate early suggestions that B7.1 predominantly costimulated TH1 responses and B7.2 predominantly costimulated TH2 responses *in vivo*, they have in some cases demonstrated differential activity between B7.1 and B7.2. One common theme has been that the B7.2 gene appears to be superior to the B7.1 gene in the generation of CTL responses *in vivo*.

Another approach that has been utilized to enhance immunization with the B7 costimulatory molecules has been the infusion of B7-Ig dimers either systemically or mixed with vaccine formulations [191]. Chimeric immunoglobulin-B7 fusion molecules, which display B7 as a dimer, are extremely potent costimulators for T cells *in vitro* and have been shown to enhance the potency of tumor vaccines *in vivo*. No toxicity has been observed with systemic administration of B7-Ig dimers, presumably because CD28 engagement in the absence of TCR engagement has little or no effect on T cells. One might imagine that this approach could have detrimental effects on tolerance to self-antigens if administered chronically. However, it is unlikely that administration of these molecules over short periods of time together with a vaccine or adoptively transferred T cells would have major effects on the maintenance of self-tolerance.

The list of potential TNF receptor family molecules expressed by T cells that may participate in modifying T-cell

responses (either upward or downward) continues to grow. Two very interesting candidate costimulatory receptors of the TNFR family are 4-1BB and OX40. Administration of putatively agonist anti-4-1BB and anti-OX40 antibodies has been shown to induce antitumor immunity when administered either alone or in the context of a vaccine [116–118]. Using a TCR transgenic model for tolerance induction, Parker and colleagues derived evidence that activation through OX40 might even be able to break anergic tolerance. 4-1BB ligand and OX40 ligand are expressed on antigen-presenting cells and these ligand-receptor pairs therefore represent candidate costimulatory signals from APC to T cell. CD27 and CD30 represent two additional TNF receptor family members on T cells that may represent interesting targets either for activation or inhibition of antigen-specific responses [192,193].

## X. APPLICATION OF CYTOKINES IN CANCER IMMUNOTHERAPY

Cytokines represent by far and away the largest category of immunoregulatory molecules and have been utilized as systemic agents, as local agents and as components of both genetically modified cell-based and recombinant antigen-specific vaccines. Rather than discussing the detailed application of cytokines to immunotherapy, a topic covered in numerous reviews, some general principles and a few selected examples of cytokine application to immunotherapy will be covered here. The major clinical application of cytokines has been in the form of systemic administration of the recombinant cytokine protein. In general, systemic administration of cytokines as single agents in cancer immunotherapy has been quite disappointing. Of all the many cytokines tested, interleukin-2 (IL-2) has an established track record in patients with metastatic renal cancer and melanoma and has been demonstrated to induce durable complete responses in these two cancers in between 3% and 10% of individuals [194]. Unfortunately, the toxicity of systemically administered cytokines (including IL-2) is quite high and significantly limits their widespread application. The therapeutic effects of IL-2 in murine tumor systems as well as in human melanoma and renal cancer are immunologically mediated, as IL-2 has no direct effect on the tumor cells themselves. However, it is unclear whether systemically administered IL-2, particularly at higher doses, enhances antigen-specific antitumor immunity when administered as a single systemic agent. Indeed, the serum concentrations achieved with “high-dose IL-2” are high enough to bind to the intermediate affinity IL-2 receptor expressed on NK cells (IL-2R $\beta$ ). Likewise, the antitumor effects of high-dose IL-12 in mice are at least partially mediated by NK and NKT cells without clear evidence that antigen-specific T-cell immunity is enhanced. Application of systemic IL-2 in conjunction with vaccination may potentially be a more effective way to utilize IL-2 to enhance systemic antigen-specific T-cell immunity. When T cells are initially activated by their cognate antigen, they express a high affinity IL-2 receptor consisting of the IL-2R $\alpha$  and IL-2R $\beta$  subunits (together with the non-IL-2 binding IL-2R $\gamma$  signaling subunit). Thus antigen-spe-

cific T cells activated in response to a vaccine will transiently respond to much lower doses of IL-2 based on their expression of the high affinity IL-2 receptor. Indeed, preliminary studies combining vaccination with lower doses of IL-2 have demonstrated evidence of synergy between these two agents.

One of the disappointing surprises in systemic cytokine administration has been the vast differences in tolerability of systemic cytokines between mice and humans. Thus cytokines, such as IL-2, TNF- $\alpha$ , and IL-12, which induce regressions of established tumors in mice at high systemic doses, are lethal to humans at doses that achieve therapeutic serum concentrations in mice. For example, the LD50 for systemic IL-2 in mice is estimated roughly 50-fold higher than in humans whereas the LD50 for TNF- $\alpha$  is roughly 300-fold higher in mice than in humans. Toxicity determinations for IL-12 are more complicated as lower doses of IL-12 can "tolerize" individuals to higher doses of IL-12. Nonetheless, the maximal tolerable doses of IL-12 in humans are significantly below the doses that achieve significant antitumor responses in mice.

As virtually all cytokines behave physiologically as autocrine or paracrine factors, it is not surprising that applying them as systemic agents results in unacceptable toxicities and side effects owing to the loss of geographical specificity that is so critical to normal cytokine physiology. Indeed, the primary motivation for building cytokines into tumor cell vaccines as well as recombinant nucleic acid or viral vectors is to maximize the expression of the cytokine at the site of antigen delivery. In the case of cytokine gene-transduced tumor vaccines, introduction of genes encoding cytokines targeted at the T cell has been less successful in priming immune responses than transduction of cytokines aimed at APCs, particularly dendritic cells. Considering that the vaccines are typically administered intradermally or in the subcutaneous space, whereas T-cell priming generally occurs in the draining lymph node, it is not surprising that tumor cell vaccines engineered to produce dendritic cell-targeted cytokines would ultimately be more effective. One important approach to cytokine-based therapeutics is the targeting of cytokines to areas of tumor metastasis where T cells originally activated in the draining lymph nodes would subsequently traffic and discharge their effector function. The function of these effector T cells would be significantly enhanced by the presence of cytokines at the sites of metastatic tumor in the periphery. Proof of principle for the efficacy of such an approach has come from studies by Reisfeld and colleagues who have linked cytokines such as IL-2 to the Fc regions of antitumor antibodies [195]. While the antitumor antibodies themselves demonstrate limited efficacy, owing to limited penetration into solid tumors by most monoclonal antibodies infused systemically, there is enough concentration in the tumors to increase the local concentration of IL-2, thereby enhancing antitumor immune responses in a T-cell-dependent fashion. It will be of great interest in the future to evaluate combination approaches between vaccination that would generate an increased population of tumor-specific T cells expressing high affinity IL-2 receptors together with IL-2-linked antitumor antibodies.

Engineering approaches to maximize the efficacy of cytokine signaling during the effector phase of antitumor

immunity have also been applied to adoptive T cell transfer approaches. Ridell and Greenberg have demonstrated that adoptively transferred tumor-specific CD8 T-cell clones home to tumors and can exert transient effector function but, in the absence of adequate T-cell help, are rapidly lost from both the circulation and sites of tumor. The requirement that CD8 effector cells have for T-cell help comes from the fact that they are very inefficient at providing their own helper cytokines such as IL-2. Provision of systemic IL-2 after adoptive transfer of CD8 cells can enhance their longevity and activity [196,197], but this approach is ultimately limited by the toxicities of systemic IL-2 as described above. In order to circumvent this problem, tumor-specific CD8 cells were transduced with chimeric receptors expressing the extracellular domains for cytokines normally secreted by CD8 cells, e.g., GM-CSF, linked to the cytoplasmic signaling domain of the IL-2 receptors. Specifically, the GM-CSFR $\alpha$  extracellular domain was linked to the IL-2R $\beta$  domain and the GM-CSFR $\beta$  extracellular domain was linked to the IL-2R $\gamma$  intracellular signaling domain. T cells transduced with these chimeric receptors transmitted IL-2-dependent signals in response to GM-CSF, thus converting GM-CSF into an autocrine growth factor for CD8 cells [198]. These engineered CD8 cells become relatively helper cell-independent and generate enhanced numbers of effectors as well as memory cells upon encounter of antigen *in vivo*.

Possibly the most promising application of T-cell costimulatory or proliferative cytokines is their incorporation as genes into recombinant nucleic acid and viral vaccines (Figure 3). Multiple studies have demonstrated that incorporation of cytokine genes to recombinant vaccines of this sort cannot only quantitatively enhance T-cell responses but can also alter the differentiation pattern of antigen-specific T cells. Again, this approach is based on the notion that both nucleic acid and viral vaccines act in part through direct infection of antigen-presenting cells thereby maximizing the paracrine effect of the cytokine on T cells to which the infected or transduced APC is presenting antigen. For example, Bersofsky and colleagues performed a detailed analysis of the type of immune responses generated by nucleic acid vaccines in which multiple different cytokine genes were incorporated. As described above, they found that GM-CSF, which acts on APCs, generated the greatest level of T-cell immunity, although the characteristics of the responses were mixed TH1 and TH2. When interleukin-12 was incorporated into the nucleic acid vaccine, antigen-specific responses were predominantly TH1 in character whereas when IL-4 or IL-10 was incorporated into the vaccine, TH1 responses were quenched and the predominant response was TH2 in character [199].

## XI. RECOMBINANT VIRAL VACCINE VECTORS FOR ANTIGEN-SPECIFIC IMMUNOTHERAPY OF CANCER

For all of the added value that recombinant DNA technology provides in engineering elements into vaccine constructs that enhance their potency, nature itself provides a virtually

limitless array of delivery systems in the form of diverse microbes with potent intrinsic immunologic properties. Of the three major microbial classes: virus, bacterium, and fungi, viruses and bacteria have been the most intensively investigated. A recent report of engineered yeast vaccines emphasizes the potential immunologic utility of the third microbial class.

Viruses are the most diverse and efficient gene transfer agents whose natural cell tropism and biologic features can significantly enhance the immunogenicity of antigens carried within them. Using standard recombination approaches, Moss and Paoletti were the first to generate recombinant viruses as vaccine vectors [200–202]. They utilized vaccinia virus because this virus had been administered to hundreds of millions of individuals in the smallpox eradication campaign. Vaccinia is a highly immunogenic virus related to smallpox; its reduced virulence is in part due to its high immunogenicity. In most cases, a single immunization with recombinant vaccinia carrying a gene expressing an antigen will generate significantly greater immune responses against that antigen than the corresponding protein or peptide epitopes mixed with standard adjuvants. This is particularly true for CTL generation. To date, many viruses have been explored as recombinant vaccine vectors, including attenuated replication-deficient poxviruses such as modified vaccinia anca, fowl pox, and canary pox [203,204]. Adenovirus, herpesviruses, and venezuelan equine encephalitis virus represent additional promising viruses that have been engineered to express specific tumor and other antigens [205,206]. Each of these viruses has various advantages and disadvantages and no clear “winner” has emerged as the absolute vector of choice. However, a number of principles are emerging. Features of viruses that can enhance their potency as vaccine vectors include their ability to replicate, thereby increasing the antigen load, to induce immunologic “danger” signals at sites of infection, and to directly infect antigen-presenting cells, thereby leading to efficient processing and presentation of encoded epitopes, particularly in the MHC class I pathway. Elements of viruses that can diminish their potency as vaccine vectors include the presence of virally encoded inhibitors of immunity [207]. These include molecules that block processing and presentation in the MHC class I pathway (such as TAP inhibitors and inhibitors of MHC class I traffic out of the endoplasmic reticulum) and cytokine decoys, to mention a few. Thus deleting immunologic inhibitory genes from recombinant viruses may enhance their vaccine potency while attenuating their virulence.

Another major limitation of virus-based vaccination comes from the presence of neutralizing antibodies in pre-exposed individuals that inhibit the initial round of infection and replication, thereby quenching their ability to immunize. The presence of neutralizing antibodies has been a major factor limiting the efficacy of recombinant adenoviral vaccines and recombinant vaccinia vaccines in previously exposed (adenovirus) or vaccinated (vaccinia) individuals. Even in individuals who have never been exposed to the vaccinating virus previously or who have very low titers at the time of initial vaccination will tend to generate very high titers of neutralizing antibody after the first vaccination,

thereby precluding subsequent vaccination with the same vector. This finding has led to the concept of cycling different viral vectors in “prime-boost” formats [208,209]. Dramatic enhancement of immunization potency has been observed in prime-boost formats between both different viruses such as fowl pox followed by vaccinia as well as between nucleic acid vaccines and recombinant viral vaccines. DNA-virus prime-boost regimens look particularly promising because, while DNA-based vaccines tend to be of relatively low potency, they are not subject to the limitations of neutralizing humoral immunity for multiple vaccinations. Furthermore, even when ineffective on their own, DNA vaccines appear to prime populations of antigen-specific T cells that respond particularly vigorously to boosting with a recombinant viral vaccine. One hypothesis for this synergy is that nucleic acid vaccines generate a population of memory T cells specific for the encoded antigen that compete more effectively with virus-specific T cells upon boosting with recombinant virus.

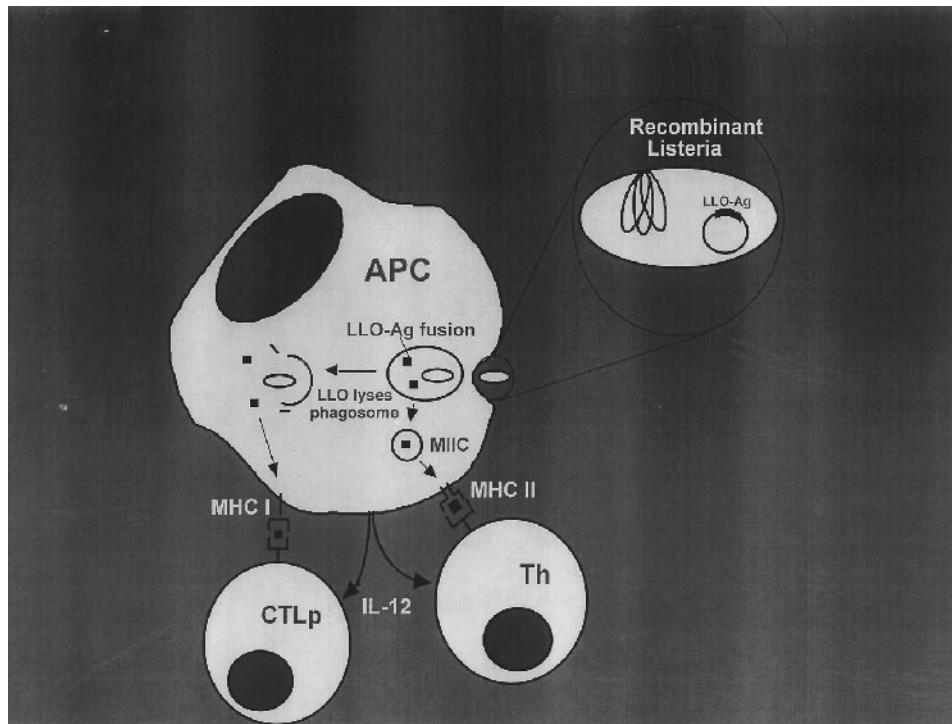

## XII. RECOMBINANT BACTERIAL VACCINES

The diverse set of bacteria whose immunopathogenesis is becoming elucidated has led to a number of interesting and promising recombinant bacterial vaccines. Genetic engineering of intracellular bacteria has produced enhanced immune responses in the case of BCG, Salmonella, Shigella, and Listeria [210–214]. The basic principle behind recombinant bacterial vaccines is that bacteria that enter antigen-presenting cells may represent a good vehicle for delivery of recombinant antigens. In certain cases, such as Listeria, the bacteria exhibit complex life cycles that involve both phagolysosomal and cytoplasmic stages. Thus recombinant Listeria monocytogenes engineered to secrete antigens will load the MHC class II processing pathway during the phagolysosomal phase and the MHC class I pathway during the cytosolic phase of the life cycle. In addition, a number of recombinant bacteria actively induce infected APCs to secrete proinflammatory cytokines such as IL-12 (Figure 5). These proinflammatory cytokines can have very potent effects on adaptive immunity.

More recently, recombinant bacteria have been appreciated to be an interesting new vector for delivery of nucleic acid vaccines [215,216]. Thus engineering plasmids with eukaryotic promoter and enhancer elements driving the antigen gene results in more potent immunity induction than when the plasmids utilize prokaryotic promoters. These results indicate that the bacteria can directly transfer plasmids into eukaryotic transcriptional compartments within infected APCs.

## XIII. AMPLIFICATION OF IMMUNITY THROUGH BLOCKADE OF INHIBITORY PATHWAYS AND REGULATORY T CELLS

As engineered immunotherapeutics continue to improve, a potency ceiling will be reached owing to the presence of hardwired inhibitory pathways that negatively regulate lymphocyte responses—so-called immunologic checkpoints. It is now clear that the quantitative response to antigen is

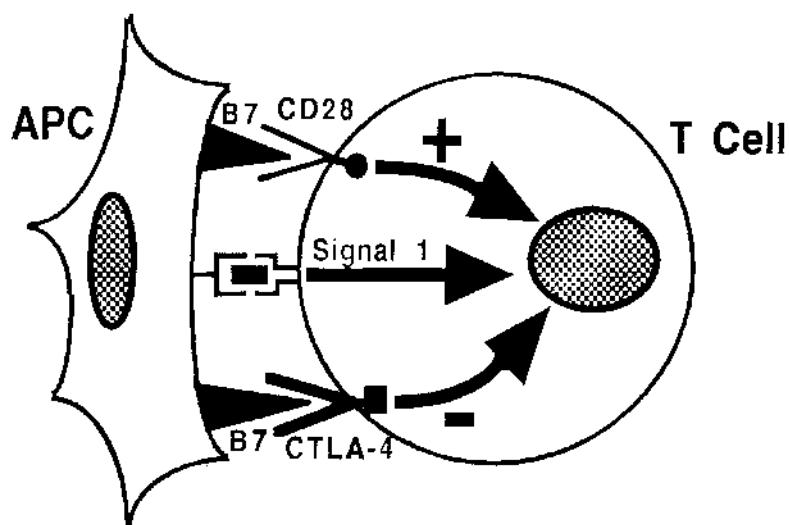

**Figure 5** Listeria monocytogenes vaccine.

balanced by both positive (costimulatory) and negative (checkpoint) signaling pathways. In the case of T-cell responses, a number of these pathways appear to have components that are either exclusively or at least selectively expressed by T cells. As they become elucidated, the signaling molecules of immunologic checkpoints will represent a major target for pharmacologic intervention. Past efforts in the development of pharmacologic agents that target the immune system have exclusively identified drugs that either inhibit or activate immune responses in a nonspecific, antigen-independent fashion. The discovery of specific negative regulatory signaling pathways that check immune responses by dampening TCR or costimulatory signaling pathways provides a wonderful opportunity for antigen-specific immunopharmacology by applying drugs (or antibodies) that block these pathways utilized together with antigen-specific activation stimuli.

Among the best studied of these counter-regulatory pathways is the one initiated by engagement of CTLA-4. Naive T cells express the costimulatory B7 receptor CD28, whose engagement amplifies TCR-dependent responses in a number of ways including increased cytokine gene transcription rates, increased cytokine mRNA stability, and inhibition of activation-induced cell death. Subsequent to T-cell activation, a second B7 receptor, CTLA-4, becomes expressed. CTLA-4 has a much higher affinity for B7.1 and B7.2 than does CD28. CTLA-4 delivers inhibitory signals to T cells that oppose the costimulatory signals delivered by CD28 [217]. CTLA-4 knockout mice die at a relatively young age of "hyperimmune" infiltrates into multiple organs, indicating that CTLA-4 is a critical negative regulator of

T-cell activity (Figure 6). Allison and colleagues have demonstrated that transient *in vivo* blockade of CTLA-4 with a blocking antibody administered at the time of tumor vaccination can enhance vaccine potency and subsequent anti-tumor immunity [218–220]. The immune-enhancing effect of anti-CTLA-4 blocking antibodies was demonstrated in the context of a number of different cell-based vaccines including B7-transduced and GM-CSF-transduced tumor cell vaccines. Results with combinations of GM-CSF-transduced prostate cancer and melanoma vaccines together with CTLA-4 blockade illustrated two important points. First, the combination of an activating stimulus (vaccine) together with blockade of an immunologic checkpoint (anti-CTLA-4) was able to induce elimination of macroscopic established and spontaneously arising tumors whereas either vaccine alone or CTLA-4 blockade alone failed to achieve these results. Second, while the combination approach induced autoimmune disease, the autoimmunity was confined to the tissue from which the tumor vaccine was derived. Thus treatment of mice with B16 melanoma-GM-CSF + anti-CTLA-4 exclusively resulted in vitiligo—an autoimmune response restricted to melanocytes. Mice receiving the prostate cancer-GM-CSF vaccine + anti-CTLA-4 developed prostatitis but no other signs of autoimmunity. These findings demonstrate that there is a hierarchy of tolerance induction in which tolerance to tissue-specific antigens may be maintained less stringently than tolerance to more ubiquitous self-antigens. This hierarchy thus provides a therapeutic window for cancers derived from dispensable tissues in which tissue-specific antigens shared by the cancer represent viable immunologic targets.

**Figure 6** The CTLA-4 checkpoint in T-cell activation.

Dissection of signaling pathways in T cells has revealed a number of additional potential targets for inhibitors of immunologic checkpoints. PD-1, a membrane molecule induced subsequent to T-cell activation, is a CTLA-4-like inhibitory molecule that decreases cytokine responses in T cells and may enhance activation-induced cell death of T cells. PD-1 is now appreciated to be a receptor for two of the newer B7 family members, B7-H1/PDL-1 and B7-DC/PDL-2. Given that both B7-H1 and B7-DC can costimulate enhanced cytokine production by naive T cells, it is likely that PD-1 represents a counter-regulatory inhibitory receptor matched against an as yet unidentified costimulatory receptor on naive T cells. PD-1 knockout mice do not develop the broad hyperimmune organ infiltrates that CTLA-4 knockout mice develop but rather display a more focal autoimmunity. PD-1 therefore represents an interesting potential target for blockade in the context of immunization analogous to CTLA-4 blockade.

A number of intracellular inhibitory signaling pathways in T cells represent promising targets for pharmacologic intervention. Some of the best candidates include Cbl-b, Cabin, certain protein tyrosine phosphatases (PTPs) as well as the tyrosine kinase Csk. Among the phosphatases, SHIP-1, SHP-1, and SHP-2 have all been implicated in down-modulating signaling pathways activated by TCR engagement [221]. More recently, the CD45 PTP has been demonstrated to negatively regulate immune responses by inhibiting JAK-1 and 2 activation, thereby downmodulating responses to certain cytokines [222]. Downstream of the JAK kinases, activation of the STAT transcription factors is inhibited by the CIS/SOCS family [223]. Csk has been well demonstrated to inhibit or downmodulate TCR signaling through phosphorylation of regulatory tyrosines on the src family tyrosine kinases, which are critical for T-cell activation [224]. Cbl-b is an adaptor protein that appears to negatively regulate T-cell activation by antagonizing CD28-mediated costimulatory pathways. Thus T cells from

Cbl-b knockout mice are hypersensitive to low doses of T-cell stimulatory ligands and are furthermore relatively CD28-independent in their activation [225,226]. Cabin is a molecule that appears to have multiple functions, including as a scaffold for coordinating transcription factors. Cabin was originally identified as a molecule that binds to and inhibits calcineurin, a critical serine phosphatase that mediates TCR-dependent cytokine activation through dephosphorylation of NFAT-c, a critical step in nuclear translocation [227]. The calcineurin-inhibiting portion of Cabin has been localized and thus represents an interesting target for pharmacologic intervention.

In light of the resurrection of suppressor T cells under the new alias of T-regulatory (Treg) cells [228,229], a discussion of tumor tolerance would be incomplete without considering the potential role of this important subset. There is relatively little specific information on the role of Treg cells in inducing or maintaining tumor tolerance under normal circumstances; however, two studies strongly support the notion that they significantly limit the efficacy of vaccine-induced antitumor immune responses and their inhibition or elimination could significantly enhance tumor immunotherapy. In one study, a combination of a GM-CSF-transduced tumor vaccine plus anti-CTLA4 was much more effective at eliminating established tumors when animals were treated with anti-IL2 receptor  $\alpha$  antibodies prior to vaccination/anti-CTLA4 treatment [230]. The notion of eliminating Treg cells came from the surprising finding that while CD4 depletion of animals significantly diminished the ability of GM-CSF vaccine/anti-CTLA4 to protect animals from subsequent tumor challenge (with B16 melanoma), the opposite effect was observed for therapy of established B16 tumors [231]. These results suggested the idea that CD4 cells predominately played an enhancing helper role when vaccine/anti-CTLA4 treatment was done prior to tumor inoculation, but once tumors were established they induced a dominant population of CD4 $^{+}$  T regulatory cells. As T

regulatory cells typically express IL2 receptor, it was reasoned that depletion of IL2 receptor positive cells prior to vaccination/anti-CTLA4 would eliminate these Treg cells.

In a second set of studies, Jaffee and colleagues demonstrated that treatment of mice with low-dose cytoxin prior to vaccination enhanced the ability of HER-2/neu/GM-CSF vaccines to protect HER-2/neu transgenic mice from challenge with HER-2/neu-expressing tumors [232]. As the cytoxin and vaccine treatments were performed prior to the tumor challenge, the enhanced effect of cytoxin could not be explained by a direct antitumor effect. Indeed, low-dose cytoxin treatment has long been touted to inhibit or kill suppressor cells, although this effect had been more recently attributed to the creation of lymphoid “space.” However, adoptive transfer experiments with CD4<sup>+</sup>IL2R<sup>+</sup> cells from noncytoxin-treated HER-2/neu transgenic mice proved that the cytoxin effect was indeed due to inhibition of Treg cells. It is likely that the next few years will see many additional demonstrations for an important role of Treg cells in blunting or blocking antitumor immunity, likely because they are a natural consequence of tolerance induction. They represent a very tempting target for inhibition as part of combination immunotherapy strategies.

#### XIV. TUMOR VACCINATION IN THE CONTEXT OF BONE MARROW TRANSPLANTATION

The curative effects of bone marrow transplantation stand as the major example of the ability of the immune system to cure cancer in humans. A paradigm shift in the bone marrow transplant field has been the appreciation that bone marrow transplantation represents a potent approach to modify host immunity and generate significant antitumor immune responses. It is now quite clear that the major antitumor effects of allogeneic bone marrow transplantation have an immunologic basis. Specifically, antitumor immunity is generated by contaminating mature donor T cells in the marrow infusion. Under some circumstances, donor-derived T cells selectively recognize tumor cells (graft-vs.-tumor effect) that express higher levels of minor histocompatibility antigens than host tissues. Graft-vs.-tumor effect is of course balanced by the significant toxicity of graft-vs.-host disease [233–235].

Ironically, the original mechanism on which allogeneic bone marrow transplantation is based—namely, the ability to deliver higher doses of radio-chemotherapy followed by rescue with tumor-free donor bone marrow—plays relatively little role in the antitumor effects of allogeneic bone marrow transplantation. While less well documented, it is likely that autologous bone marrow transplantation exerts some of its antitumor effects through immunologic means. It is now clear that autologous BMT, even with documented tumor-contaminated marrow, can result in long-term tumor-free survival and cancer cure.

Given the documented immunologically based antitumor effects of bone marrow transplantation, but also the severe toxicity of this procedure, it was logical to combine bone marrow transplantation and vaccination in an attempt

to more selectively focus immune responses on tumor-specific antigens. Initially, Borrello et al. demonstrated that vaccination with a GM-CSF-transduced cell-based vaccine generated more potent antitumor effects when delivered in a window of time post autologous bone marrow transplantation [236]. They demonstrated that vaccination in this setting resulted in a greater expansion of antigen-specific T cells. This effect was attributed to two potential mechanisms—general systemic enhancement of APC activation in the bone marrow transplant setting and increased “lymphoid space” created by the initial induction regimen prior to bone marrow transplantation. Indeed, evidence exists for both mechanisms. The radiation and chemotherapy regimens used for induction prior to bone marrow transplantation cause subclinical gut damage, which results in the release of bacterial products such as LPS systemically. These ultimately serve to globally activate antigen-presenting cells that are critical to the activity of virtually all vaccines, as described above. It is also well documented that lymphoablation results in the upregulation of cytokines, such as IL7 and IL15, which not only participate in “homeostatic” T-cell expansion but also enhance the generation and persistence of memory T cells subsequent to immunization [237,238].

Synergistic effects between allogeneic bone marrow transplantation and vaccination with both antigen-based vaccines and cell-based vaccines have likewise been documented in a number of animal models [239,240]. Because the basis for the antitumor effect of allogeneic transplantation comes from donor mature T cells, it would be expected that these donor lymphocytes would not have been rendered tolerant to tumor antigens as they come from a tumor-free individual. Indeed, vaccination of donors prior to BMT plus DLI can result in dramatic enhancements of antitumor immunity; however, concomitant increase in graft-vs.-host disease is also observed [241,242].

A very different mechanism of antitumor immunity has been observed when vaccination is applied in the context of nonmyeloablative allogeneic BMT. Originally, nonmyeloablative allogeneic BMT was developed in order to produce diminished graft-vs.-host disease, allowing one to titrate in doses of donor lymphocytes to skirt the balance between graft-vs.-tumor effect and graft-vs.-host disease [243–245]. Despite initially encouraging reports, the value of this approach remains to be validated. Standard conditioning regimens for nonmyeloablative bone marrow transplant ultimately inhibit the host immune system to the extent that full donor reconstitution ultimately ensues. However, Luznik and Fuchs have developed modified conditioning regimens that can result in stable mixed chimerism in which host and donor immune systems coexist [246]. Under such a circumstance, tumor vaccination exhibits much greater potency without any significant graft-vs.-host disease [247]. The enhanced antitumor effect surprisingly comes predominately from activation of host tumor-specific T cells but nonetheless requires both CD4 and CD8 cells in the donor lymphocyte infusion. Experiments in CD40 knockout mice suggest a mechanism in which host DLI recognize minor histocompatibility antigens on host APCs, thereby enhancing their activation state and ability to present tumor antigens from

the vaccine to residual host T cells. These findings point out both the promise and complexity of generating antitumor immune response in the bone marrow transplant setting.

## XV. FUTURE PROSPECTS FOR SUCCESSFUL IMMUNOTHERAPY

The weight of evidence that established cancers induce immune tolerance to their antigens defines the major challenge to successful immunotherapy. While the mechanisms by which chronic viral infections avoid immune elimination are still largely unknown, it is likely that common mechanisms as well as distinct mechanisms relative to non-virus-associated cancers will be operative. The barriers of immunologic tolerance, together with the failure of cancer vaccines as single agents to achieve sufficient success in randomized Phase III trials in patients with advanced cancer, have raised a significant degree of skepticism about immunotherapy of cancer in general. However, the most promising vaccination strategies—indeed, most of those described in this chapter—have only just begun to enter early stage clinical trials. It is therefore premature to conclude that the cryptic repertoire of tumor-specific (and virus-specific) T cells known to exist in patients with cancer and chronic viral disease cannot be mobilized with therapeutic success.

A major theme to have emerged from the growing preclinical animal model immunotherapy investigations is the importance of combination approaches that target different regulatory points in the immune response from priming to amplification to effector function. The most clear-cut benefits of combination approaches are demonstrated by the synergy observed with vaccination and CTLA-4 blockade as well as vaccination after elimination or inhibition of T regulatory cells. In addition, vaccination in the context of bone marrow transplantation shows great promise due to the effects of BMT on multiple elements of T-cell-dependent immune responses. Innovative combinatorial immunotherapies are becoming a major focus of translational efforts in many different cancer types.

Finally, as with all cancer therapies, the selection of appropriate patient populations is as critical as the therapy itself. A number of potentially promising cancer vaccine approaches have been tested in patients with advanced bulky metastatic disease. In fact, multiple lines of evidence suggest that immunotherapies may be most effective in the minimal residual disease state. An analogous circumstance with chronic viral diseases has been the shift in emphasis on the application of therapeutic HPV vaccines to women with premalignant cervical lesions rather than established cervical cancer. Given the relative lack of toxicity of most immunotherapies—particularly vaccines—their application in earlier stages of disease seems quite reasonable. Rapid advances in early detection as well as prognostication have resulted in detection of many cancers at a much earlier stage. These advances should lay the groundwork for development of the most promising immunotherapies in the most effective possible fashion.

### ABSTRACT

Cervical cancer is one of the commonest causes of cancer death among women worldwide, and is initiated by infection with a limited subset of human papillomaviruses (PV). Prophylactic vaccines, based on recombinant virus particles, are designed to produce virus neutralizing antibody. They are now in late-phase clinical trials, and, if these trials demonstrate efficacy, it is anticipated that vaccines might be available for routine clinical use within the next 5 years. Therapeutic vaccines, based on viral nonstructural proteins, are in early-phase clinical trials. There is little information on the nature of the immune response that will be required for a therapeutic effect. This article reviews the current knowledge base on human papillomavirus vaccines, discusses some areas of uncertainty concerning vaccine development and deployment, and highlights where the field may progress over the next few years.

### I. NATURAL IMMUNITY TO PAPILLOMAVIRUS CAPSIDS

Papillomaviruses (PV) infect the superficial epithelium of many vertebrate species. As nonlytic viruses whose non-structural proteins alter the growth and differentiation of epithelial cells, this family of viruses produces lesions ranging from macroscopically undetectable disturbances of epithelial architecture to floridly protuberant warts. There are estimated to be in excess of 200 human papillomavirus (HPV) genotypes [1], and these can be divided into several major phenotypic groups (Table 1).

The World Health Organization recognizes several papillomaviruses as antecedents of cervical cancer, and current data [2] suggest that 99.8% of cervical cancer is caused by infection with human papillomavirus. Since the first recog-

nition in the 1980s of an association between cervical cancer and papillomavirus infection [3], development of a vaccine has been mooted. Productive infection with genital and skin genotypes of papillomavirus is generally self-limiting, and resolution of infection, which occurs over months to years, requires an immunocompetent host. Immune responses to PV infection are generally slow to appear, and less robust in comparison with those seen with lytic or systemic virus infections [4]. Deficits in cell-mediated immunity reduce the clearance of existing infections, and increase the risk of progression of infection to malignancy [5,6]. The extent to which prior infection protects against subsequent exposure to the same or other genotypes of HPV is moot. However, infection with cutaneous papillomaviruses is universal in early childhood, and is rare among adults, including those involved with the care of young children. Similarly, infection of the genital tract is commonest among those recently sexually active [7,8], and is not common among older sexually active individuals, including sex workers at high risk through exposure [9]. Thus while there is some epidemiological data for HPV16 to suggest that prior infection may convey only partial protection on subsequent exposure, a broad conclusion can be entertained that infection with papillomaviruses protects against subsequent exposure in immunocompetent subjects, giving reasonable grounds for believing that a prophylactic vaccine is possible.

### II. CROSS PROTECTION BETWEEN PAPILLOMAVIRUS GENOTYPES

More than 80 sequenced papillomaviruses infect man, and several hundred genotypes are postulated to exist based on partial sequence data. While over 80% of cervical cancers are associated with one of the five common genital genotypes of PV [10], even these have minor sequence variations within

**Table 1** Broad Classification of Papillomaviruses

Papillomavirus group	Typical member	Clinical manifestations	Natural history	Precursor of malignancy
Epithelial	HPV1,2	Flat or verrucous warts on squamous epithelium	Self-limiting over months to years in immunocompetent subjects	No
EV associated	HPV5,8	Minimal lesions in healthy individuals Warts in patients with epidermodysplasia verruciformis	Persistent infection without lesions in immunocompetent subjects?	Uncertain in healthy individuals Definite in patients with EV or chronic immunosuppression
Genital warts	HPV6, 11	Protuberant warts on anogenital mucosal epithelium and in aerodigestive mucosa	Self-limiting over months to years in immunocompetent subjects	Rarely in aerodigestive tract
Genital cancer associated	HPV16, 18, 33, 35	Minimal dysplastic epithelial changes of anogenital epithelium	Generally self-limiting over months to years in immunocompetent subjects: 2% persistence rate	Up to 10% lifetime risk of cancer, particularly of transition zones between squamous and glandular epithelium, if infection persists

their capsid proteins. Therefore it becomes of considerable importance to understand the extent to which genotypes are immunotypes, and whether there is cross-protection between closely sequence related PV types, or even more distantly related types. Clinical data suggest that infection with one PV genotype conveys little or no protection against subsequent infection with another type [11], despite relative conservation of the sequence of the L1 protein between different PV genotypes. The solution of the crystal structure of a  $t = 1$  structure comprising 12 HPV 16 L1 pentamers [12] allowed recognition as to which regions of the L1 protein are external to the virion, and therefore likely to be susceptible to the effects of neutralizing antibody. Perhaps unsurprisingly, in view of previous data on genotype specificity of neutralizing antibody, the majority of intraspecies genotypic variation in the generally highly conserved L1 protein was found among amino acid residues that were exposed to solvent on the external face of the virus. Thus it seems unlikely that antibody raised to one PV genotype will provide protection against challenge with others, and to the extent that animals reflect humans, this observation seems to be valid for data generated using vaccines designed to prevent infection with animal PVs [13]. The relative conservation of PV L1 sequence across genotypes might nevertheless allow for development of T helper responses active across a range of PV genotypes, which might result in some partial cross protection against persistent or severe disease. T helper cell cross reactivity has been observed in man following immunization with HPV 11 viruslike particles (VLPs) [14], and in experimental models following immunization with a HPV6b poly-nucleotide vaccine [15], although the biological significance of such cross reactivity remains to be established.

### III. PRODUCTION AND QUALITY ASSURANCE OF PAPILLOMAVIRUS CAPSIDS FOR VACCINES

Papillomaviruses are icosahedral viruses comprising 360 copies of the major L1 capsid protein, assembled from 72 pentameric rings [16,17]. Although they were among the first demonstrably infectious filterable agents [18], a major problem with developing a vaccine to prevent papillomavirus-associated disease has been production of sufficient virus material to be the basis of a vaccine. Papillomaviruses cannot easily be grown in tissue culture, and therefore recombinant DNA technology has been required to produce papillomavirus capsids that, by analogy with effective virus vaccines, might be used to induce neutralizing antibody and thus prevent papillomavirus infection. Recognition that the capsid proteins of papillomavirus self-assemble into virus-like particles, if expressed in eukaryotic expression systems [19], has facilitated development of particle-based prophylactic vaccines [20]. Although early studies on expression of the L1 and L2 capsid proteins of papillomavirus using recombinant DNA technology demonstrated production of capsid protein in prokaryotic and eukaryotic expression systems [21–24], attempts to isolate virus particles were unsuccessful, although self-assembly of capsid proteins in cell culture had been shown for other viruses [25]. Observation that the L1 protein of HPV16, if expressed from the second methionine initiation codon, could assemble into virus-like particles in Cos 1 cells [19] stimulated further work on production of VLPs in a range of expression systems [26–31]. Papillomavirus L1 proteins of a range of genotypes produced VLPs in greater yield than was initially observed

for HPV16, and production of HPV16 VLPs was improved following recognition that the prototype HPV16 L1 clone had a nonconservative mutation [32], not seen in subsequent clinical isolates, that impaired assembly of VLPs from L1 protein. Production of VLPs on a larger scale was facilitated by expression of L1 protein in insect cells using recombinant baculovirus, and in yeasts. These observations paved the way for early vaccine studies in a range of animals using species-specific papillomaviruses [31,33].

The desire for efficient production of VLPs for vaccine use has prompted more thorough examination of the minimal requirements for assembly of capsid proteins into quaternary structures sufficiently resembling the virus to invoke host protective immunity. Expression of PV capsid protein in *E. coli* produces small amounts of VLPs [34] as determined by density gradient purification and electron microscopy analysis—following denaturation and renaturation from amorphous inclusion bodies, significant amounts of L1 protein assemble into L1 pentamer capsomers, which are immunogenic [35] and retain at least some of the structures necessary to induce virus neutralizing antibody. When L1 is expressed in *S. typhimurium*, VLP particles are also observed [36], although the practical utility of a particle or capsomer production system based on prokaryotic systems remains uncertain.

Stability of virus particles once assembled is critical for the development of a successful vaccine. While it is clear that the current generation of vaccines is stable for sufficient time to allow their use in clinical trials, there is little published literature on PV stability [37,38]. One strategy to avoid issues of VLP stability and the requirement for a cold chain for vaccine deployment might be to use polynucleotide vaccines to express the L1 capsid protein, as the stability of polynucleotide vaccines is well defined. Efficient expression of the L1 protein in mammalian cells can be achieved by codon modification of the primary gene sequence to avoid codon biases, which prevent efficient expression of the PV protein [39,40]. A polynucleotide vaccine expressing a codon-modified L1 protein invokes expression of L1 protein that assembles into capsid structures, as the induced antibody recognizes virus-like particles rather better than denatured L1 [41].

#### IV. PAPILLOMAVIRUS CAPSIDS AS PROPHYLACTIC VACCINES

Demonstration that papillomavirus vaccines induce antibody, and protection against virus challenge, in a range of natural PV infections in animals including the Cottontail rabbit [31], the cow [42], and the beagle dog [43], paved the way for early-phase clinical trials in man. These studies, in subjects with and without HPV infection, have confirmed the safety and immunogenicity of VLP-based vaccines of HPV types 6, 11, and 16, given intramuscularly with or without adjuvant (Table 2). Three administrations of VLPs with adjuvant induce peak antibody levels at least 10 times those seen in subjects naturally infected with HPV, and levels of antibody above those produced by natural infection are sustained for at least 18 months post vaccination. In experimental animals, small doses of VLPs (<1 µg) are immuno-

genic [33]. In the clinical trials published to date, and in others reported at international meetings but not yet published [44], a dose of 10–50 µg, given on three occasions, gives optimal antibody titers. Antibodies are neutralizing in a range of in vitro and in vivo assays [45–48], including the neutralization of PV virions mixed with foreskin epithelial cells and transplanted under the renal capsule of a nude mouse, and the prevention of infection of susceptible cell lines by papillomavirus pseudovirions.

The primary aim of prophylactic vaccination with HPV vaccines is to prevent cervical cancer, and pre-cervical cancer lesions (e.g., CIN 2/3), which require evaluation and treatment. Secondary aims of vaccination are to prevent less severe cervical lesions (e.g., CIN 1), genital warts, and persistent infection/transmission of HPV. A large Phase II study to evaluate the efficacy of an HPV 16 L1 VLP vaccine against incident persistent HPV infection has recently been completed [49]. Two thousand, three hundred and ninety-two (2392) young women (aged 16–23 years) were enrolled in a randomized, double-blind, multicenter study. Subjects received three doses of either 40 µg of HPV 16 L1 VLP vaccine or placebo over a 6 months vaccination regimen. Subjects were evaluated for HPV 16 infection and disease at baseline and every 6 months by collection of cervicovaginal samples for HPV 16 DNA testing and Pap smear. Colposcopy and biopsy were performed as indicated based upon Pap smear findings. Subjects with polymerase chain reaction (PCR) or serologic evidence of HPV 16 infection at baseline or PCR evidence of HPV infection prior to completion of the vaccination regimen were excluded from the primary analysis. With a median duration of 17.4 months of follow-up after completion of the vaccination regimen, the combined incidence of persistent HPV 16 infection or HPV16-related CIN was 3.8/100 subject-years at risk (SYR) in the placebo group and 0.0/100 SYR in the vaccine group for an estimated vaccine efficacy of 100% (95% CI = 90–100%). Of the 41 cases in the placebo group, 31 had persistent HPV 16 infection without CIN, 5 had HPV 16-related CIN 1, 4 had HPV 16-related CIN 2, and 1 had a single HPV 16 PCR + finding at her last visit prior to being lost to follow-up. These results suggest that intramuscular administration of an HPV L1 VLP vaccine induces a systemic immune response that is sufficient to prevent vaccine-type HPV infection and HPV-related CIN in a high majority of young women. Furthermore, the anti-HPV 16 titers persisted at levels at least fivefold to tenfold higher than those seen after natural HPV 16 infection during the course of follow-up.

VLPs have also been delivered to humans without adjuvant [50]. Delivery without adjuvant is more likely to induce Th1-type responses and CTL, perhaps because of the ability of VLPs to be efficiently taken up by dendritic cells via both the endogenous and exogenous antigen presentation pathways,\* and to directly activate immature dendritic cells [51,52] to produce a more mature phenotype. However, delivery with alum adjuvant may give a more sustained immune response, perhaps because adjuvanting proteins with alum can increase their stability in vivo.

\*Gao et al, submitted.

**Table 2** Published Studies of Papillomavirus VLP Vaccines in Man

Recruitment strategy	Dose and delivery schedule	Population size	Outcome measures	Conclusions	Ref.
19–45 years, healthy, not at risk for STD	Baculovirus HPV11 VLPs 3, 9, 30 or 100 µg im with alum 3:1 active: placebo 0, 4, 16 weeks	24 m, 41 f	Antibody to VLPs T cell proliferation Cytokine release (7-day in vitro stimulation)	Safe (pain in most, rash in 6, hives in 1) Immunogenic at all doses—no real dose-response curve Antibody non-cross-reactive Proliferation/cytokines cross-reactive between types	[14]
18–29 years, healthy, not at risk for STD	Baculovirus HPV16 VLPs 10, 50 µg im with nil, alum, or MF59 5: 1 active to placebo 0, 4, 16 weeks	14 m, 58 f	Antibody	Safe (pain in most) Antibody, more with higher dose antigen, more with no adjuvant or MF59 than alum	[50]
18–56 years, warts, no other active STD	Baculovirus HPV6 VLPs 1,5,10 µg im with nil no placebo 0, 4 ,8 (12, 16, 20) weeks	6 m, 27 f	Antibody, DTH	Safe Antibody, more with 5 and 10 than 1 µg DTH, most subjects Wart resolution, 25 of 33 subjects	[99]

Papillomaviruses naturally infect mucosal surfaces and there is therefore a case for utilizing a vaccine designed to induce neutralizing antibody specifically through the mucosal immune system. A number of studies have shown that VLPs delivered to mucosal surfaces [53–56] or, perhaps surprisingly, systemically can induce significant titers of antibody at mucosal surfaces. However, administration of VLPs to dogs intranasally, while producing reasonable titers of mucosal antibody, did not protect against challenge with canine oral papillomavirus (COPV) whereas systemic administration was protective [57]. These data, together with the somewhat erratic immune responses to mucosally administered vaccines, cast some doubt on the viability of a vaccine program based on mucosally administered VLPs.

## V. FURTHER DEVELOPMENT AND USE OF PROPHYLACTIC HUMAN PAPILLOMAVIRUS VACCINES

The encouraging Phase II results described above have lead to initiation of Phase III testing. Although the primary aim of vaccination is to prevent cervical cancer, and pre-cervical cancer lesions, Phase III study endpoints were primarily based on pre-cervical cancer lesions because such lesions serve as a suitable surrogate marker for cancer as they are treated and removed when discovered in clinical practice. Recent data from epidemiologic and clinical studies suggest that high-grade cytologic abnormalities (HSIL or CIN 2/3) may develop relatively early (within months to several years) after incident HPV infection with high-risk HPV types. Thus Phase III studies utilizing high-grade cytologic abnormali-

ties as endpoints are feasible and ongoing, albeit large (10,000–15,000 subjects) and logically challenging.

To bolster the benefits of a prophylactic HPV vaccine, efficacy against low-grade cytologic abnormalities (e.g., CIN 1), genital warts, and persistent HPV infection is also highly desirable and the subject of Phase III evaluations. Although most CIN 1 lesions spontaneously resolve, they often result in patient anxiety, increased health care costs because of follow-up evaluations, and potentially unnecessary diagnostic and ablative procedures. Genital warts cause discomfort and psychosocial problems, and are often prolonged and difficult to eradicate. Persistent HPV infection allows for HPV transmission (and subsequent HPV disease) to sexual partners and throughout the sexually active community.

When prophylactic HPV vaccines become available for routine use, predictions of their role and impact on public health strategies for reduction of HPV disease await findings from large-scale clinical trials. If HPV vaccines are shown to be effective for preventing pre-cervical cancer lesions, administration to all young teenage girls before the onset of sexual intercourse should be considered to increase the proportion of young women who will benefit from the intervention. If HPV vaccines are also demonstrated to be effective for preventing genital warts, and for preventing persistent HPV infection/carriage in men, their routine use in young boys might be warranted as well.

The impact of vaccination on HPV disease will also be a function of the number of high-risk HPV types included in the vaccine and will vary according to the health care practices in regions where they are used. In populations without cervical cancer screening programs, the impact of vaccination should be greater than in populations with active screen-

ing programs. But even in populations with active screening programs, a highly effective prophylactic HPV vaccine should further reduce cervical cancer rates, particularly in young women, beyond what has been gained from cervical cancer screening programs and may allow a recommendation for an increase in the age for first Pap smear testing and a longer interval between routine Pap smear testings.

Although results from early clinical trials offer promise for an effective prophylactic HPV vaccine, such a vaccine would not be expected to have an immediate and profound impact on HPV disease worldwide. The absence of obvious clinical disease in the majority of those infected with the virus, long periods of infectivity following virus acquisition, difficulties in achieving high rates of vaccine uptake in adolescent populations, and problems with cost and distribution of vaccine to developing world populations combine to suggest that HPV disease would continue as a public health problem for decades to come.

## VI. VIRUS-LIKE PARTICLES INCORPORATING ADDITIONAL ANTIGENS

The observed natural immunogenicity of VLPs from a range of viruses in animals and man has provoked studies of their use as delivery systems for antigens other than the major viral capsid proteins [58,59], and papillomavirus VLPs have also been tested in this manner [60–62]. In general, PV VLPs seem to behave like other particulate antigens of viral size, which are good inducers of immunity and can carry nonviral epitopes to the immune system to induce potent humoral and cellular immune responses. The particular ability of PV virus-like particles to activate dendritic cells [52] is not essential for their immunogenicity, as particles coated with additional protein that do not in consequence invoke DC activation (J. Schiller, personal communication), are nevertheless potent inducers of a humoral immune response to the incorporated epitopes [63].

Three alternative methods have been used to incorporate antigen into PV VLPs. Firstly, there is a region at the C' terminal of the L1 protein of most tested PV genotypes that is relatively permissive for deletion and replacement with incorporation of novel amino acid sequences of up to about 60 amino acids [60]. Secondly, the incorporation of the L2 minor capsid protein into VLPs allows substitution of portions of this protein with novel epitopes [61] that may be displayed on the virus surface. The advantage of incorporating novel epitopes into L2 is that this protein can harbor longer amino acid sequences, although the copy number is lower than that incorporated to L1, and the natural immune response to L2 is not as striking as that to L1. Thirdly, additional proteins can be physically or chemically conjugated to the VLPs using a range of technologies [63]. Each of these methods has the potential to impair to greater or lesser extent the stability of the virus particle structure—particles may appear larger and may degrade faster, to produce the characteristic ~40 kDa cleavage product of L1 protein. It has been recently shown that pentameric L1 capsomers can induce protective immunity against COPV challenge [35]. Therefore chimeric pentamers expressed in bacteria might be

the basis of a more stable chimeric VLP-like vaccine, although the relative immunogenicity of pentamers and VLPs has yet to be established in man.

In experimental animals, robust immune responses can be obtained to epitopes incorporated into VLPs from a range of proteins, including the nonstructural proteins of papillomavirus, and the L2 capsid protein [64]. There is particular interest in VLPs incorporating nonstructural proteins because of their potential to invoke cell-mediated immunity that might be host protective against PV infection, or alternatively therapeutic for early preclinical infection, as has been shown in the rabbit [65,66] and the beagle dog. In a range of models, both humoral and cellular immune responses have been invoked using chimeric particles that can be variously therapeutic for transplanted tumors [61,62], or neutralizing of soluble autoantigen cytokines [63]. Responses to incorporated epitopes can be similarly invoked using polynucleotide vaccines, although it is necessary to encode a ubiquitin sequence at the N' terminal of the protein to allow efficient degradation of the chimeric protein, and induction of good CTL responses to the incorporated epitope [67]. A vaccine combining a ubiquitinated and nonubiquitinated sequence can invoke both host protective neutralizing antibody against PV virions and cell-mediated immune responses against PV early proteins, allowing one approach to a combined prophylactic/therapeutic vaccine for PV infection for the developing world.

The concept of using chimeric VLPs as a delivery system for antigens of interest raises the issue of the effects of prior immunity to the carrier protein on the immune response mounted to the novel epitope. Established immunity to the carrier PV genotype enhances the response to the carrier VLP, following administration as a vaccine, but specifically blocks induction of at least some cellular immune responses to a novel incorporated epitope. High titers of VLP-specific antibody can passively transfer inhibition [68]. Inhibition, which can be overcome by choosing a carrier VLPs of a type not immunologically cross reactive with the existing VLP-specific response, does not appear to be a consequence of CTL epitope dominance [15].

## VII. THERAPEUTIC VACCINES FOR CERVICAL CANCER AND PRECANCER

Papillomavirus capsid vaccines using conventional adjuvants are likely to be available within the foreseeable future, as discussed in the preceding section. These vaccines induce high titers of virus neutralizing antibody and will likely prevent new viral infections, but antibody is unlikely to have a therapeutic effect against existing infection. It can be estimated that 5 million women worldwide will die with cervical cancer over the next 20 years, and the majority of these women are already infected with the papillomavirus that will initiate their cancer. A prophylactic HPV vaccine will not offer protection against tumor development to already infected women; therefore papillomavirus-specific immunotherapy is a much-needed adjunct to a prophylactic HPV vaccine program. As therapeutic vaccines are currently not available for any infection, successful development of

PV-specific immunotherapy will require new understanding about how immune responses might eliminate virally infected cells in the absence of local inflammation, and about how such responses might be induced in man.

Direct and indirect evidence allows the conclusion that virus-specific immune responses occur following natural infection with PV, and may cause resolution of infection. Greater than 50% of HPV infections resolve without intervention [69], and resolution is significantly impaired in subjects immunocompromised by immunosuppressive therapy [6] or by HIV infection [70]. Further, the relative risk of cervical cancer is significantly increased in subjects immunosuppressed in relation to renal transplantation, and the median time from onset of immunosuppression to development of cancer is about 4 years [71], suggesting that the role of the protective immune response is predominantly to prevent persistence or progression of HPV associated premalignancy, rather than to prevent initial infection. More direct evidence comes from a study demonstrating that resolution of CIN is significantly associated with cutaneous delayed type hypersensitivity to peptides derived from two transforming proteins (E6 and E7) of human papillomavirus [72]. It is noteworthy that while cell-mediated immune responses are described to PV nonstructural proteins in a number of studies of patients with CIN, there is little evidence of humoral immune responses to these proteins [73], prior to the onset of invasive cervical cancer [74], suggesting that the common immune response to PV non-structural protein is predominantly Th1 type.

### **VIII. THE NATURE OF THE IMMUNE RESPONSE REQUIRED TO ELIMINATE INFECTED EPITHELIUM**

The immune effector mechanisms that might result in elimination *in vivo* of epithelial cells expressing a non-self–non-MHC antigen in somatic cells are not completely understood. In different systems, either CD4 or CD8 restricted antigen-specific T cell responses can be necessary and sufficient for elimination of skin grafts expressing such antigen [75–77]: In these models, antigen is also expressed in professional antigen-presenting cells. Elimination can be specific for cells expressing antigen [78], or alternatively can also eliminate neighboring cells not expressing the relevant antigen [79]. Indeed, immune responses recognizing antigen (cross) presented only by professional APC in skin can eliminate the surrounding epithelial cells [80]. Thus it seems likely that a range of T cell delivered effector mechanism may be able to eliminate infected epithelium, including direct lytic mechanisms such as perforin and granzymes, or fas–fasL interactions, which would be expected only to eliminate cells expressing the relevant antigen, and indirect cytokine-mediated mechanisms including IFN  $\gamma$  or TNF  $\alpha$ , which might induce more general epithelial damage. The extent of local activation of the effector mechanisms of a primed antigen-specific effector T cell will likely depend not only on the level of expression of the relevant MHC/peptide on the target epithelial or antigen-presenting cell, but also on the local pro- or anti-inflammatory cytokine environment in

the epithelium, and on the levels of costimulatory molecules expressed by the target [81]. A key question for HPV immunotherapy will be to establish which mechanism is the most effective for eliminating PV-infected epithelium. No particular immune effector mechanism response has proven sufficient for effective elimination of E7+ epithelium *in vivo* in an animal model involving grafted skin expressing HPV16 E7 [82], although such elimination can be induced by coadministration of E7 expressing skin and nonspecific immune stimuli [83], and CD4+ and CD8+ T cells are each necessary and sufficient for graft rejection in this model (unpublished data) as for other grafting models in which antigen other than MHC is expressed in skin. *In vitro*, CD8-restricted, E7-specific CTL clones are unable to kill E7 transgenic keratinocytes in a 4-hr cytotoxicity assays [83a], although epithelial cell killing could be observed following IFN  $\gamma$  treatment, which we deduced increased the processing of E7 protein for presentation. However, using a keratocyte colony formation assay, the same CTL clone over a longer period was able to specifically inhibit formation of epithelial colonies from E7 transgenic epithelial precursors, and the inhibition of colony formation could also be achieved with perforin –/– CTL clones (Harris, unpublished observation) suggesting that slower, cytokine-mediated inhibition of growth may be important for eradication of HPV-infected epithelium.

### **IX. THE VIRAL ANTIGENS TO TARGET**

Expression of papillomavirus proteins in epithelium following HPV infection is spatially and temporally controlled [84]. Episomal PV DNA replicates in the most basal cells, requiring E1 and E2 protein [85]. Expression of PV E6 and E7 protein is observed in the basal and suprabasal epithelium [86]. These proteins direct amplification of the pool of PV-infected cells by disturbing the progress of epithelial cells toward a differentiated phenotype. E4 nonstructural protein, and the viral capsid proteins (L1 and L2), are regarded as late genes, which are abundantly expressed in cells already terminally differentiated, although mRNA encoding these proteins can be detected earlier in the process of cell development. E6 and E7 papillomavirus proteins have been demonstrated to be targets for immunotherapy when overexpressed in transplantable tumors in murine models [87,88]. However, it is not clear from these data whether sufficient protein is expressed, or, if expressed, processed and presented by the relevant epithelial cells, such that an immune response could eliminate the infected epithelium. Thus it is necessary to establish in natural infection what PV antigens can be effectively targeted, as well as to determine what sort of immune response is required for immune-mediated elimination of infected epithelium.

### **X. IMMUNOTHERAPY OF NATURAL HUMAN PAPILLOMAVIRUS INFECTION IN ANIMAL MODELS**

Defining an effective therapeutic immune response for PV-infected skin is hard using transplantable tumors, in part

because the tumors used can grow faster than the immune response following immunization, and in part because the transplanted tumors are not epithelial. However, for at least one model transplantable tumor expressing PV antigens, TC-1, therapeutic responses can be shown in primary and metastatic models [89,90]. In this system, many antigen delivery systems have proven effective, although a hierarchy of efficacy becomes apparent under limiting conditions of initial tumor burden.

Three well-characterized animal papillomavirus infections might be used to examine for immunotherapeutic effects. Bovine papillomavirus (BPV) produces skin lesions following viral challenge, which spontaneously regress over weeks to months. Canine oral papillomavirus (COPV) produces mucosal warts that spontaneously regress over weeks. Cottontail rabbit papillomavirus(CRPV) produces nonregressing skin warts, which in some rabbit strain can progress to invasive cancer. The natural course of established CRPV infection, which at least to some extent mimics nonregressing PV infection in man, can be modified by immunization with a cocktail of PV E1, E2, E6, or E7 proteins; significant inhibition of the progression of infection to malignancy is seen, and some regression of existing lesions is reported. Immunization can be delivered as recombinant protein [65,91], or as a polynucleotide vaccine [65], and immunization with single proteins have some efficacy, although the efficacy seems greater if more are used. The natural regression of BPV-associated warts can be accelerated by immunization with E7 [92]; similar studies have been initiated with COPV, although the rapid natural regression of these diseases makes interpretation of therapeutic efficacy difficult.

## XI. HUMAN TRIALS OF IMMUNOTHERAPY OF HUMAN PAPILLOMAVIRUS INFECTION AND TUMORS

Trials of immunotherapy of PV-associated cancer or pre-cancer with papillomavirus proteins have been undertaken in man [93–96]. Published studies have utilized the E6 and E7 nonstructural proteins of HPV16, as these proteins are expressed in invasive cancer cells, and HPV16 is the PV genotype most commonly associated with cervical cancer. These early-phase studies have used peptides [97] or whole protein [95] delivered with proprietary adjuvants, or recombinant vaccinia virus encoding E6 and E7 proteins modified to ablate the transforming functions of the proteins [96]. They have generally been conducted in patients with late-stage cervical cancer, although more recent unpublished studies have also been undertaken in patients with precancerous lesions of the cervix or the anus. Early-phase therapeutic studies have also been undertaken in subjects with genital warts [98]. Each of these studies have established that immunotherapy appears safe in the short term, and that immune responses can be induced to the relevant viral proteins in at least some immunized patients. A recent study has examined the safety and efficacy of specific immunotherapy for high-risk HPV. Patients with CIN ( $n = 31$ ) were recruited to a placebo-controlled dose ranging study of

immunotherapy with CerVax™ 16 vaccine, a mixture of HPV 16 E6E7 fusion protein formulated with the ISCOM® adjuvant. Immunotherapy was well tolerated, and immunized subjects mounted HPV16 E6E7 specific humoral and cellular immune responses. Of 14 subjects presenting with CIN associated with HPV16 infection, 7 had no measurable HPV16 after immunotherapy, and HPV copy number in cervical tissue was significantly reduced in the other 7. Thus CerVax™ 16 vaccine was shown to be safe and immunogenic, and immunotherapy may facilitate clearance of HPV16 infection from cervical epithelium, which should reduce the risk of progression of HPV infection to cervical cancer.

Until a papillomavirus therapeutic vaccine has been demonstrated efficacious, no immunological marker can be held to be a surrogate for an effective immune response. To date, antibody, cutaneous DTH, T helper, and cytotoxic T cell responses have all been reported in some percentage of immunized subjects, and, as many have significant tumor burdens and have had chemotherapy and or radiotherapy, these results must be regarded as encouraging. Studies have not been designed to look for clinical efficacy, and the clinical outcomes reported to date, while encouraging in some patients, are anecdotal.

## XII. THE FUTURE

Many studies over a number of years have demonstrated problems with the antigen-presenting machinery in a wide range of epithelial tumors including cervical cancers. These variously result in reversible or nonreversible downregulation of MHC class I expression on tumor cells. These observations, together with those on the requirement for CD4-mediated immune responses for elimination of epithelial grafts *in vivo*, and the capacity of CD4 cells to mediate bystander killing, suggest that immunotherapy for HPV infection may be more focused on generating an appropriate CD4 response than on producing CD8-restricted cytotoxic T cells specific for papillomavirus antigen. It remains to be established whether any particular papillomavirus antigens are sufficiently cross-presented by the professional APCs in infected lesions to allow immune elimination by this mechanisms. If such is the case, it will then be necessary to determine how to induce and target such immune responses in man.

### I. INTRODUCTION

This chapter considers an approach to vaccination that is being tested in the setting of malignant melanoma. The method constitutes actively immunizing cancer patients with a sample of their own dendritic cells (DCs) charged with melanoma antigens (MelAgs). The latter can range from previously defined melanoma peptides to a broad group of MelAgs delivered with melanoma cells or RNA derived from there. This active immunization approach is very different from standard approaches of injecting vaccine antigens intramuscularly or intracutaneously, and, clearly, cell therapy is useful only in select contexts. Nevertheless, research on DCs in cancer therapy could be broadly instructive. First, the approach provides a means to load DCs with many tumor antigens, which may be vital in eliciting protective immunity to human cancers. Second, the use of ex vivo-derived, antigen-loaded DCs provides an opportunity to monitor and to manipulate several aspects of DC physiology that are pertinent to the control of immune responses. Third, DC therapy represents a nontoxic means to study the immune response to human cancers in patients who often do not have alternative therapies, as in stage IV melanoma. At this stage, it is not established if active immune cells, once generated by active immunization with DCs, will bring about tumor regression and prolong survival in patients, but some preliminary Phase I studies are encouraging, as summarized briefly below.

Our plan is to outline some of the roles of the distinct lineage of DCs in the control of immunity, and then to consider a few points from studies of DC vaccination to date.

The field is just in its infancy, with many variables to be worked out. In spite of the demands of human research, the methods and rationale are improving continually.

### II. FUNCTIONS OF DENDRITIC CELLS IN THE CONTROL OF IMMUNITY

#### A. Adjuvants—Enhancing Adaptive Immunity

After it became apparent that DCs were specialized and potent stimulators of T-cell-mediated immunity in tissue culture, it was decided to use these cells as adjuvants *in vivo* in rodents. Some of the first examples of this transition from *in vitro* to *in vivo* experiments are described below. Dendritic cells were found to be powerful stimulators of the mixed leukocyte reaction in tissue culture. Lechner and Batchelor [1] were able to show that DCs were major stimulators of graft rejection *in vivo* and at small doses. Likewise, hapten-modified DCs were noted to be potent stimulators of hapten-specific CD8 T-cell responses in culture. Macatonia et al. [2] tested hapten-modified DCs *in vivo*, and the cells induced contact sensitivity. Dendritic cells also primed antigen-specific helper T cells in culture. Inaba et al. [3] pulsed DCs *ex vivo* with protein antigens, reinfused the cells, and found that the animals could be primed specifically to the protein antigen captured by the DCs. In the latter experiments, the proteins first had to be given to the DCs in their immature or antigen-capturing state (which is the state of most DCs *in vivo*), and then the maturing DCs were injected.

Investigators then considered more challenging antigenic targets. Again the DCs served as adjuvants for strong T-cell priming. Dendritic cells pulsed with tumor antigenic peptides, or with viral vectors recombinant for tumor antigens, were able to elicit protective immunity to tumor challenge, and in some instances caused existing tumors to undergo some regression [4,5]. Dendritic cells pulsed with microbial antigens could also induce protective immunity to infection [6,7], whereas DCs bearing autoantigens could trigger autoimmunity [8,9]. Because it is well known that proteins and preprocessed antigenic peptides are poor immunogens unless they are administered together with adjuvants, DCs seemed to be functioning as “nature’s adjuvants” [3].

### B. Sentinels—Innate Immunity

Dendritic cells are specialized to respond quickly to the entry of a pathogen and set the stage for an adaptive immune response (above). For example, DCs can mobilize other innate effector cells, such as NK cells and NKT cells. Another example of an innate response is the capacity of DCs to make large amounts of certain cytokines, usually upon stimulation of Toll-like receptors (TLRs) by microbial ligands. The curious finding is that different subsets of DCs can express different TLRs and, upon signaling, make different cytokines [10]. The plasmacytoid DC expresses TLR9 and, upon stimulation with CpG deoxyligonucleotides, produces large amounts of IFN $\alpha$  (also IFN $\beta$  and IFN $\gamma$ ). In contrast, certain monocyte-derived DCs express TLR4 and make abundant IL-12 and tumor necrosis factor- $\alpha$  (TNF $\alpha$ ) upon stimulation with lipopolysaccharide. When a TLR receptor is shared, as is the case of TLR7, stimulation with the ligand imiquimod leads to IFN $\alpha$  production by plasmacytoid DCs, and IL-12 and TNF $\alpha$  from monocyte-derived DCs [11]. Therefore the type of DC subset that will be used in immune therapy can influence the type of cytokine that can be produced, and perhaps other features. More details are provided below.

### C. Gatekeepers—Immune Tolerance

It is becoming increasingly apparent that DCs have important roles in immune tolerance. It is accepted that DCs in the thymic medulla contribute to negative selection, efficiently capturing self antigens and deleting newly formed self-reactive T cells. In addition, peripheral tolerance mechanisms are available for the immune system to avoid reactivity to antigens that escape negative selection, or environmental proteins to which reactivity must not be induced. The need for peripheral tolerance is dramatized by the fact that when DCs are eliciting immunity to microbial antigens, they are also capturing self-antigens in the form of dying infected cells, as well as harmless environmental proteins in the environment. Therefore it has been proposed that DCs function in the steady state, prior to infection or inflammation, to capture dying self-cells and environmental proteins and to induce peripheral tolerance [12].

When proteins or dead cells are targeted to DCs *in vivo* in the steady state, the antigens are processed with high

efficiency and tolerance is induced [13–15]. The tolerance can occur through the deletion of reactive T cells, or, alternatively, DCs might induce regulatory T cells that suppress the function of other T cells. Therefore in terms of immunotherapy, it is important that the correct DC be used to avoid the tolerizing roles of DCs. In addition, it is possible that autoreactivity will not be a major obstacle to immunotherapy because DCs will have controlled this problem prior to the exposure to antigens from tumor cells.

## III. SOME MECHANISMS OF DENDRITIC CELL FUNCTION

### A. Dendritic Cells as Antigen Processing Machines—Antigen Uptake and Formation of Major Histocompatibility Complex–Peptide Complexes

Dendritic cells have a very large number of receptors for adsorptive uptake. Through the use of antigens incorporated into antireceptor antibodies, it is evident that these endocytic receptors enhance presentation on major histocompatibility complex (MHC) class II. In some cases, such as DEC-205 and Fc $\gamma$ R, endocytosed antigens are also delivered to MHC class I, the so-called “exogenous” pathway to MHC class I. Once taken into the DCs, the conversion of antigen into MHC–peptide complexes seems to be efficient, although more quantitative work needs to be done. To illustrate, when DCs process a membrane protein from dead B cells, the formation of MHC class II peptide complexes is >1000 times more efficient than if the DCs are exposed to preprocessed peptides [16]. Therefore DCs are efficient at processing complex antigens, including whole cells, and present antigenic fragments on both MHC class I and class II products to CD8 $^{+}$  and CD4 $^{+}$  T cells, respectively.

### B. Dendritic Cells as Costimulatory Cells—T-Cell Binding and Activation

Even when antigens do not require processing (such as superantigens, allogeneic MHC–peptide complexes, and anti-CD3 antibodies), DCs are much more potent stimulators of T-cell responses than other antigen-presenting cells. Two potentially relevant mechanistic features are the expression of DC-SIGN, a C-type lectin that allows DCs to bind resting T cells via ICAM-3 [17], and high levels of CD86 [18,19], a T-cell costimulator that clusters with MHC–peptide complexes on DCs [20]. Dendritic cells express several other families of molecules. These include molecules for T-cell adhesion (such as CD54/ICAM-1 and CD58/LFA-3), TNF receptors (CD40 and CD95/fas), TNF family members (CD27, 4-1BBL, and OX40L), and several B7 family members (CD80, CD86, ICOS-L, and PD-L2). In addition to these many cell surface molecules for productive T-cell interactions, DCs can produce cytokines such as IL-2 [21] and IL-12 [22,23], and additional growth factors such as cysteine and thioredoxins. These products help to explain the potent effects of DCs on the magnitude and quality of the T-cell response.

### C. Dendritic Cell Properties In Vivo—Positioning for Antigen Capture and Migration to the T-Cell Areas

Dendritic cells are designed to navigate peripheral tissues, where they can pick up antigens, enter the afferent lymphatics, and then home to the T-cell areas (reviewed in Refs. 24 and 25). During DC-based immunotherapy, these homing properties should allow the antigen-bearing DCs to find those T cells that are capable of producing an immune response. To execute these migratory functions, DCs control their expression of chemokine receptors in a sequential manner. CCR6 (responding to MIP-3 $\alpha$  or CCL20) may target DCs to epithelial surfaces. During inflammation, additional DCs bearing CCR5 (responding to MIP-1 $\alpha$  and MIP-1 $\beta$ ) or CXCR3 (responding to IP-10, Mig, ITAC, and CCL9-11) may be recruited from the blood. With maturation, CCR7 (responding to CCL19 and CCL21) is upregulated, enhancing entry into lymphatics and homing to the T-cell areas. An important intermediary in the function of chemokine receptors are the cysteinyl leukotrienes LTC and LTD, which are pumped out of DCs through multidrug resistance family proteins and then act on the DCs to influence chemokine responsiveness. In summary, DCs are specialized to capture and handle antigens, to migrate into tissues and then to lymphoid organs in vivo, and to stimulate and control the quality of the immune response.

## IV. INTERFACING DENDRITIC CELL PHYSIOLOGY WITH IMMUNOTHERAPY

### A. Method of Antigen Loading into Dendritic Cells

From the above considerations, DC-based immunotherapy has considerable demands but potential as well. One example is the capacity to load DCs ex vivo with a large spectrum of tumor antigens, which in turn can be presented on both MHC class I and class II to elicit a combined immune response by CD4 $^{+}$  helper and CD8 $^{+}$  cytotoxic T lymphocytes (CTLs). This ex vivo step may bypass a fundamental defect in the patient's natural immune response, which is that in spite of their many potential antigens, tumor cells are ineffective in presenting their antigens to T cells, or the tumor cells may not be captured by DCs in vivo. The status of the patient's immune system in progressive cancer was recently assessed directly in multiple myeloma [26]. In this tumor, it is possible to take T cells from the tumor environment (the bone marrow) and to assess their capacity to develop immunity to authentic myeloma tumor cells as targets. No immunity was detected ex vivo, but strong immunity could be generated when DCs were loaded with myeloma cells (coated with antisyndecan antibody) and used to expand bone marrow T cells to form strong myeloma-specific CTL responses. The optimal method for tumor antigen loading is far from established for DC-based active immunization. The approaches under consideration for delivering a large spectrum of tumor antigens are antibody-coated tumor cells, apoptotic and necrotic tumor cells, exosomes, mixtures of MHC class I

and class II binding peptides, and tumor-derived RNA. Some of these approaches provide an opportunity for tailoring the immunotherapy to those tumor antigens that are being expressed in a patient-specific manner.

### B. Monocyte-Derived Dendritic Cells

Beyond the methods for antigen delivery, the subset of DCs could prove critical. Much of the current research is being carried out with monocyte-derived DCs [27–29], which are potent and homogenous stimulators of immunity. Monocyte-derived DCs can be reproducibly generated within a few days in large numbers (300–500 million mature DCs per apheresis) from precursors in blood without any need for pretreating the patients with cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF) or Flt3-L [27–29]. It is possible to obtain populations of immature DCs by exposing monocytes to GM-CSF $^{+}$  IL-4, and these can then be differentiated into mature DCs by various stimuli such as TLR ligands (e.g., microbial products such as LPS or poly I:C), inflammatory cytokines such as those in monocyte-conditioned medium (IL-1 $\beta$ , TNF $\alpha$ , IL-6, and PGE $_2$ ), or CD40L. The use of DCs that have received a maturation stimulus is likely to be important to induce strong immunity, as it has become clear that antigen delivered on immature or incompletely matured DCs can even induce tolerance (above). However, the type and the duration of the maturation stimulus remain to be determined and may influence efficacy. For example, the use of PGE $_2$  as part of the maturation stimulus allows one to obtain CCR7-expressing Mo-DC that migrates in response to CCL19 and CCL21 and should help guide DCs into lymphoid organs [30,31]. At this time, the monocyte-derived DC populations are the most accessible and homogenous preparations of DCs.

### C. Two Dendritic Cell Subsets with Distinct Biological Functions Emerge from Cultures of Cord Blood CD34 $^{+}$ Hematopoietic Progenitor Cells

Early studies with CD34 $^{+}$  hematopoietic progenitor cells (HPCs) used cord blood to produce DCs, including distinct subsets of DCs. Differentiation was induced by culture with GM-CSF/TNF or IL-3/TNF [32,33]. In these culture conditions, the cooperation between TNF $\alpha$  and GM-CSF/IL-3 was critical for the development of DCs from CD34 $^{+}$  HPC. Indeed, although prior work had suggested TNF as an inhibitor of hematopoiesis, TNF was then observed to stimulate the proliferation of CD34-HPC together with either IL-3 or GM-CSF [34]. Limiting dilution analysis indicated that TNF increased both the frequency of IL-3 responding cells and the average size of the IL-3-dependent clones [34]. After 12 days of liquid culture, CD34-HPC cultured with GM-CSF and TNF generated both adherent and nonadherent cells with a dendritic morphology. For optimal generation of DC, TNF was mainly required during the first days of the culture, where it upregulated the expression of the common  $\gamma$ -chain subunit of the GM-CSF/IL-3/IL-5 receptor. Another important site of action of TNF in the CD34-HPC cul-

tures was the inhibition of granulopoietic differentiation and proliferation [35]. In particular, TNF reversibly blocked granulocytic differentiation at the level of uncommitted CD13<sup>-</sup> CD15<sup>-</sup> blast cells that accumulated in TNF-enriched cultures. Furthermore, the growth of committed granulocytic progenitors (CD15<sup>+</sup>) was inhibited through an arrest of cell cycle in G<sub>0</sub>/G<sub>1</sub>. Tumor necrosis factor also blocked erythropoiesis in these cultures [36]. These effects of TNF on growing CD34-HPC were mediated through the p55 TNF receptor [37].

Two precursor subpopulations emerged under these culture conditions: CD1a<sup>+</sup> and CD14<sup>+</sup> [38,39]. Both precursor subsets matured at days 12–14 into DCs with typical morphology, phenotype (CD80, CD83, CD86, CD58, and high HLA class II), and function. CD1a<sup>+</sup> precursors gave rise to cells with the characteristics of epidermal Langerhans cells (Birbeck granules, Lag antigen, and E-cadherin). In contrast, the CD14<sup>+</sup> precursors matured into CD1a<sup>-</sup> DCs lacking Birbeck granules, E-cadherin, and Lag antigen, but expressing CD2, CD9, CD68, and the coagulation factor XIIIa described for dermal or interstitial DCs. Interestingly, the CD14<sup>+</sup> precursors, but not the CD1a<sup>+</sup> precursors, represented bipotent cells that could be induced to differentiate, in response to M-CSF, into macrophage-like cells, lacking accessory function for T cells. These DC subsets differed with regard to: (a) antigen capture—interstitial DCs were more efficient in Dextran uptake and in binding immune complexes than LC; (b) lysosomal activity—interstitial DCs expressed higher levels of enzymatic activity; (c) capacity to induce naive B cell differentiation—interstitial DCs were uniquely able to prime naïve B cells, including differentiation into IgM-secreting plasma cells through the secretion of IL-12 [40,41]; and (d) whereas both subsets expressed IL-12 upon CD40 ligation, only interstitial DCs expressed IL-10. Unique functions of LCs remain to be established, but there are some reports suggesting that CD34-DCs with an LC component are more efficient in CD8 T-cell priming than monocyte-derived DCs [42,43]. In circumstances such as the induction of tumor-specific CTLs, CD34-DCs could thus be advantageous.

Granulocyte colony-stimulating factor (G-CSF)-mobilized CD34<sup>+</sup> HPCs from adult blood also yielded two DC subsets, including peripheral blood mobilized by G-CSF in patients with advanced melanoma. As in cord blood cultures, two populations could be identified at day 9 (i.e., CD1a<sup>+</sup> CD14<sup>-</sup> LCs and CD1a<sup>-</sup> CD14<sup>+</sup> interstitial DCs). About 50% of cells in these cultures remained at a precursor stage and only gave rise to DCs upon further culture. Thus, these cultures are asynchronous, a parameter that needs to be taken into consideration when using these DC preparations for vaccination.

#### D. The Efficiency with Which Dendritic Cells Home and Survive In Vivo

This critical area needs to be assessed further and more likely controlled better in human studies to improve the efficacy of DC therapy. It is of concern that, currently, DCs are being injected into skin sites in large numbers, possibly more than the lymphatics can handle, especially when the lymphatics

may not be expressing sufficient chemokines needed for proper DC entry and migration. In addition, once DCs reach the T-cell area, they can die within hours to 1–2 days and be processed by other DCs. The death may limit function, and the reprocessing by recipient DCs in the steady state could lead to tolerance. At this time, the vast majority of DCs that are being injected during immunotherapy studies may not gain access to their proper site of action in the lymphoid organs.

#### V. RESULTS FROM VACCINATION OF HEALTHY VOLUNTEERS

When methods became available to generate large numbers of DCs from monocytes, using culture methods that required only human products (recombinant cytokines and human plasma), it became feasible to assess if autologous DCs could act as immune adjuvants in healthy volunteers. It was evident that humans could be stimulated with their own DCs pulsed with KLH or with an influenza virus peptide, in the absence of any other adjuvant. The antigens by themselves were not detectably immunogenic. Interestingly, the CD4<sup>+</sup> T-cell response to KLH was decidedly Th1 in nature [44], whereas the memory CD8<sup>+</sup> T-cell response to flu matrix peptide seemed to select for higher-affinity T cells (i.e., T cells responsive to low doses of peptide) [45]. Importantly, when the DCs were of an immature type, antigen-specific IL-10-producing T cells were generated and the cells suppressed the responses of IFN $\gamma$ -producing T cells [46]. These initial proof-of-concept studies suggest that DCs have the potential to enhance or to dampen the human immune response in patients.

#### VI. ADVANCED MELANOMA PATIENTS IMMUNIZED WITH CD34-DERIVED DENDRITIC CELLS PULSED WITH MELANOMA PEPTIDES

Banchereau et al. [47] vaccinated 18 HLA A\*0201<sup>+</sup> patients in stage IV melanoma with CD34-HPC-derived DCs pulsed with six antigens: influenza matrix peptide (Flu-MP), KLH, and peptides derived from the four MelAggs: MART-1/Melan A, gp100, tyrosinase and MAGE-3. The DCs were loaded with KLH, Flu matrix peptide and HLA-A2 binding peptides derived from four MelAggs, MAGE-3, MART-1/MELAN A, GP-100, and tyrosinase, and administered biweekly over 6 weeks (four subcutaneous injections). Vaccination of patients with advanced melanoma with antigen-pulsed CD34-DCs has proven to be well tolerated and results in enhanced immunity to both “nonself” (viral peptide and KLH protein) and “self” (melanoma peptides) antigens [47]. It was observed that the level of immune responses in the blood correlated with early outcome at the tumor sites. Indeed, antigen-pulsed CD34<sup>+</sup> HPC-derived DCs induced primary and recall immune responses detectable directly in the blood. An immune response to control antigens (KLH and Flu-MP) was observed in 16 of 18 patients. An enhanced immune response to one or more MelAggs was seen in these

same 16 patients, including 10 patients who responded to  $> 2$  MelAg. The MelAg-specific T cells elicited after DC vaccine are functional and detectable in effector T-cell assays without the need for prior ex vivo expansion. They are also capable of proliferation and effector function after short-term (1 week) coculture with antigen-bearing DCs, without the need for exogenous cytokines or multiple restimulations with antigen. The two patients failing to respond to both control and tumor antigens experienced rapid tumor progression. Of 17 patients with evaluable disease, six of seven patients with immunity to two or less MelAg had progressive disease at 10 weeks after study entry, in contrast to tumor progression in only 1 of 10 patients with immunity to more than two MelAg. Regression of more than one tumor metastases was observed in seven of these patients. The overall immunity to MelAgs following DC vaccination was associated with clinical outcome ( $P = 0.015$ ). This initial study suggests that the measurement of immune responses in the blood helps evaluate vaccine efficacy.

The analysis of blood immune responses demonstrated that antigen-pulsed CD34-DCs could lead to rapid induction of CD4 $^{+}$  and CD8 $^{+}$  T-cell immunity. Indeed, a single DC vaccination was sufficient for the induction of KLH-specific responses in six patients and Flu-MP-specific responses in eight patients. A single DC vaccine was sufficient to induce tumor specific effectors to  $\geq 1$  MelAg in five patients. None of these five patients showed early disease progression. Only one of six patients with rapid KLH response experienced early disease progression. Rapid and slow Flu-MP responders did not differ with regard to disease progression. Thus, a patient's ability to rapidly respond to CD4 epitopes and MelAgs could be an early indicator of clinical outcome after DC-based vaccination. In other studies in which the induction of immunity was demonstrated [48,49], such correlation was less strict. This might be due, in part, to the fact that more advanced stage IV patients with a larger number of metastases were included. Such a situation clearly enhances the chances of tumor escape, for example, by loss of MHC class I molecules and/or tumor antigens, which occurs in about half of melanoma metastases. The number of metastases will have to be considered in comparing clinical outcome.

## VII. ACTIVE IMMUNIZATION WITH MONOCYTE-DERIVED DENDRITIC CELLS

Monocyte-derived DCs were the first DCs to be used for the treatment of melanoma patients, and several pilot studies have been published (see Table 1). Most used defined antigens in the form of peptides, but in some studies, tumor lysates or autologous DC tumor hybrids were also employed. The first trial published in 1998 by Nestle et al. [50] aroused great interest given an overall response rate of 30% in stage IV patients (i.e., distant metastases) including complete responses. The DCs were delivered directly into the inguinal nodes under ultrasonographical guidance, to circumvent the need for the active migration of the DCs from the skin into the nodes, but this rationale remains to be substantiated. The first study also used fetal calf serum (FCS) during DC gener-

ation, and this might have contributed to the observed effects by providing unspecific helper epitopes and by promoting the maturation of DCs. Jonuleit et al. [51] directly compared within each of eight patients the immunogenicity of immature DCs (generated according to Nestle et al. in FCS containing media using GM-CSF and IL-4) versus mature DCs [generated in the absence of FCS and matured by a cocktail consisting of TNF $\alpha$ , IL-1 $\beta$ , IL-6, and PGE $_2$  (these mimic the composition of monocyte-conditioned medium)] upon intranodal administration into opposite inguinal lymph nodes. FCS-free mature DCs induced stronger T-cell responses, both to the two recall antigens used (tetanus toxoid and PPD/tuberculin) and to tumor peptides. Interestingly, however, both immature as well as mature DCs showed an expansion of peptide-specific T cells by tetramer staining, yet only mature DCs induced IFN $\gamma$ -producing and lytic CD8 $^{+}$  T cells. These findings indicate the interesting possibility that the immature DCs might have induced regulatory T cells, rather than effector T cells, as observed in volunteers [44,46].

Thurner et al. used monocyte-derived DCs matured by monocyte-conditioned medium and cultured in the absence of FCS. The cells were pulsed with MAGE-3 peptide and tetanus toxoid, and injected into HLA-A1 $^{+}$  melanoma patients who suffered from advanced stage IV disease [48]. In contrast to the study by Nestle et al., the patients in this study had all been treated by chemotherapy or chemoimmunotherapy and were nevertheless progressive. For three biweekly vaccinations, 3 million DCs were administered intradermally and 3 million were administered subcutaneously followed, after 2 weeks, by 6 million and, finally, 12 million intravenously. Immune monitoring involved a simplified form of a limiting dilution assay. Significant expansions of MAGE-3A1-specific CD8 $^{+}$  CTL responses were observed in 8 of 11 patients. This was an encouraging finding given the advanced disease status and the fact that CTL responses (by the methodology used) had not been observed previously in less advanced melanoma patients vaccinated with MAGE-3 A1 peptide itself [52]. Regression of individual metastases was observed in 6 of 11 patients. A complete response did not occur upon short-term follow up, but upon prolonged vaccinations (including also other tumor peptides), disease proved stable in several patients and resolved completely in one.

In a follow-up study, Schuler-Thurner et al. [53] immunized terminal HLA-A2.1 $^{+}$  stage IV melanoma patients. They found that three to five biweekly vaccinations of mature, monocyte-derived DC (three vaccinations of 6 million subcutaneously followed by two intravenous doses of 6 and 12 million, respectively) pulsed with MAGE-3A2.1 tumor and influenza matrix A2.1-positive control peptides as well as the recall antigen tetanus toxoid (in three of eight patients) generated in all eight patients antigen-specific, IFN $\gamma$ -producing effector CD8 $^{+}$  T cells that were detectable in blood directly ex vivo [53]. The lack of significant clinical responses (only one disease stabilization was observed) despite the induction of antitumor immunity may be due to the properties of the MAGE-3A2 epitope, which is now known to be presented suboptimally by most melanomas.

Recently, Schuler-Thurner et al. reported that mature, monocyte-derived DCs loaded with multiple (five HLA-1-

restricted, eight HLA-A2.1-restricted, and three HLA-A3-restricted) MHC class I peptides (each peptide pulsed onto a separate batch of 4 million DCs to avoid competition at the level of a given MHC molecule) and MHC class II peptides (again loaded in a noncompeting fashion) rapidly induced MAGE-3.DR13 and MAGE-3.DP4-restricted, IFN- $\gamma$ -producing Th1-type, tumor-specific T cells. The T cells were detectable directly ex vivo [49]. The basic characteristics of several other studies employing monocyte-derived DCs are listed in Table 1 and compared to those employing CD34 $^{+}$  HPC-derived ones [47,54–59].

It is of note that many trials employing monocyte-derived DCs have not used maturing DCs. Mature DCs, when reinjected following ex vivo loading with tumor peptides, express demonstrable migration to lymph nodes, induction of tumor-specific cytotoxic and helper T cells, and movement of tumor antigen-specific T cells into regressing metastases. Recently, newer approaches to charge DC with antigens have been developed, such as the capacity of DCs to express antigens introduced through RNA electroporation [60]. This now allows one to administer to DCs both defined antigens, including universal ones such as telomerase or survivin as well as the total antigenic repertoire of a given tumor (as total tumor or polymerase chain reaction-amplified RNA). The use of dying tumor cells, notably antibody-coated ones, is an alternative [26]. Other preclinical research works have shown that the delivery of defined antigens as antigen–antibody complexes to DC enhances cross-presentation and allows for the potent induction of both CD4 $^{+}$  and CD8 $^{+}$  T-cell responses [61–63]. Therefore it is rational and timely to optimize the use of DCs as vectors for the delivery of antigens to vaccinate against cancer, although Phase III studies with current methods are underway.

In summary, vaccination with monocyte-derived DCs loaded with tumor antigens in the form of peptides has been shown to induce: (a) tumor-specific killer and helper T cells (“proof of concept”), and (b) occasional regression of metastases even in far-advanced cancer patients, including rare complete responses with (c) absence of significant toxicity. The final safety profile is, however, clearly not yet defined as the number of patients is still small, and it is not yet established what happens if, upon optimization of the strategy, stronger immune responses result and prolonged vaccinations are performed. At this point, the various trials are difficult to compare as the maturational status of DC, and many other variables such as DC dose, interval, and route are also very much different.

## VIII. DISCUSSION

The field of active immunization with autologous DCs charged with tumor antigens is underway. A small sample of published studies has been discussed here to illustrate that it is feasible to energize a patient’s endogenous immune response to tumor antigens. There are many additional questions to be studied: the optimization of Th1 and CTL responses to tumors, the induction of immunity to large numbers of tumor antigens, and the capacity of DCs and T cells to infiltrate and function within tumors. From a re-

search perspective, DC therapy additionally provides an opportunity to assess the incidence of tumor-specific tolerance. Fortunately, answers to these questions are going to be facilitated by the improved capacity to monitor the human immune response in tandem with the measurement of clinical endpoints including survival.

This discussion emphasizes active immunotherapy based on DC priming of tumor-specific T cells. Dendritic cells also provide an opportunity to control the function of other types of lymphocytes—NK, NKT, and B cells—and not just T cells. Many of the current studies emphasize patients with advanced cancer, but vaccination in the setting of minimal residual disease could show enhanced value. Long-term vaccination studies also remain to be described.

## Vaccines Against Alzheimer's Disease

Roy M. Robins-Browne, Richard A. Strugnell, and Colin L. Masters

*University of Melbourne, Parkville, Victoria, Australia*

### I. INTRODUCTION

Alzheimer's disease (AD) is a progressive neurological disorder that imposes an enormous burden on society [1]. Unlike some other progressive neurological diseases, such as subacute sclerosing panencephalitis, progressive multifocal leukoencephalopathy, and Creutzfeldt–Jakob disease, there is no evidence to suggest that AD is the result of an infection. Hence it is all the more remarkable that AD may be the first of the chronic degenerative neurological diseases to be amenable to specific intervention through therapeutic and preventative immunization.

In common with other degenerative diseases of the nervous systems, AD is characterized by gradually evolving progressive neuronal degeneration, which leads to global impairment of memory and other cognitive functions in a way that interferes with normal social or occupational performance (dementia) [2]. As the disease progresses, behavioral changes occur including passivity and withdrawal, accompanied by impairment of attention, judgment, recognition, insight, and language. Later, agitation, suspiciousness, wandering, and hallucinations may occur. In the final stages, patients may enter a vegetative state and be mute and uncomprehending.

The condition was formally described in 1907 by Alois Alzheimer who reported the clinical and pathological findings of a disease in a 51-year-old woman with progressive dementia [3]. Although senile dementia (dementia occurring in older people) was well known at that time, this patient was unusual because of her young age and because an autopsy revealed large numbers of "amyloid plaques" and "neurofibrillary tangles" in her brain. This unique combination of clinical and pathological features came to be known as AD, a term which was originally limited to "presenile" dementia, i.e., dementia occurring below the age of 65, but now is applied to all patients with these clinicopathological features regardless of age.

Although AD may affect people in younger age groups, most patients are aged over 65 with the prevalence increasing with advancing age, such that up to 10% of the population

over 65 and 50% over 80 may be affected [2]. The duration of the disease from the time of diagnosis to death may exceed 20 years, although the average length is from 8 to 10 years. In 1993, Rice et al. [4] estimated the cost of AD in the United States to be \$63.3 billion, made up from direct financial outlays, such as nursing care, and indirect costs, including loss of productivity of the patients themselves and the family members who care for them. As people born in the population boom which followed World War II reach their 60s and 70s, these costs are poised to escalate considerably unless something is done to reduce the incidence of AD.

### II. PATHOLOGY

The hallmark pathological lesions of AD are the extracellular neuritic or amyloid plaques and the intracellular neurofibrillary tangles originally described by Alzheimer. The characteristic plaques are distributed throughout the cerebral cortex at a high density and are made up mainly of degenerated neuronal processes (neurites) and deposits of beta-amyloid ( $A\beta$ ) protein, which also occurs within the walls of cerebral blood vessels. Neurofibrillary tangles are intraneuronal structures that appear as paired helical filaments when viewed by electron microscopy. They are particularly evident in medial temporal lobe structures, including the hippocampus, a region of the brain that is important for memory [2]. Neurons which contain these tangles have a tendency to lose their synaptic connections and eventually die leaving "ghost tangles." Although the accumulation of amyloid plaques and neurofibrillary tangles may occur in the brain of nondemented persons, both types of lesion occur at a far higher density in the brain of patients with AD [2].

### III. PATHOGENESIS

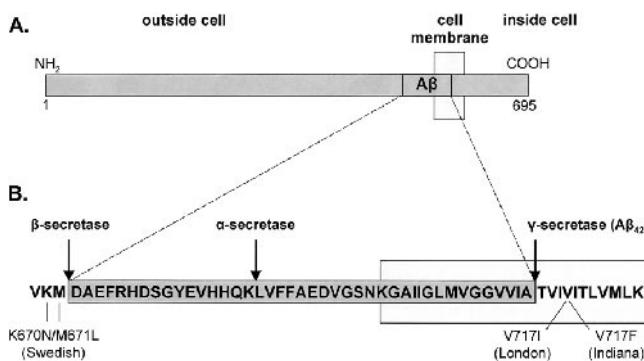

An overwhelming body of evidence points to the fact that the  $A\beta$  protein plays a central role in the pathogenesis of AD.  $A\beta$  is derived from amyloid precursor protein (APP), a

type I transmembrane protein encoded by the *APP* gene on chromosome 21 [5]. Amyloid precursor protein is expressed in a variety of tissues, including neurons and glia, and contains a large extracellular domain, a single transmembrane domain, and a small cytoplasmic tail (Figure 1). There are three main isoforms of APP derived by alternative splicing of the single *APP* gene. The two larger forms known as APP<sub>751</sub> and APP<sub>770</sub> contain a 56-amino acid domain with homology to serine protease inhibitors [6]. APP<sub>695</sub> is the shortest form because it lacks this domain and is the most common form in neurons. The function of APP<sub>695</sub> is not known, but in neurons it occurs mainly in synapses and seems likely to influence neuronal communication. Overexpression of APP suggests that it may have an antiadhesion function. Mice lacking APP show only minor defects in neural function, perhaps due to compensation by an APP-like protein. Amyloid precursor protein is subject to extensive posttranslational modification in the endoplasmic reticulum, the Golgi apparatus, and the trans-Golgi network before being exported to the cell surface [5]. It is then further modified by proteolytic cleavage by a series of enzymes collectively termed secretases. Most APP is processed by cleavage with  $\alpha$ -secretase releasing a soluble ectodomain APP <sub>$\alpha$</sub>  into the extracellular space with retention of an intracellular C-terminal fragment (CTF <sub>$\alpha$</sub> ). Processing via this pathway prevents the formation of full-length A $\beta$  (Figure 1). By contrast,  $\beta$ -secretase (also known as  $\beta$ -APP cleaving enzyme or BACE-1) cleaves APP at a site immediately N-terminal to the A $\beta$  sequence, approximately 16 amino acids closer to the extracellular N-terminus of APP [7] (Figure 1). In the nervous system,  $\beta$ -secretase activity is more prominent than in other tissues, thus favoring the production of A $\beta$ . Another key enzyme in the production of A $\beta$  is  $\gamma$ -secretase which cleaves APP within the transmembrane region at the C-terminus of A $\beta$  in a manner that releases soluble A $\beta$  from the cell [8]. The exact cleavage site of  $\gamma$ -secretase may vary slightly giving

rise to peptides 40 to 43 amino acids in length. The most common species is A $\beta$ <sub>40</sub> which is typically found in non-neuronal cells and tends to be more soluble than A $\beta$ <sub>42</sub> and A $\beta$ <sub>43</sub> [8]. However, neuronal cells have a greater propensity to produce A $\beta$ <sub>42</sub> which is a major protein species at the center of senile plaques. Even in the brain, however, 90% of A $\beta$  is A $\beta$ <sub>40</sub>, with the remainder being the less soluble and more fibrillogenic A $\beta$ <sub>42/43</sub> [5]. If the rate of production of A $\beta$ <sub>42</sub> exceeds its rate of clearance, it may accumulate in the brain to cause neuronal toxicity.

The basis of the toxic action of A $\beta$  is unknown, but there is a suggestion that secreted oligomers of A $\beta$  can inhibit hippocampal long-term potentiation, thus interfering the development of memory [9]. In addition, the accumulation of A $\beta$  fibrils on the cell surface may encourage the formation of free radicals that damage cell membranes and lead to neuronal death [10].

The neurofibrillary tangles, which are the other hallmark histopathological lesion of AD, are made up mainly from the microtubule-associated protein *tau*, the normal function of which appears to be to stabilize microtubules. This function is regulated in the cell by the reversible phosphorylation and dephosphorylation of *tau*. The observation that *tau* in neurofibrillary tangles is excessively phosphorylated suggests that in affected neurons, the balance between the action of kinases and phosphatases is disturbed [1]. In neurons, microtubules are involved in the axonal transport of proteins. The accumulation of abnormally phosphorylated *tau* may lead to destabilization of the cytoskeleton, neuronal dysfunction, and eventually to neuronal death. One possible underlying cause of the abnormal phosphorylation of *tau* in AD may be the presence of A $\beta$  itself. Interestingly, mutations in the *tau* gene lead to accumulation of aggregated *tau* [11]. Patients with this type of disordered *tau* present with dementia which unlike AD is characterized by frontal lobe atrophy and prominent behavioral abnormalities.

**Figure 1** A. Diagrammatic representation of amyloid precursor protein (APP<sub>695</sub>). B. An enlarged view of amyloid  $\beta$ -protein (A $\beta$ ). The  $\alpha$ -,  $\beta$ -, and  $\gamma$ -secretase cleavage sites are indicated by arrows, and selected familial Alzheimer disease mutations are shown below. Transgenic mice with the Swedish, London, and Indiana mutations and variations thereof have been used in some immunization studies.

#### IV. GENETICS OF ALZHEIMER'S DISEASE

Apart from age, the most significant risk factor for the development of AD is genetic. Familial AD, which accounts for fewer than 10% of all cases, is inherited in an autosomal dominant fashion. Apart from the fact that it generally occurs at a younger age, often less than 60, familial AD is indistinguishable, clinically and pathologically, from the sporadic form of the disease. Importantly, unraveling the genetic basis of familial AD has provided key insights into the molecular pathogenesis of AD in general, including strong support for the idea that A $\beta$  plays a central role in its pathogenesis.

Early evidence for the role of chromosome 21 in the development of AD came from the observation that individuals with Down's syndrome (trisomy 21) show identical pathological changes in the brain to those found in AD and often develop this condition while still in their 30s [12]. Intensive study of chromosome 21 revealed that some individuals with familial AD carry a point mutation within the *APP* gene [5,13]. One of these mutations is the so-called

"Swedish" mutation, a two-point mutation at amino acids 670 and 671 from Lys-Met to Asp-Leu. This change is upstream of the  $\beta$ -cleavage site (Figure 1) and results in a fivefold to eightfold increase in the formation of both A $\beta$ <sub>40</sub> and A $\beta$ <sub>42</sub>. A second mutation at amino acid 717, the "London" mutation, Val→Ile, is adjacent to the  $\gamma$ -cleavage site and specifically increases the production of A $\beta$ <sub>42</sub>. Although cases with these mutations account for less than 3% of all patients with early onset familial AD, the discovery of these mutations was vital in showing the clear link between abnormal APP processing and AD. Presumably, the association of Down's syndrome with AD is due to the overproduction of APP and consequently A $\beta$  [12].

The largest proportion of patients with familial AD carries mutations in the presenilin gene (*PS1*) on chromosome 14 [5]. The product of this gene is a large transmembrane protein that is likely to be an integral component of  $\gamma$ -secretase [14]. *PS1* shares homology with a gene on chromosome 1 known as *PS2* [15]. One consequence of *PS1* mutations is enhanced production of A $\beta$ <sub>42</sub>, suggesting that these mutations influence the activity of  $\gamma$ -secretase. Thus, collectively, most early onset familial forms of AD are explained by excessive production of A $\beta$ <sub>42</sub> either as a result of missense mutations in APP at or near the cleavage site of  $\beta$ - or  $\gamma$ -secretase or by abnormal  $\gamma$ -secretase activity per se.

Despite the persuasive evidence incriminating A $\beta$  metabolism as the key abnormality in familial forms of AD, the molecular pathogenesis of sporadic, late onset of AD is poorly understood. The risk of late onset AD is linked with the inheritance of particular isoforms of apolipoprotein E (ApoE) [16]. Apolipoprotein E is a major serum protein involved in cholesterol metabolism transport and storage. The gene for ApoE is located on chromosome 19 and occurs as three common allelic variants termed ApoE2, ApoE3, and ApoE4, the products of which differ by only 1 amino acid. Individuals with the ApoE4 allele are significantly more likely to develop AD than those without it, with ApoE4 homozygous individuals at greatest risk [16]. Although there is no evidence to suggest that ApoE4 is directly responsible for the development of AD, it may modify the expression of the disease by involvement in A $\beta$  deposition or clearance.

## V. ANIMAL MODELS

Because much of the research which led to the serendipitous possibility of prophylactic and therapeutic immunization for AD has come from animal models of this disease, it is useful to consider some of these models. Before the identification of the genetic mutations associated with familial AD, animal models were mainly developed to reproduce the nonspecific neuropathology of AD, such as neuronal damage. The discovery of the genetic basis of familial AD, however, permitted the generation of transgenic mice which display various features of AD [5,13,17].

Early attempts to develop transgenic AD mice involved transfection with the normal human APP gene either in its entirety or as a C-terminal fragment. However, these animals failed to develop plaques presumably because they pro-

duced APP at approximately endogenous concentrations. Subsequent work showed that a key factor in plaque development is an elevated concentration of A $\beta$ <sub>42</sub>. This can be achieved through the use of promoters, such as platelet-derived growth factor (PDGF), prion protein, or Thy-1, to drive higher levels of protein expression [5]. High concentrations of A $\beta$  are also obtained when APP with the Indiana, London, or Swedish mutations are used for transfection instead of the wild-type gene.

The first successful mouse model of AD was reported in 1995 by Games et al. and termed PDAPP[18]. This model is based on a complex genetic construct consisting of the promoter for the  $\beta$ -chain of PDGF and a mini-gene containing cDNA of portions of APP introns 6–8 bearing a V717F mutation in APP. PDAPP mice contain approximately 40 copies of the transgene and produce human APP mRNA at levels significantly greater than endogenous App transcripts and levels of APP approximately 10 times greater than endogenous mouse APP. At 8 months of age, these animals develop deposits of A $\beta$  in the hippocampus, corpus callosum, and cerebral cortex. Although they suffer no significant loss of neurons, they do show impaired ability to perform novel "spatial" memory tasks in an age-dependent manner that correlates with the accumulation of A $\beta$  deposits [19].

In 1996, a second mouse model, termed Tg2576, was developed. These animals express the 695 amino acid form of human APP carrying the Swedish mutation (K670N/M671L) under the transcriptional control of the hamster prion gene promoter, PrP [20]. The levels of APP produced by these mice are approximately 5 to 6 times higher than endogenous App, and they develop A $\beta$  deposits at 9 to 11 months of age. Tg2576 mice also show disordered behavior and memory in tasks involving different types of mazes. Another cDNA transgenic model that has been used in vaccine studies is termed TgCRND8 [21]. These mice carry full-length APP695 cDNA with both the K670N/M671L and V717F mutations under the control of hamster PrP. In these animals, the APP transgene is expressed at levels 5 times greater than endogenous App, and A $\beta$  deposits occur as early as 3 months of age. The development of these and several other varieties of transgenic mice, which express abnormal APP, has established the relationship between APP, A $\beta$  production, and disorders of memory. Interestingly, however, although some of these transgenic mice show modest loss of neurons and nerve synapses, none of these animals develops full-blown neurofibrillary tangles or shows the pronounced neurodegeneration that is found in patients with AD [5]. These observations suggest that the production of A $\beta$  is not directly related to the development of tangles in mice, although it is possible that mice do not live long enough to develop this pathological change.

## VI. IMMUNIZATION

The first indication that AD may be amenable to prevention or even treatment by immunization came in 1999 from a report by Schenk et al. [22] of Elan Pharmaceuticals. In this study, PDAPP transgenic mice were immunized 11 times

with 100 µg of a synthetic peptide preparation of human A $\beta$ <sub>42</sub> together with Freund's adjuvant. Control mice received either serum amyloid peptide (SAP), phosphate-buffered saline (PBS), or were left untreated. Mice given A $\beta$ <sub>42</sub> developed and maintained high titers of serum antibody to this peptide. These antibodies cross-reacted with mouse A $\beta$  without causing obvious tissue damage. One group of mice in this study was immunized over a period of 11 months starting at 6 weeks of age, i.e., before the development of amyloid plaques. These mice were killed at age 13 months, and their brains were compared to those of the three control groups. The results showed that mice immunized with A $\beta$ <sub>42</sub> had significantly less ( $P \leq 0.001$ ) A $\beta$  burden (0%, as measured by quantitative image analysis) compared with the groups which received PBS (2.2%), SAP (5.7%), or no treatment (2.7%). In addition, the presence of dystrophic neurites was reduced from 0.3% in controls to 0% in immunized animals, and immunoreactivity for glial fibrillary acidic protein, which is a marker of A $\beta$  plaque-associated gliosis, was reduced from 6% in control mice to 1.6% in those given A $\beta$ <sub>42</sub>. This study indicates that immunization with A $\beta$ <sub>42</sub> can prevent the development of AD-like neuropathological lesions in PDAPP mice. However, it was unclear if immunization could influence the course of the disease if plaques were present when immunization was started. To address this important issue, Schenk et al. [22] immunized some PDAPP mice that were 11 months old, an age when numerous A $\beta$  plaques are already present. Half the mice were killed after 4 months of treatment, and the rest were killed 3 months later. The results were that immunized mice showed a 96% reduction in plaques after 4 months treatment, and greater than 99% reduction after 7 months, compared with controls ( $P < 0.001$ ). Moreover, the A $\beta$  burden in the 7-month treatment group was 0.01% compared with 4.9% in control animals given PBS. Similar findings have been reported by other workers using DgCRND8 and Tg2576 mice [21,23].

Despite these encouraging results, it was not known if the reduction in pathological changes due to the immunization would result in improvements in cognitive function. This question was addressed by Morgan et al. [23] who used a combination of a swim maze and radial arm maze to evaluate cognitive defects in Tg2576 and PS1N146L double transgenic mice. These mice show high levels of A $\beta$  production and plaque development by 12 weeks of age that increases nearly 200-fold by 1 year. The memory task used by Morgan et al. [23] requires mice to learn the spatial location of a submerged escape platform on the basis of visual clues and to navigate the platform from different starting points. Transgenic and control mice were immunized with either A $\beta$ <sub>42</sub> or a placebo protein, the keyhole limpet hemocyanin (KLH). Normal mice showed no change in cognitive function after immunization with either protein, demonstrating that immunization with A $\beta$ <sub>42</sub> has no overt deleterious effect on these animals. As expected, transgenic mice immunized with KLH at 11.5 months of age showed virtually no learning ability 4 months later, but the A $\beta$ -immunized transgenic mice showed cognitive performance similar to that of nontransgenic animals. A $\beta$ -immunized mice also demonstrated a partial reduction in amyloid burden at the

end of the study. Similar findings were obtained by Janus et al. [21] in TgCRND8 mice (APP<sub>695</sub>K670N/M671L and V717F), which normally develop increased soluble A $\beta$ , amyloid plaques, and deficits in spatial learning at 3 months of age. In this study, age- and sex-matched transgenic mice and nontransgenic littermates were immunized at 6, 8, 12, 16, and 20 weeks of age with either A $\beta$ <sub>42</sub> or a control protein, islet-associated polypeptide, as  $\beta$ -pleated sheets. Through the use of the more conventional water maze than that used by Morgan et al. [23], these investigators showed that repeated vaccination of TgCRND8 mice with A $\beta$ <sub>42</sub> reduced cognitive dysfunction concurrently with reduced cerebral fibrillar A $\beta$  compared with control mice, although total levels of A $\beta$  in the brain were not affected. Based on these somewhat unexpected results, Janus et al. concluded that either an approximately 50% reduction in dense-core A $\beta$  plaques is sufficient to improve cognition or that immunization may modulate the activity or abundance of a small subpopulation of especially toxic A $\beta$  species [21].

Analysis of the immune response of *PS1* transgenic mice to immunization with A $\beta$ <sub>42</sub> in complete Freund's adjuvant revealed that specific antibodies are detectable only after the third boost [24], with highest antibody responses directed against the N-terminus of A $\beta$ . After the sixth dose, antibody titers tend to plateau and thereafter are maintained above the half-maximal titer for at least 5 months without further boosting. Assays of specific immunoglobulin isotypes in mice immunized with A $\beta$  have demonstrated a preponderance of specific IgG<sub>1</sub> and IgG<sub>2B</sub>, indicating a Th2-type immune response [24].

The key role of specific antibodies in mediating the amyloid depleting effects of A $\beta$  immunization has been shown in a series of studies involving passive immunization with anti-A $\beta$  antibodies. Bard et al. [25] treated 8- to 12-month-old PDAPP mice for 5 months with weekly injections of murine monoclonal or polyclonal antibodies directed against A $\beta$  and reduced plaque burden by more than 80% with a corresponding reduction in cortical levels of A $\beta$ <sub>42</sub>. The key role of antibodies was confirmed by the finding that T cells from passively immunized mice showed no proliferative response when stimulated with A $\beta$ , indicating that plaque clearance does not require T-cell immunity. An important finding in this study was that, contrary to expectations, antibodies that had been administered peripherally entered the central nervous system and bound to amyloid plaques [25]. An ex vivo assay with sections of brain tissue from PDAPP mice or patients with AD showed that antibodies to A $\beta$  could trigger microglial cells to clear plaque through Fc receptor-mediated phagocytosis with subsequent peptide disaggregation. A separate study showed that the direct application of anti-A $\beta$  antibodies to the surface of the brain of living PDAPP mice can reduce A $\beta$  deposits in the immediate vicinity of the application [26]. The unexpected finding that peripherally administered antibodies can traverse the blood-brain barrier may be explained by the fact that A $\beta$  itself is transported across this barrier by a receptor-mediated pathway, and that antibodies bound to A $\beta$  may be able to utilize the same pathway [27]. For passive immunization to succeed in humans, therefore, there needs to be a critical concentration of circulating A $\beta$ , which gen-

erally is far lower than in transgenic mice [28]. Another potential problem with passive immunization of humans against AD is that A $\beta$  peptides within the plaques of transgenic mice are physically and chemically distinct from those found in AD, with the latter often displaying a degraded N-terminus, extensive posttranslational modifications, and a reduced tendency towards disaggregation [29]. On the other hand, some studies suggest that the major targets of anti-A $\beta$  antibodies are not plaques per se, but soluble toxic oligomers of A $\beta$  [9,30]. This observation provides an explanation for the finding that the cognitive function of TgCRND8 mice immunized with A $\beta$  showed significant improvements without a major reduction in plaque burden [21].

An alternative view of how peripherally administered antibodies may be beneficial in mouse models of AD has been provided by DeMattos et al. [31] who administered an anti-A $\beta$  monoclonal antibody intravenously to PDAPP mice and showed that this leads to a 1000-fold increase in plasma levels of A $\beta$ . Because levels of A $\beta$  in plasma of untreated animals are low, DeMattos et al. proposed that antibodies in the plasma act as a "peripheral sink" which promotes the efflux of A $\beta$  from the brain to the plasma. These authors went on to show that long-term administration of antibody significantly reduced A $\beta$  burden in the brain without the antibody crossing the blood-brain barrier or binding to intracerebral A $\beta$ . The reasons for the differences between the findings of Bard et al. [25] and DeMattos et al. [31] regarding the transport of anti-A $\beta$  antibodies across the blood-brain barrier are not clear, but there is no doubt that peripherally administered antibodies can deplete A $\beta$  in the brain of transgenic mice. Whether such treatment will be effective in humans with AD is unknown. If the principal target of anti-A $\beta$  is soluble A $\beta$ , active or passive immunization of patients with established AD may be less effective than vaccinating individuals with early disease. Accordingly, effective implementation of a vaccine for AD would necessitate large-scale screening of the general population to identify at-risk individuals who could benefit from immunization.

Because there are no established animal models of AD other than transgenic mice, further studies of A $\beta$  vaccine efficacy would need to be undertaken in humans. In preparation for this, several investigators have examined modes of vaccine delivery that do not require Freund's adjuvant, which is not licensed for use in humans. Some of the alternative approaches to vaccine delivery, which have been successfully trialed in animal models, include mucosal (intranasal) immunization with A $\beta$ <sub>40</sub> [32] and parenteral administration of A $\beta$ <sub>42</sub> in biodegradable poly(lactide-co-glycolide) microspheres [33].

In an attempt to reduce the potential toxicity of A $\beta$ <sub>42</sub>, which can cross the blood-brain barrier to form toxic fibrils and possibly seed new fibril formation, Sigurdsson et al. [34] used nontoxic-nonamyloidogenic A $\beta$  homologous peptide (K6A $\beta$ <sub>1-30</sub>-NH<sub>2</sub>) to immunize Tg2576 mice. This peptide retains the two major immunogenic sites of intact A $\beta$ , which are contained within residues 1-11 and 22-28 of A $\beta$ <sub>42</sub>. This study showed that administration of this compound for 7 months reduced cortical and hippocampal brain amyloid

burden by between 80% and 90% and reduced brain levels of soluble A $\beta$ <sub>42</sub> by 57% [34]. An even more reductionist approach to immunization was taken by Frenkel et al. [35] who immunized guinea pigs with a genetically engineered filamentous phage displaying the epitope, EFRH, which correspond to amino acids 3-6 within A $\beta$  (Figure 1). As this region of A $\beta$  controls the formation and the disaggregation of A $\beta$  fibrils, binding of antibodies to this epitope prevents self-aggregation of A $\beta$  as well as enabling the resolubilization of preformed aggregates [36]. Apart from lower toxicity, the phage delivery system also has the advantage of being highly immunogenic, thus obviating the need for separate adjuvants. The use of a phage delivery system may also overcome the immune hyporesponsiveness to A $\beta$  found in certain strains of transgenic mice, which could of itself contribute to the pathogenesis of AD while simultaneously reducing the potential efficacy of future immunization strategies based on A $\beta$  [37].

## VII. IMMUNIZATION OF HUMANS

The encouraging results obtained with A $\beta$  immunization of transgenic mice were followed by safety data in monkeys and led to fast tracking of human trials of A $\beta$  immunization [38]. A Phase I/II trial to examine the safety of a synthetic A $\beta$ <sub>42</sub> vaccine, known as AN-1792, administered as a single dose to patients with moderate AD was commenced in December 1999 and showed the vaccine to be well tolerated. In early 2002, however, reports emerged of a severe reaction resembling experimental allergic encephalitis in 15 of 400 recipients of AN-1792 [39]. As a result, all clinical trials with this material have been suspended [40]. Whether other modalities of A $\beta$  immunization would produce similar reactions is not known, but clearly, this early setback will necessitate improved understanding of vaccine action and toxicity. Possible explanations for the toxicity of AN-1792 include harm directly attributable to the peripheral administration of A $\beta$ <sub>42</sub> per se or the development of immunity to APP and A $\beta$  peptides which are normal constituents of brain tissue. In this regard, the success of A $\beta$  immunization in transgenic mice may rely on the fact that immunity is directed against a protein of human origin and that endogenous mouse proteins are less well recognized or affected by antihuman A $\beta$  antibodies. For this reason, it would be important to know the effects of hyperimmunizing mice with murine A $\beta$ .

The setback experienced in early human trials of AD vaccines does not necessarily spell the end of immunization against this disease. One major consequence of the experience with AN-1792, however, will be an increased need to address the safety of future vaccine candidates. Strategies to avoid vaccine-induced encephalitis could include the construction of vaccines lacking the T-cell epitopes which trigger adverse reactions or vaccines that target novel epitopes on abnormal forms of A $\beta$ . The design of such second-generation vaccines would be facilitated by an improved understanding of the pathogenesis of AD, including the physiological roles of APP and A $\beta$  and the consequences of artificially induced anti-A $\beta$  immunity. The increasing prevalence of AD, its potentially enormous costs, and the

promise of its prevention or arrest through immunological interventions ensure that the search for an effective AD vaccine will continue.

## Vaccines Against Atherosclerosis

Carl R. Alving

Walter Reed Army Institute of Research, Silver Spring, Maryland, U.S.A.

### I. SUMMARY

The possibility of creating vaccines against atherosclerosis has evolved from epidemiological analyses based on statistical correlations that suggest that certain metabolic states, or even infections, might play a role in the initiation of the atherosclerotic process. Although many theories exist, it is well known that alterations in lipoprotein metabolism, including elevations in low-density lipoprotein (LDL) cholesterol or decreased levels of high-density lipoprotein (HDL) cholesterol, are associated with increased risk of atherosclerosis. Low-density lipoprotein cholesterol may be deposited in vessel walls, leading to buildup of plaque, and HDL serves as a scavenger for removal of circulating cholesterol. The atherosclerotic plaque lesions are associated with chronic inflammatory reactions affecting the endothelial layer of vessel walls.

In recent years, atherosclerotic lesions or adverse events due to atherosclerosis have also been associated with a variety of infectious agents, particularly bacteria (*Chlamydia pneumoniae* and *Helicobacter pylori*), viruses (cytomegalovirus, herpes simplex viruses, and hepatitis A virus), and even periodontal infections, or combinations of the above. Although a vaccine against a single organism (such as *C. pneumoniae*) might have utility, such a vaccine might not serve as a generic antiatherosclerosis vaccine. This is because the adverse effect caused by the total pathogen burden of multiple infections appears to be a much greater risk factor than that associated with any single organism. Among the mechanisms associated with infections, the process of inflammation, as detected by elevation of serum C-reactive protein (CRP), may be an important factor that correlates with atherosclerosis.

Other atherosclerosis vaccine strategies that have been proposed, besides those directed at infectious organisms, include metabolic vaccines that directly target cholesterol or influence lipoprotein distribution patterns. Cholesterol is a strong antigen when combined with the proper adjuvant, and antibodies to cholesterol react with LDL but not HDL.

Immunization with cholesterol results in a lowering of serum LDL levels and partial protection against cholesterol-induced atherosclerosis in rabbits. An alternative metabolic vaccine consists of therapeutic immunization against endogenous cholesteryl ester transfer protein (CETP), a key intermediary in the distribution of cholesterol between HDL and LDL. Antibody-mediated inhibition of CETP causes substantial elevation of HDL relative to LDL in rabbits. If this result is also observed in the Phase 2 studies that are currently ongoing in humans, it may be an important observation because elevations of HDL are not easily achieved by current drug therapy strategies. Metabolic vaccines may serve as an alternative to, or may be complementary to, current dietary or therapeutic methods for control of LDL cholesterol levels.

### II. INTRODUCTION

Although deaths due to atherosclerosis in the United States declined approximately 20% between 1978 and 1998, cardiovascular disease still contributes 80% as much total mortality as all other diseases combined, and 71% of the total cardiovascular disease is due to atherosclerosis-related diseases [1,2]. This is all the more remarkable because mortality due to atherosclerotic coronary heart disease, one of the biggest killers, decreased by about 60% between 1963 and 1998 [2]. More than 400,000 coronary artery bypass graft (CABG) surgeries are performed each year [3]. If each CABG were to cost an average between \$50,000 and \$75,000, this alone would amount to an annual economic outlay of \$20–\$30 billion. The annual bill for pharmaceuticals or nutriceuticals for lowering cholesterol levels also amounts to tens of billions of dollars. These staggering statistics make a strong case that development of a vaccine strategy for controlling atherosclerosis would have immense public health benefits for reducing pain and suffering, and such a strategy would also have extremely important economic benefits.

The purpose of this chapter is to introduce two general types of vaccine strategies that have been proposed for prophylaxis or treatment of atherosclerosis. First, a brief overview of recent data is presented that suggests that certain infectious diseases that might be controlled with vaccines may be associated with atherosclerosis. Second, it is well known that high levels of LDL and low levels of HDL are classic and important risk factors for atherosclerosis. Unique vaccines, which I refer to as metabolic vaccines, are described that may serve to improve the profile of circulating lipoproteins and thereby decrease the risk of atherosclerosis.

#### A. What Is Atherosclerosis?

Amazing as it may seem, the answer to the above question has not yet been completely worked out. There are multiple conflicting theories. The most popular viewpoint among those who specialize in this field is that atherosclerosis is an ongoing process. The atherosclerotic process may be viewed as either a local inflammatory reaction involving endothelial linings and smooth muscles of arterial vessels, or a local immune reaction leading to destructive inflammatory effects [4,5]. The popular term for atherosclerosis, hardening of the arteries, is a reflection of the gradual buildup of inflammatory atherosclerotic plaque below the endothelial surface that becomes hardened due to accumulation of inflammatory cells and deposition of fibrous material containing cholesterol, lipoproteins, calcium, and other molecules, a process known as atherogenesis. In the advanced stages of this process the enlarging plaque may either directly interfere with the flow of blood, or may rupture, often with the resultant formation of a thrombus in the vasculature that prevents the delivery of oxygen to tissues and causes the diseases known as myocardial or cerebral infarction, gangrene of extremities, or other diseases or syndromes that are commonly associated with oxygen deprivation.

The histological evidence for a pathological local inflammatory reaction in arterial walls seems clear enough, but what causes the process to begin, and why does it continue? Definitive answers to these important questions would yield significant benefits for continued scientific development of rational preventive or therapeutic measures that could help to control atherosclerosis and its sequelae. Many etiological theories have been floated, among which are the so-called "insult" hypothesis; the metabolic dysfunction hypothesis; the processes of pathological innate or adaptive immune reactions; and various theories about the colonization of arterial walls by infectious agents.

According to the insult hypothesis, "The lesions result from an excessive inflammatory-fibroproliferative response to various forms of insult to the endothelium and smooth muscle of the artery wall" [4]. One view of the metabolic dysfunction hypothesis is that "Atherosclerosis is an inflammatory disease induced by a lipid metabolic disturbance at sites of hemodynamic strain in the vasculature." [5]. According to the innate or adaptive immunity hypothesis, "The inflammatory response is controlled by the immune system, components of which are abundant in the atherosclerotic plaque" [5].

Atherosclerosis is obviously a multifactorial process that probably does not have a single cause. Epidemiological studies have identified numerous risk factors that have led to a variety of recommendations by the National Cholesterol Education Program for prevention of coronary heart diseases (CHDs) [6]. Primary among these risk factors are high LDL cholesterol, low HDL cholesterol, cigarette smoking, hypertension, family history of premature CHD, and increased age [6]. Numerous other risk factors have also been cited, including abdominal obesity, and secondary dyslipidemia due to diabetes, hypothyroidism, obstructive liver diseases, chronic renal failure, and certain drugs, such as progestins, anabolic steroids, and corticosteroids, that increase LDL cholesterol and decrease HDL cholesterol [6]. If the cardiovascular system were viewed as a kind of river, the identification of risk factors for atherosclerosis at any given point would provide epidemiological evidence of upstream factors unrelated to atherosclerosis that may or may not encourage the downstream development of localized atherosclerotic lesions in vessel walls in a given individual. Just as the deposition of silt occurs at the outlet of a river, or accumulation of pollution occurs at a downstream location, atherosclerosis in an artery is an adverse local effect that may be caused or initiated by upstream forces that may be quite distant or unrelated to the local environment of the damaged area. Research on risk factors for atherosclerosis has led to the pinpointing of effective public health measures and therapeutic strategies for lowering the incidence of cardiovascular diseases.

### III. INFECTIOUS DISEASE HYPOTHESIS

#### A. *Chlamydia pneumoniae* as an Etiological Agent for Atherosclerosis

The infectious disease hypothesis of initiation of atherosclerosis is an idea proposed many decades ago (reviewed in Ref. 7). The hypothesis was given renewed impetus by the rediscovery, in Finland, of an epidemiological association of a serological reaction to lipopolysaccharide from *Chlamydia* species, a gram-negative bacterial venereal infection associated with lymphogranuloma venereum, with acute myocardial infarction [8–10]. *C. pneumoniae* probably existed for many decades, or longer, but the organism was first isolated in 1965 [11]. It causes mild episodes of chronic pneumonia [12], and has been estimated to be the cause of perhaps 10% of community-acquired pneumonia, and 5% of bronchitis and sinusitis [11]. Infection with *C. pneumoniae* is thought to occur in virtually all individuals in their lifetimes, and it can have a detectable antibody prevalence of 80% in certain populations [11]. *C. pneumoniae* has been directly suggested as a factor in the initiation or exacerbation of atherosclerosis-associated diseases and in precipitation of acute thrombotic events [13–18].

The case for *C. pneumoniae* as an etiological agent has been further strengthened by direct observation of the organism in lesions, both by electron microscopy and by a variety of other microscopic and analytic techniques, and by culture of the organism from atherosclerotic lesions [19,20].

Interestingly, it has also been reported that peptides isolated from outer membrane proteins of several *Chlamydia* species exhibit sequence homology to murine heart muscle-specific alpha myosin heavy chain [21]. When *Chlamydia* DNA was used as an adjuvant, the peptides also induced autoantibodies and inflammatory heart disease in mice [21].

It has been estimated that "since 1988 more than 30 worldwide, epidemiological studies indicated correlations between *C. pneumoniae*-associated serological markers ... and atherosclerotic vascular disease" [22]. However, the conclusion that *C. pneumoniae* is a risk factor has caused considerable controversy, and other serological studies have failed to identify *C. pneumoniae* as a risk factor for atherosclerosis [23,24]. Therefore, despite the large amount of interesting data that suggests that *C. pneumoniae* may be a risk factor, the precise role, if any, of the organism in initiation of atherosclerosis is an important question that is still unresolved. Nonetheless, the hypothesis, and the considerable evidence, that *C. pneumoniae* might play a role, has started a growing interest in the possible effects of infectious agents in atherosclerosis.

### B. Role of Other Infectious Agents

Numerous other infections have also been implicated in the pathogenesis of atherosclerosis including, most prominently *H. pylori*, cytomegalovirus, herpes simplex virus, Epstein-Barr virus, measles virus, hepatitis A virus, and even markers of chronic dental infection, such as severe periodontal disease and missing teeth [24–26]. Although the infectious disease risk hypothesis for atherosclerosis was initially associated mainly with *C. pneumoniae*, other studies have found independent risks associated with other infections, but not for *C. pneumoniae* [24]. In evaluating the role that infection may play in atherosclerosis, it is not clear why some individuals who have been exposed to an organism associated with atherosclerosis develop severe disease, while others similarly exposed, who have equivalent levels of additional risk factors, are disease free.

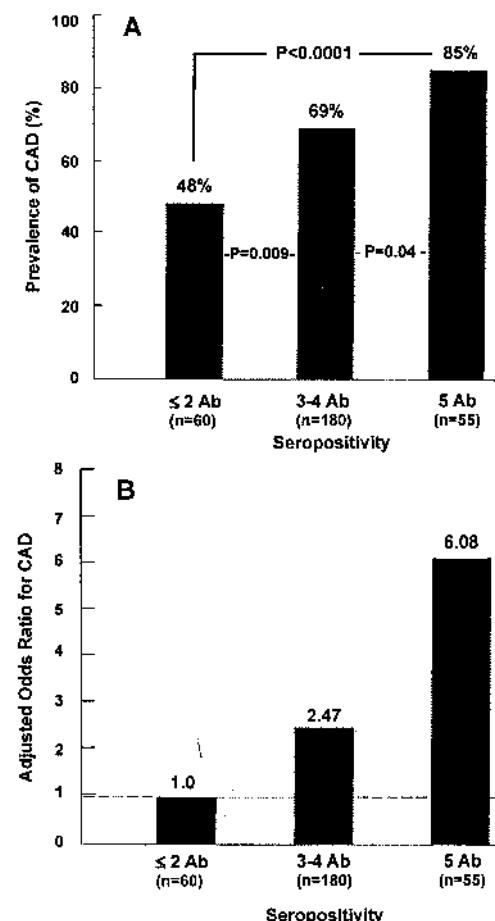

Regardless of the specific role of any single infectious entity, the exciting possibility has been introduced from the above studies that atherosclerosis and its associated diseases might be prevented with one or more vaccines. To date, the major vaccine focus has been associated with *C. pneumoniae* [27]. Numerous studies on the effects of antibiotics on development of atherosclerosis have also been undertaken [28–34], but definitive results have not yet been reported that could lead to a recommendation for preventive or therapeutic interventions.

### C. Role of Total Burden of Infectious Pathogens

As indicated above, the evidence is abundant and strong for including various infections as risk factors for atherosclerosis. Many of the pathogens that have been studied "were selected because each was either an obligate intracellular pathogen known to establish a persistent lifelong infection and/or elicited a persistent lifelong immune response (as manifested by increased antibody levels)" [35]. However, the remarkable number of organisms that have been implicated

has also generated a complicated and confusing picture. Likewise, it is not clear why some cross-sectional or prospective epidemiological studies seem to implicate certain organisms and other studies implicate entirely different organisms. The overall evidence does not unequivocally point to a single organism that could be a sole target for a generic vaccine against atherosclerosis.

Because of the above issues, the concept was introduced by Zhu et al. that "total pathogen burden" is more important as a risk factor than infection with any individual pathogen [36]. Although each pathogen may or may not be independently associated with increased risk for adverse atherosclerotic events or death, the accumulated risks of multiple infections may be additive [36–38]. Figure 1 illustrates a study of 233 patients in the United States in which the association between exposure to different numbers of pathogens, as determined by seropositivity, was correlated with the prevalence of, and odds ratio for, coronary artery disease [36]. As a further example of some of the considerable

**Figure 1** (A) Association between numbers of pathogens to which individuals were exposed (as reflected by seropositivity) and the prevalence of coronary artery disease. Overall linear trend achieves significance ( $P = 0.001$ ). (B) Adjusted odds ratios for coronary artery disease. Overall linear trend achieves significance ( $P = 0.001$ ). Ab = antibody. (From Ref. 36.)

evidence that has recently been accumulated for this concept, it was estimated that after a follow-up of 3.2 years of 572 patients studied in Germany, "cardiovascular mortality was 7.0% in patients with advanced atherosclerosis and seropositive for 0 to 3 pathogens compared with 20% in those seropositive for 6 to 8 pathogens" [39].

#### D. Multiple Mechanisms by Which Infections May Induce or Exacerbate Atherosclerosis

When the focus shifts from a single organism to multiple organisms, the question naturally arises whether infection per se is the underlying mechanism or whether other factors are more important and whether infection might even be an epiphenomenon rather than an etiological agent. For example, increased infections are also associated with poor socio-economic status, decreased access to vaccination, and lessened access to health care in general. This has been partly considered by studying relatively homogeneous populations [24], but the point is well taken. Of course, other risk factors, such as smoking, could have a confounding effect on determining the etiology of atherosclerosis in the presence of chronic infections [37].

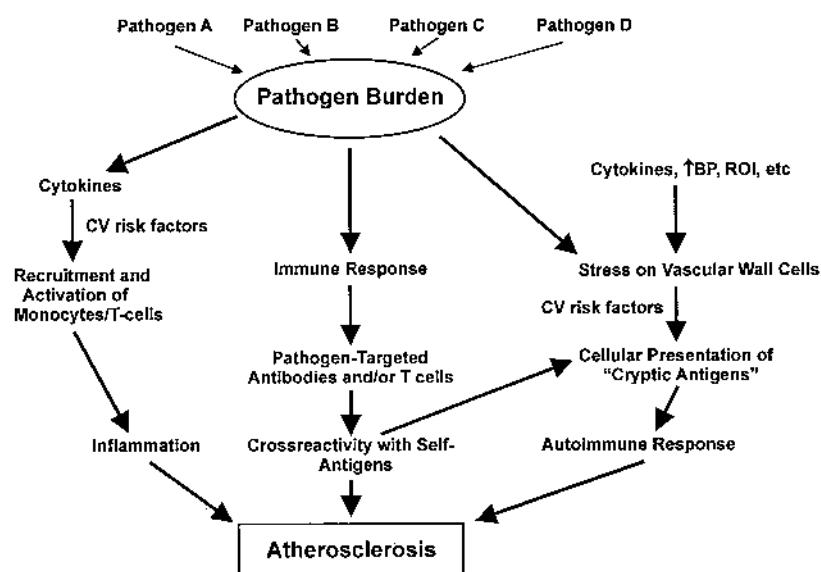

The existence of inflammations, often associated with chronic infections, may sometimes be detected by elevation of serum CRP levels, and correlations between CRP levels and atherosclerotic risk have been reported. However, CRP elevation is a nonspecific indicator, the exact significance of which is ill-defined. Moreover, it is likely that the increased risk for coronary artery disease and increased CRP levels are

both related to the primary variable of infectious burden [35,36].

The focus of understanding the possible role of infections has shifted in some laboratories to efforts to understand multiple possible direct and indirect effects that could link infection, particularly the effects of increased pathogen burden and atherosclerosis [25,35] (Figure 2). Where does this leave the question of whether vaccines can be developed for targeting atherosclerotic disease? There is no clear answer to this. Numerous infections do constitute risk factors for atherosclerosis, but recent data suggest that the risk posed by the burden of many infections is greater than the risk associated with any particular single infection. For this reason, a vaccine against a single organism, such as *C. pneumoniae*, probably could not serve as a generic vaccine against infection-associated atherosclerosis, but would reduce the atherosclerotic risk associated with this particular infection.

#### IV. METABOLIC VACCINES

Two metabolic vaccines have been proposed for inducing beneficial autoimmunity that changes distribution patterns of plasma lipoprotein cholesterol, with the aim of preventing cholesterol buildup in atherosclerotic plaques. Vaccines that have been proposed, or are being developed, have targeted either cholesterol itself [mainly in the form of LDL cholesterol or very low density lipoprotein (VLDL) cholesterol], or cholesteroyl ester transfer protein, as an antigen. The latter protein is an important factor that regulates cholesterol

**Figure 2** Multiple mechanisms by which infection may contribute to atherosclerosis development and course. The model depicted illustrates the role that infections by multiple pathogens, contributing to pathogen burden, has on the development of atherosclerosis. The mechanisms include factors leading to inflammation, and to immune and autoimmune responses, as well as their complex interactions. These mechanisms play out on a background of cardiovascular risk factors, which importantly influence any effect infection has on atherosclerosis development and progression. CV indicates cardiovascular; ROI, reactive oxygen intermediates. (From Ref. 35.)

transfer and distribution of cholesteryl esters among lipoproteins. In each case, the purpose of a metabolic vaccine is to increase the ratio of HDL/LDL, either by lowering LDL or by raising HDL.

### A. Anticholesterol Vaccine

The question of the immunogenicity of cholesterol, whether as a hapten or as an antigen, indeed even the issue of the possible existence of antibodies to cholesterol, has had a long and interesting history that goes back as far as 1925 (reviewed in Ref. 40). Antibodies that apparently could bind to cholesterol or phospholipids were produced in rabbits by intravenous injection of cholesterol or phospholipid mixed together with heterologous serum (pig serum). Numerous studies with cholesterol-haptenated compounds subsequently suggested that antibodies that could bind to cholesterol could be produced [40]. The immunogenicity of cholesterol, and the existence of antibodies to cholesterol, were definitively demonstrated by immunization with a protein-free cholesterol-loaded liposome/lipid A formulation that was used for the production of murine monoclonal antibodies that reacted directly with highly purified cholesterol [41].

The goal of preventing atherosclerosis by creating a vaccine that induces antibodies against cholesterol is based on the intriguing idea that antibodies might be induced that could differentially bind to, and reduce the levels of, LDL, VLDL, and intermediate-density (IDL) lipoprotein cholesterol, without reducing HDL cholesterol [42–45]. Murine monoclonal and polyclonal antibodies induced by injection of cholesterol-loaded liposomes containing lipid A do indeed bind to LDL but not to HDL cholesterol [44]. The antibodies recognize the 3-hydroxy group of cholesterol, and this group is apparently sterically blocked from binding to anticholesterol antibodies by the greater amount of overlying apoprotein that is present in HDL compared to LDL.

Studies with heterologous beta-LDL [46,47] and with a cholesteryl-albumin conjugate [48,49] suggested that immunization with a formulation containing a heterologous protein could partially protect rabbits against diet-induced hypercholesterolemia and aortic atherosclerosis. Subsequent work with the rabbit model demonstrated that a protein-free formulation of liposomes heavily loaded with cholesterol, and containing lipid A as an adjuvant, could induce antibodies that reacted with purified cholesterol and with LDL cholesterol, IDL cholesterol, and VLDL cholesterol, and that also partially blocked diet-induced hypercholesterolemia and aortic atherosclerosis [43]. Protection against diet-induced hypercholesterolemia and atherosclerosis was confirmed after intravenous immunization with cholesterol-loaded liposomes lacking lipid A [50]. Immunization against cholesterol was performed intravenously rather than intramuscularly in the latter study, and complete blockade of cholesterol-induced atherosclerosis was observed.

It would be reasonable to worry whether a vaccine that induces antibodies against such a fundamental compound as cholesterol might be detrimental to health. Cholesterol plays a central role in the dynamics of cell membranes and it is a

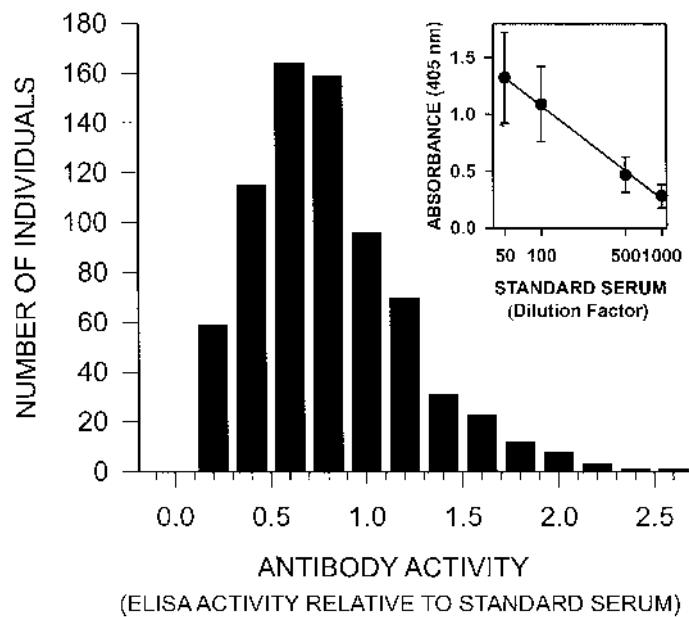

precursor in the synthesis of all of the steroid hormones. Nonetheless, immunization of rabbits and mice against cholesterol does not appear to induce any detectable toxicity in the animals. However, perhaps the most convincing evidence that antibodies to cholesterol are not deleterious is provided by the discovery that antibodies to cholesterol, both IgG and IgM, occur naturally in virtually all normal humans [45,51] (Figure 3). Based partly on this observation, it has been proposed that naturally occurring antibodies to cholesterol might play a beneficial role in helping to regulate the normal levels of LDL cholesterol [45]. A secondary consequence of this latter hypothesis, of course, is that many of the circulating anticholesterol antibodies in plasma might be hidden in the form of immune complexes with LDL. This would be analogous to the circulation of hidden antiphospholipid antibodies in normal human plasma, in which the antibodies are bound as immune complexes with phospholipids [52].

In view of the ubiquitous existence of varying levels of naturally occurring antibodies to cholesterol, it would seem reasonable to conclude that induction of higher levels of antibodies to cholesterol as part of a vaccine strategy would not be expected to have any adverse consequences. Of course, if subsequent research were to indicate that complement activation by naturally occurring antibodies to cholesterol also play some role in acute pathogenesis of atherosclerosis, for example, a role in accelerated atherosclerosis or acute reactions due to interaction of antibodies with cholesterol derived from a ruptured plaque, as suggested elsewhere [53–55], then the antibodies induced by the vaccine might also contribute to this hypothetical situation [40].

The summation of the anticholesterol vaccine approach is that it appears to be effective for preventing diet-induced hypercholesterolemia and atherosclerosis in animal models. There are experimental data, both in animal models and in the detection of naturally occurring antibodies to cholesterol in humans, that suggest that, although the immunization induces autoantibodies to an important body constituent (i.e., cholesterol), it may be expected to be safe for application as a human vaccine. The safety issue would have to be resolved through clinical trials in humans. It is possible that such a vaccine could be effective as an adjunct to other dietary and drug treatment strategies for lowering serum LDL levels in humans.

### B. Anticholesteryl Ester Transfer Protein

Levels of plasma HDL and LDL are strongly and continuously influenced by remodeling of lipoproteins caused by the activity of CETP [56,57]. CETP serves as a transfer protein, one function of which involves facilitating donation of cholesteryl esters from HDL to LDL. It is a hydrophobic glycoprotein that is secreted by the liver, and it circulates mainly bound to HDL. Most of the circulating cholesteryl esters originate from HDL, where they are initially deposited by the catalytic action of lecithin:cholesterol acyl transferase. Triglycerides, originally derived from chylomicrons and VLDL, are also transferred to HDL and LDL. The CETP then changes the different lipoproteins by promoting an equilibrium of various lipids between lipoprotein classes. A

**Figure 3** Anticholesterol antibodies in normal human sera. Dilutions (1:50) of each of 742 human sera were tested in triplicate by ELISA with purified nonoxidized cholesterol as antigen and mixed-affinity purified anti-human IgG, IgM, and IgA (H and L chains). Titrations of a standard serum used for comparison was performed with each group of ~15 volunteers (inset shows mean  $\pm$ SD of 52 assays of the standard serum). Binding was not observed when cholesterol was omitted. (From Ref. 45.)

net effect of this activity is a pattern of chemical and physical changes in the HDL particles that results in a remodeling of, and reduction in the amount of, cholesterol-rich HDL particles.

High-density lipoprotein is generally viewed as an anti-atherogenic fraction, and the action of CETP may therefore have atherogenic effects through the reduction of HDL cholesterol. As noted earlier, reduced HDL has been cited as a risk factor for atherosclerosis [6]. In contrast to the numerous therapeutic agents that are available for reduction of LDL, therapeutic interventions for elevation of plasma HDL levels are inefficient and limited in their potency [6,58,59].

Through the induction of autoantibodies to CETP, an ongoing active immunotherapeutic vaccine program seeks to promote elevated HDL and lowered LDL levels in humans [60–62]. Preliminary experiments in rabbits have suggested that significant increases of HDL can be achieved by inhibition of CETP with a monoclonal antibody to CETP [63], or by immunization with a vaccine that induces antibodies to CETP [60]. The vaccine consists of a 31 amino acid synthetic chimeric peptide that contains 16 residues of human CETP that contain a B-cell epitope, an additional 14 residues containing a T-cell epitope from tetanus toxin, and a linker peptide [60]. The vaccine, known as CETi-1, has successfully completed Phase 1 safety studies in humans, and “measurable antibody titers” were observed in all groups in a pattern that suggested a dose-response relationship [62]. The sponsoring company (Avant Immunotherapeutics, Inc.) initiated a Phase 2 placebo-controlled efficacy trial in patients with low levels of HDL cholesterol in August 2001 [61,62].

Clearly, the net effect of CETP is proatherogenic in rabbits, and inhibition of CETP has a beneficial effect for

reduction of diet-induced atherosclerosis in that species. However, because of uncertainty regarding the role of CETP in transferring cholestryll esters between lipoproteins in different species, it is not yet certain whether the enhancement of plasma HDL by active immunization that was observed in rabbits will carry over to humans. Nonetheless, there is a strong likelihood that the same result will occur in humans in view of the very high levels of HDL that characterize individuals who are genetically deficient in CETP (reviewed in Ref. 60).

Despite this latter theoretical prediction of a favorable outcome, and despite the promising safety results of the Phase 1 trials, it is still not clear whether the fundamental role and net effect of CETP is universally proatherogenic or antiatherogenic in humans, or whether CETP might have one effect in certain populations and another effect in others (reviewed and discussed in Refs. 57 and 60). CETP plays a very complicated role in lipoprotein distribution patterns, and it does have certain functions that are viewed as antiatherogenic. For example, by virtue of its ability to transport cholesterol from peripheral tissues to the liver for excretion in bile, a process known as reverse cholesterol transport (RCT), CETP can promote the elimination of cholesterol from tissues. Inhibition of CETP therefore might have proatherogenic effects in certain individuals [57,60]. One example that has been cited as circumstantial evidence of a proatherogenic effect associated with deficiency of CETP is an epidemiological study that found that a subset of Japanese-American men having a genetic deficiency of CETP and only modest elevations of HDL had an increased tendency to coronary heart disease [64]. In the same study, deficient individuals with higher HDL did not have higher atherosclerotic risk, and it was concluded that

although CETP deficiency is an independent risk factor for coronary heart disease under certain circumstances, the dynamics of RCT and the HDL concentration both play a role in the epidemiological determination of risk. In contrast to this, a much larger epidemiological study of men and women in Japan concluded that increased HDL was associated with a low prevalence of coronary heart disease, including among those with genetic CETP deficiency [65]. Because of various remaining uncertainties, although a vaccine against CETP is interesting, and potentially exciting, the jury is still out as to whether autoantibodies to CETP will be beneficial (antiatherogenic), or perhaps even detrimental (proatherogenic), in some or all humans who might require therapeutic alterations of lipoprotein metabolism [57,60]. Further judgement on the efficacy and safety of this approach must await additional data from ongoing human trials.

## Vaccine Therapy

**Donald S. Burke**

*Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, U.S.A.*

### I. INTRODUCTION

The word *vaccine* is usually restricted to describe an immunogen administered to healthy subjects at risk prior to their becoming exposed to a microbial pathogen. This word is also often used when the immunogen is administered early after exposure but before the onset of disease manifestations; in such circumstances the qualifying prefix “postexposure” is employed. Given the conventional use of the word vaccine, the term vaccine therapy might seem to be an oxymoron. However, historical precedent suggests that the term *vaccine therapy* should be used to describe administration of a microbe-specific antigen for therapeutic purposes (after the onset of established disease) [1]. Indeed, “vaccine therapy” and “vaccinotherapy” have been used continuously for this purpose as medical subject headings in the *Index Medicus* since 1911. While alternative terms have been proposed (immunoregulation, immunotherapy, immunostimulation), they are overly general and fail to convey the meaning that the immunity sought in vaccine therapy is both active and directed against microbe-specific antigens. Thus vaccine usage can be categorized relative to the time of microbial exposure: (1) true prevention or prophylaxis, (2) postexposure prophylaxis, and (3) therapy or reduction of recurrences.

Modern biotechnology has led to a renewed interest in vaccine therapy [2–5]. This chapter reviews the usage of vaccines after the moment of exposure (infection), emphasizing the therapeutic use of vaccines; however, post-exposure vaccination is also reviewed for the purpose of comparison.

### II. HISTORY OF VACCINE THERAPY

Edward Jenner, in his epochal 1798–1800 papers on the use of vaccinia in preventing smallpox, briefly commented on the apparent success of postexposure vaccination (see below) to prevent clinical smallpox [6]. However, he never proposed treatment of established smallpox with vaccinia. The French syphilologist Joseph-Alexandre Auzias-Turenne saw paral-

lels between the benign and fatal pox disease variants and the benign and fatal variants of genital chancres and proposed that matter from benign chancres be used for protection against or even treatment of syphilis. He championed syphilization—an intentional contraction of the terms syphilis and vaccination—as a public health tool [7,8]. For therapy he proposed that matter from a benign lesion could be inoculated serially, up to dozens of times, into the skin of a patient with established syphilis in an effort to achieve a cure. “Syphilization” was a major topic of debate at the 1st International Medical Congress in Paris in 1867. Of course, the clinical efficacy of his approach was never proved or even fully accepted, because he clearly confused syphilis with chancroid and genital herpes.

As Louis Pasteur was beginning his studies of vaccines in the late 1870s, he chanced to receive a copy of Auzias-Turenne’s collected works. Pasteur’s nephew and laboratory assistant, Adrian Loir, contends that Pasteur read this book avidly and that he was greatly influenced by Auzias’ ideas [9]. Loir reports that Pasteur repeated some of Auzias’ experiments of pre- and postexposure immunization, particularly with bovine pleuropneumonia [10]. Pasteur also almost certainly read Auzias’ speculative paper (written in 1864) on possible uses of material from rabies-infected tissues for purposes of therapeutic vaccination [7,11].

Pasteur’s legendary success with postexposure prophylaxis in the case of 9-year-old Joseph Meister led to widespread acceptance of postexposure vaccination for rabies [12,13]. Less widely known is the fact that Pasteur had already used a rabbit brain rabies vaccine in attempts to treat two cases of clinically apparent rabies [14]. These two cases are probably the first true trials of antigen-specific “vaccine therapy.” One patient died less than a day after receiving the therapy but the other apparently survived. Pasteur never published or otherwise publicly reported on these cases (Geison discovered the cases in Pasteur’s laboratory notebooks [14]).

Robert Koch reported in 1890 that he had discovered a cure for tuberculosis, leading tuberculosis patients from around the world to flock to Berlin to receive the treatment

[15–19]. The “cure” was a solution or suspension of glycerin and extracts from tubercle bacillus cultures, a composition similar to “tuberculin.” Like Pasteur, Koch had reported that microbe-derived antigens could stimulate immunity in patients who were already infected. However, reports from colleagues using the material were less than enthusiastic [20]. Cures and remissions were infrequent, and severe reactions, including several deaths, were commonplace. While tuberculin was a failure as a vaccine therapy, these trials led to its use as a diagnostic reagent and opened the field of delayed-type hypersensitivity.

Impressed by Koch’s experiments, Almroth Wright in England developed vaccine therapies for other microbes that could be cultivated in vitro [21,22]. He reported the use of heat-killed cultures of *Staphylococcus aureus* as a vaccine therapy [23]. Using an assay developed by William Boog Leishman, he measured the ability of sera to facilitate the ingestion of bacteria by leukocytes. He coined the term opsonization for this activity and correlated changes in the serum opsonic index with outcome in his vaccine therapy patients [24]. Almroth Wright became a zealous champion of vaccine therapy [25].

Based on his discussions with Wright, George Bernard Shaw wrote *The Doctor’s Dilemma*, a play whose plot revolved around the selection of patients for slots in a tuberculosis vaccine therapy trial [26]. One memorable line from this play—a vaccine therapist’s credo—reads: “There is at bottom only one genuinely scientific treatment for all diseases, and that is to stimulate the phagocytes. Stimulate the phagocytes. Drugs are a delusion.” Of course, not everyone was persuaded by Sir Almorth Wright’s data. One wag dubbed him “Sir Almost Wright.”

Vaccine therapy flourished during the first decades of the 20th century. Even Alexander Fleming wrote an effusive testimonial about its virtues [27]. A *Journal of Vaccine Therapy* appeared, and textbooks with guidelines on vaccine therapy for general practitioners were published. Pharmaceutical companies advertised concoctions of heat-inactivated organisms, typically 10 to 100 million per inoculation, for use as therapeutic vaccines [28,29]. Different mixtures were to be used for different disease syndromes such as pneumonia, urinary tract infections, or skin infections; U.S. practitioners commonly used vaccine therapy in their practice, most often for furunculosis or tuberculosis [30].

Despite their widespread use, bacterial therapeutic vaccines were never proved to have clinical efficacy. The early literature on vaccine therapy is difficult to interpret due to the total lack of appropriately controlled trials. Clinicians who used tuberculin vaccine therapy frequently reported increased inflammation at the sites of clinical tuberculosis, especially at readily visible sites on the skin [31]. Similarly, Wright and coworkers show reproducible increases in the serum opsonic index in *Staphylococcus* trials [32,33]. Some experimental studies in animal models also suggested immunogenicity (but none showed proof of efficacy) [34]. Enthusiasm for vaccine therapy plummeted when potent antibiotics such as streptomycin, chloramphenicol, and penicillin became available. In the 1950s and 1960s there continued to be sporadic efforts to develop and test therapeutic vaccines but none showed much promise [35–42]. By the

1970s, antibiotic treatment completely eclipsed antigen-specific treatment, and vaccine therapy became a forgotten art.

### III. EFFICACY OF VACCINATION FOR POSTEXPOSURE PROPHYLAXIS

The observation that vaccination *after exposure* to an infectious agent can afford protection against clinical disease carries obvious implications for a general understanding about how vaccines work: complete or “sterilizing” immunity, with total suppression of the very first rounds of microbe replication, is not necessary for a vaccine to be effective. This suggests that in some circumstances vaccines might be useful even later in the course of an infection, for therapy of overt disease.

There is reasonable evidence for the efficacy of postexposure vaccination in at least four human infectious diseases. All four are viral infections where an exact time of exposure can be determined with relative ease, the incubation period is at least 2 weeks, and an effective vaccine is available. Because these reports on postexposure vaccination are the only evidence that vaccines can be effective after, rather than before, infection, they are presented here in some detail, in historical order.

#### A. Smallpox

In 1800, Edward Jenner presented the first anecdotal evidence for the efficacy of postexposure vaccination [6]: “Some striking instances of the power of the cow-pox in suspending the progress of the smallpox after the patients had been several days casually exposed to the infection have been laid before me...” The largest and most detailed study of post-exposure vaccination against smallpox was conducted by Dr. William Hanna, Medical Office of the Port of Liverpool, who collected 75 cases [43]. Most were travelers from Boston who landed incubating smallpox during the severe outbreak in that city in 1902–1903. All were promptly vaccinated regardless of the time since exposure and then confined to the Port Isolation Hospital. Among those who were previously vaccinia-naïve and vaccinated within 6 days of exposure, all 10 of 10 developed only mild or moderate disease; of those vaccinated within 7–14 days of exposure but before rash, 7 developed mild moderate and 6 severe disease (1 death); of those vaccinated only after the rash had begun, 3 developed moderate and 4 severe disease (2 deaths).

Among those who had previously been vaccinated and then revaccinated within 6 days of exposure, 10 developed mild disease, 2 moderate, and 1 severe disease; of those revaccinated within 7–14 days of exposure but before rash, 14 developed mild disease and 1 moderate disease; and of those revaccinated only after the rash had begun, 7 developed mild disease and 10 moderate disease.

Evidence of a successful vaccine “take”—local vesiculation—during the incubation period also correlated strongly with protection against severe disease in the vaccinia-naïve cases [43]. Among those not previously vaccinated, a successful take during the incubation period led to severe disease in only 2 of 19, whereas an unsuccessful vaccination

(which occurred typically in those cases vaccinated later after exposure, often where symptoms had already begun) led to severe disease in 8 of 11.

Dixon reported on the efficacy of post-exposure vaccination in Tripoli in 1946 and compared the spectrum of disease severity among persons who had never been vaccinated to that among those who were successfully vaccinated postexposure [44]. His findings were remarkably similar to those of Hanna: among 21 cases successfully vaccinated with 5 days of exposure, all developed only mild illness. But when successful vaccination was not performed until the 6th to the 10th day after contact ( $n=36$  cases), the spectrum of disease severity was not different from that among unvaccinated persons.

For obvious ethical reasons, there are no prospective controlled trials of administration of vaccinia at different intervals after exposure, so precise data are impossible to obtain. The two retrospective series presented here identified cases for inclusion by the appearance of at least some smallpox papules. Persons with no evidence at all of smallpox would have been excluded. Indeed, the data in these two series may present a conservative estimate of the efficacy of postexposure vaccination against smallpox, because some individuals that were completely protected would not have been counted.

Fenner pointed out that the clinical course of infection following intradermal vaccinia inoculation (fever in 6–7 days) is much more rapid than the clinical course of typical variola major in an unvaccinated subject (fever in 14 days) or even that of intradermal inoculation smallpox in a naive subject (10–12 days) [45]. He speculates that this alacrity of vaccinia might be an important factor in the success of postexposure vaccination against smallpox.

## B. Rabies

Surprisingly, active vaccination for postexposure prophylaxis of rabies, widely considered to be the classic example of postexposure prophylaxis, is of uncertain clinical benefit. The first attempts at rabies postexposure prophylaxis in humans were conducted by Pasteur in mid-1885. By this time he had already tried vaccine therapy of clinically apparent rabies in two patients, with inconclusive results [46]. He first used postexposure rabies vaccine on July 6 on Joseph Meister, who had been bitten 2 days earlier. The boy apparently did well. On October 20, Pasteur began vaccination of his second case, teenager Jean-Baptiste Jupille, who had been severely bitten while defending a group of younger children from an apparently rabid dog. Six days later Pasteur announced his new method to the Academy of Science in Paris. One eminent colleague took the floor to proclaim that date of October 26, 1885, would live “forever memorable in the history of medicine and forever glorious for French science.” Pasteur had presented only two clinical cases, with follow-up periods of 4 months and 1 week, respectively. During the next year, over 2000 rabies-exposed patients from throughout Europe flocked to Paris to receive the postexposure vaccination. No controlled clinical studies were done.

Geison has recently shown that there are serious reasons to doubt the efficacy of Pasteur’s original postexposure vac-

cine [47]. The first were “scientific” concerns. For treatment of Meister and Jupille, Pasteur employed a 14-day series of injections of ground-up rabid spinal cords taken from rabbits intracranially inoculated with a “fixed” (rabbit brain-adapted) rabies virus. For the human cases, he began with 14-day dried rabbit cord and progressively each day inoculated a 1-day fresher cord until, on the last day, he inoculated fresh rabbit brains. Although never clearly expounded, his theory was that he was inoculating successively “less attenuated” virus each day. Modern authorities have established that rabbit brain-fixed virus can be virulent for humans. Most of Pasteur’s colleagues assumed that his animal experimental work had laid a careful foundation for postexposure rabies vaccination of bitten humans. However, at the time he treated Joseph Meister, Pasteur had not tested the efficacy of the regimen used on him in animals but instead only a variety of other exploratory vaccines and regimens. Furthermore, Geison has also raised legitimate questions about the statistical significance of Pasteur’s animal experiments [47].

Serious concerns (and lawsuits stemming from those concerns) were promptly raised about rabies cases in humans that occurred despite (or perhaps because of?) the first-generation Pasteur vaccine. Within a few years, the Pasteur Institute switched to a carbolic acid-inactivated vaccine. Nonetheless, the bulk of uncontrolled clinical data on postexposure rabies vaccination suggested that the method was reasonably safe and (arguably) effective.

Webster reviewed the world’s literature on experimental rabies postexposure vaccination in animal models [48,49] and concluded “it appears that Pasteur’s tests on the immunization of dogs by vaccination following bite have not been confirmed. Nine workers over a period of 50 years have stressed the relatively unsatisfactory results obtained in a series of over ninety experiments.” McKendrick, after reviewing results of the first 1 million rabies postexposure vaccinations at Pasteur institutes throughout the world [50], concluded that there were no differences in rabies mortality with respect to the type of vaccine employed (killed, live, heated, or other), regardless of the probability of the presence of rabies in the biting animal, location, or severity of the bite. Furthermore, delay in commencing vaccine treatment, even beyond 14 days, failed to show increases in rabies mortality. Other studies also failed to demonstrate any significant efficacy of postexposure rabies vaccination in humans [51].

Although passive postexposure immunization with antirabies immune serum was used sporadically as early as the 1890s, it was not until the 1950s that the efficacy of antirabies serum was studied in controlled field trials in humans [52,53]. Wolf-bite victims were solidly protected by postexposure vaccine plus serum but not by vaccine alone. Subsequent experimental studies of rabies in dogs and in mice have shown that passive immunity with serum and active immunity with vaccine is synergistic when given in the right doses [54,55]. There have been no controlled trials, or even uncontrolled trials, of the newer, safer “third-generation” cell culture-grown rabies vaccines alone (without passive antibodies) for postexposure vaccination. Current recommendations for rabies postexposure prophylaxis call for simultaneous administration of rabies immune glob-

ulin, regardless of the type (human diploid cell, Vero cell, rhesus diploid cell), route (intramuscular or intradermal), or dose of vaccine. Early experience with vaccinia and canarypox-vectored rabies proteins suggests that these genetically engineered vaccines might have advantages [56,57].

### C. Hepatitis B Virus

By comparison to rabies, the history of hepatitis B virus (HBV) postexposure vaccination is straightforward; evidence for postexposure efficacy was found in the first prevention vaccine trials. In 1978–1980, a randomized, placebo-controlled, double-blind study of plasma-derived vaccine was conducted among 1083 homosexual men in New York who were known to be at risk for HBV infection [58]. The overall reduction in incident infections was 92%. Hepatitis B events occurring in the first 75 days after the first vaccine injection were analyzed as a subset, as these were thought to be HBV infections that were incubating at the time of vaccination. Although the total *incidence* of new infections in the first 75 days was not reduced by vaccination, disease *severity* was substantially less in vaccine recipients than placebo recipients.

The same postexposure protective effect was found among early infections in another study of the plasma-derived vaccine conducted among 1402 homosexual men in five American cities in 1980–1981 [59]. After the plasma-derived vaccine was proved efficacious, it became difficult to prove the efficacy of the newer genetically engineered HBV vaccines in placebo-controlled trials. Data from a placebo-controlled trial and a comparative trial (compared to plasma-derived vaccine) in China have shown that yeast-expressed recombinant HBV vaccine alone (without HB immune globulin) was highly efficacious in postexposure prophylaxis to prevent chronic perinatal HBV infection [60,61].

### D. Varicella

Evidence for the efficacy of postexposure vaccination against varicella has also been directly demonstrated in several studies. In one early study where vaccine was administered within 3 days of exposure, protective efficacy against disease was essentially 100% [62]. Subsequent studies have shown that protective efficacy against disease is directly related to how soon after exposure the vaccine is administered and how much vaccine virus is administered [63]. When a dose of vaccine greater than 1000 PFU is administered within 3 days of exposure, postexposure protection is excellent. Although postexposure vaccination against varicella is an efficacious strategy, preexposure vaccination is recommended for persons at risk as a more reliable approach.

### E. Vaccine Therapy for Infections that Are Preventable or Modifiable by Postexposure Vaccination

There is no evidence that the vaccination of patients with *clinically overt* smallpox, rabies, or varicella has any favorable impact on disease course. Similarly, studies of chronic

HBV infection have not recorded any beneficial effect of immunization (see below).

## IV. CONTEMPORARY VACCINE THERAPY EFFORTS

New findings in immunology and molecular biology have prompted a modest resurgence of interest in vaccine therapy for chronic infectious diseases. Today there are ongoing efforts to develop and test therapeutic vaccines for several problems of public health significance; dozens of clinical trials have been reported just within the past few years. However, because there is no solid proof of efficacy for any of the therapeutic vaccines in these studies, they are reviewed here in outline form only.

### A. Human Immunodeficiency Virus

When acquired immunodeficiency syndrome (AIDS) was discovered to be caused by human immunodeficiency virus type 1 (HIV-1) and it became understood that symptomatic illness was the end stage of a slow but inexorable progressive viral infection, several groups began vaccine therapy trials. The vaccines tested thus far have spanned the full gamut of conceivable approaches from crude unpurified preparations to genetically engineered replicating vectors.

Some of the earliest attempts were made to treat HIV with crude infusions of infected whole blood or materials derived from blood [64–66]. One approach has been to autovaccinate patients with autologous-inactivated HIV obtained by cytapheresis of the patient's blood, in an effort to stimulate immunity against the patient's own viral quasi-species. Another approach has been to infuse infected blood taken directly from patients with stable asymptomatic infections into patients with advanced disease, in the hope that the newly introduced virus would be more immunogenic and provoke an effective immune response. There is little evidence that these attempts at therapeutic vaccinations with blood products had any favorable impact. More promising early results were obtained by vaccine therapy with inactivated antigens or subunit proteins. Zagury and colleagues immunized patients with paraformaldehyde-fixed autologous lymphocytes that expressed genetically cloned vaccinia-expressed HIV antigens [67–70], but this approach had some inherent safety problems for use in persons with compromised immune systems [71].

Within the past 5 years there have been at least 20 published reports on clinical vaccine therapy trials of 11 different HIV vaccine approaches (see Table 1).

Salk and colleagues inoculated patients with cell culture-grown whole inactivated virions [72–76]. The vaccine test product, "Remune," was studied in a large multicenter, double-blind, placebo-controlled, randomized trial conducted at 77 centers among HIV-infected adults with early-to mid-stage disease progression (at least 300 CD4 cells per cubic mm) [77]. A total of 2527 patients were randomized to receive the vaccine or adjuvant only. Fifty-three subjects clinically progressed in each treatment group, and there were 19 and 23 deaths in the placebo and immunogen groups.

**Table 1** Recent Vaccine Therapy Trials for HIV-Associated Diseases

Vaccine	Disease	Country	N patients	Placebo	Year	Author	Reference
Whole inactivated virions	Early stage	United States	2527	yes	2000	Kahn	77

gp160 DNA	Early stage	Switzerland	4	no	2001	Weber	100

These results were taken as evidence by the principal investigator and his colleagues that Remune failed to demonstrate an increase in HIV progression-free survival. In a separate publication, measurements of HIV viral load, CD4 cells, and HIV-1-specific immunity all in a predefined subset of 252 subjects were reported to show beneficial effects from vaccination [78]. In an unprecedented step, the parent company, the Immune Response Corporation, brought legal action against the principal investigator of the clinical trial for refusing to include what they referred to as these more “meaningful and detailed” data in the full report on clinical outcomes [79]. Another adjuvant-controlled double-blind trial of Remune was conducted among 297 asymptomatic patients in Thailand [80]. Over a relatively short 40 weeks of follow-up, the vaccine group was reported to show a better preservation of CD4 cell levels. No effect on disease progression or mortality was reported from this study.

Other early pioneers of HIV-specific vaccine therapy were Redfield and Birx who studied vaccine therapy with a genetically engineered HIV surface envelope protein (gp160) that had been expressed from recombinant baculoviruses in

insect cells; they demonstrated that the approach was safe and immunogenic [81–83]. Results of six large and/or long-term clinical trials, carried out in several countries, have been reported in the last few years. In Italy, 99 early-stage patients were treated with gp160 for a 2-year period, but the treatment was inferior to zidovudine monotherapy [84]. In Canada, 278 early-stage patients were treated for 3 years, but no differences were observed in CD4 cells, time to initiation of therapy, plasma viral loads, or death [85]. In Sweden, 835 early-stage patients received gp160 every 3 months for 3 years [86]. HIV-1 T-cell immunoreactivity was induced in vaccine recipients, but the treatment did not lead to clinical benefit. In another study in Sweden, repeated immunizations for 5 years among 40 asymptomatic patients were safe and may have resulted in a transient improvement in CD4 cell count, but the study was too small to measure clinical impact [87]. In the United States, a large long-term (5-year) carefully conducted study among 608 HIV-infected asymptomatic patients found no evidence for efficacy as measured by the change in CD4 cell count or Walter Reed stage [88]. As in the Swedish study, a transient improvement in CD4 cell count

was observed, but this did not translate into improved clinical outcome. Only one study has been reported of vaccine therapy with gp160 among patients with advanced HIV infection [89]. As in early-stage patients, the treatment was safe, and new and augmented immune responses were observed, but there were no evident clinical benefits.

The third major class of candidate therapeutic HIV vaccines to be tested in clinical trials is envelope protein subunits expressed in mammalian cells. Two trials of gp160 (expressed by vaccinia in Vero cells) were recently reported. In Germany, 208 patients were immunized repeatedly over 2 years [90]. Despite the induction of new lymphoproliferative responses, there was no clinical benefit. A smaller study in the United States showed similar findings [91]. Several trials of gp120 expressed from Chinese hamster ovary cells have recently been reported from the United States. In one study, 573 early-stage patients were randomized in a placebo-controlled double-blind study; more vaccine-treated patients than placebo recipients showed a 50% decrease in CD4 cell count, but the result was not statistically significant [92]. Schooley and colleagues studied four different gp120 candidate vaccine preparations [93]: 164 late-stage patients were immunized with CHO expressed gp120 (MN strain) and alum adjuvant, while 128 early-stage patients were randomized to receive either that vaccine, CHO expressed gp120 (III B strain), CHO expressed gp120 (SF-2 strain) in MF-59 adjuvant, or a nonglycosylated gp120 (SF-2 strain) produced in yeast. New lymphoproliferative responses developed in only 30% of patients, more commonly among patients who had an undetectable level of HIV-1 RNA at baseline. Proliferative responses were usually HIV-1 strain restricted.

A fourth HIV-1 therapeutic vaccine approach reported to have been carefully studied is a canarypox engineered to express gag, pol, env, and nef gene products (ALVAC vCP1452) [94]. This study was unusual in that only patients with primary HIV infection were studied. All 148 patients were treated with highly active antiretroviral treatment (HAART), and those with sustained ablation of viremia were continued on HAART and randomized to receive ALVAC, ALVAC plus Remune, or no vaccine. The study is ongoing.

The long-term effects of p17/p24 viruslike particles as therapeutic vaccines have also been studied. In HIV-infected early-stage patients, the vaccine is well tolerated but does not induce new anti-p24 antibodies nor consistently induce cellular responses. Fifty-six patients were followed long-term, but no effect on disease progression was observed [95,96].

Other HIV-1 therapeutic vaccine approaches that have been reported recently are envelope peptides, tat toxoid, and DNA vaccines [97–100]. These approaches appear safe and moderately immunogenic, and clinical studies continue. Studies to determine the clinical efficacy of these approaches have not yet been done.

## B. DNA Containing Viruses: Herpesviruses, Papillomaviruses, and Hepadnaviruses

DNA viruses that can cause chronic or recurrent clinical disease, including herpes simplex viruses, varicella-zoster vi-

ruses, papillomaviruses, and hepadnaviruses, are logical targets for vaccine therapy (Table 2).

### 1. Herpes Simplex Viruses

Because recurrent herpes infections are thought to occur as a consequence of a decline in antiherpes immunity, this disease has been a particularly attractive target for vaccine therapy. Numerous therapeutic herpes vaccines produced by inactivation of cell culture-grown virus have been tested in humans [101]. Most early trials were inadequately controlled, and in those few clinical therapeutic herpes vaccine trials done where controls were adequate, results were inconsistent [102–105]. Nonetheless, there continues to be reports in the medical literature of uncontrolled series of thousands of patients treated with therapeutic herpes simplex vaccines [106].

Recent scientific efforts have focused on the development and testing of herpes subunit protein vaccines. HSV-2 envelope protein gD2 with an alum adjuvant was used to prevent the recurrence of genital herpes in a double-blind placebo-controlled trial among 98 patients with frequent recurrences [107]. Vaccine recipients reported fewer recurrences and had fewer virologically confirmed recurrences. The authors of this study concluded that “these results inspire optimism about the potential use of vaccine for the treatment of chronic, recurring viral diseases.” The same research group then studied what was thought to be an improved vaccine that included envelope proteins gD2 and gB2 in MF59, and oil-in-water adjuvant. Although glycoprotein-specific and neutralizing antibodies were boosted by vaccination, and the duration and severity of the first study outbreak was reduced significantly, overall the rate of recurrences was not significantly improved [108]. The investigators were unsure why the gD2/gB2/MF59 vaccine failed to show efficacy whereas the gD2/alum vaccine did in the preliminary study. One possible reason is that a lower dose of envelope protein antigens (10 µg each of gD2 and gB2) was used in the second study, compared to (100 µg of gD2) the first study.

### 2. Varicella Zoster Viruses

The varicella zoster virus (VZV) has also been thought to be a good candidate for vaccine therapy, but for prevention of zoster, not treatment of acute disease. After primary infection VZV remains latent in dorsal root ganglia cells and can reactivate to cause pain and skin lesions. Reactivation is thought to be the result of an age-related decline in VZV-specific T-cell immunity. At least four studies have been reported on the use of live attenuated varicella vaccine to boost immunity to VZV in the elderly [109–116]. Doses ranging from 3000 to 42,000 PFU have been tested. Collectively, local reactions are present in less than one-third of patients and are usually mild. Increased immunity to VZV has been documented by skin testing, lymphocyte proliferation assays, and responder cell frequency assays. Levin summarized studies to date by concluding that “there is anecdotal information from approximately 1200 patient years of follow-up that the incidence of zoster will not be reduced” but that in these preliminary studies “a clinical impression was that all of the events were unusually mild and pain was rarely

significant and never persistent” [115]. The impression is that the “breakthrough zoster” is converted into a minor illness analogous to the “breakthrough varicella” seen in vaccinated children. A large 38,000-patient study—the Shingles Prevention Study—is now underway in the United States in an effort to collect reliable efficacy information.

### 3. Papillomaviruses

Vaccine therapy for cutaneous warts in cattle has been a common veterinary practice for decades [117]. Infections with bovine papillomavirus typically result in benign lesions that regress spontaneously. Occasionally warts can persist and give rise to squamous cell carcinomas. Commercial therapeutic wart vaccines were widely used but had questionable efficacy. Autogenous vaccines (made from glycerol-saline suspensions of lesions) were reported to have excellent efficacy and were recommended by experts [118,119]. Remarkably, in some locales autogenous vaccines continue to be used as experimental therapy in humans [120]. One recent report proposed that excision followed by autogenous tissue

vaccine is the most effective treatment for perianal condyloma acuminata [120].

There is now solid proof that human papillomavirus infection is causally associated with cervical cancer, most often HPV type 16. Recent research has shown that the E6 and E7 early gene products are nucleoproteins that can malignantly transform human cells, and there is evidence that continued expression of these proteins occurs in cancer cells. At least six small studies have been reported on the use of HPV16 E7 (with or without E6) to treat patients with cervical cancer [121–127]. In some of these trials only patients with the common HLA haplotype A2 were studied, so as to assure optimal HLA class I antigen presentation and epitope-specific recognition. All of the vaccine approaches thus far tested have been safe, and varying degrees of immunogenicity have been detected. In one careful study, vaccine therapy with short E7 peptides provoked and increased dendritic cell infiltrate in cervical biopsies, with clearing of HPV from cervical scrapings but not HPV RNA from biopsy samples [126]. None of the studies thus far conducted has been blinded or controlled, then there has

been no compelling evidence of clinical efficacy. Larger clinical trials are ongoing.

Genital warts are benign neoplastic tumors in humans most often caused by HPV types 6 and 11. At least two studies have been reported on using HPV structural proteins (L1 or L2) as a therapeutic vaccine. In one uncontrolled open label study, a fusion protein consisting of HPV 6 L2 and E7 was given to 27 subjects [128]. Of these, 19 made antigen-specific T-cell proliferative responses to L2/E7, and 5 patients completely cleared their warts. A report from China describes a study in which patients with genital warts were immunized with an HPV 6b L1 viruslike particle vaccine [129]. Remarkably, complete regression of genital warts was observed in 25 of 33 evaluable subjects. Although increased anti-L1 antibodies were found, no studies of cellular immunity were reported.

#### 4. Hepatitis B Virus

Hepatitis B virus infection can lead to chronic infection with a high risk for chronic hepatitis and/or hepatocellular carcinoma. Two European groups have recently reported on their studies of HBV envelope proteins as therapeutic vaccines. In France, a pilot open study and a randomized controlled study have been done on patients with chronic HBsAg carriage, detectable serum HBV DNA, and chronic hepatitis [130–133]. Antigen-specific lymphocyte proliferative responses were detected, but in only a minority of patients. Disappearance of serum HBsAg was not observed in any of the patients, but there was a transient decline in serum HBV DNA in the vaccinated groups. Because of a concern that escape mutants might emerge, amino acid sequences of the “a” antigenic determinants were determined for nonresponder and responder patients. No common escape mutations were detected. In Germany, a

combination of immunotherapy with alpha-interferon and vaccine therapy with HBsAg was tested in 18 patients who were unresponsive to alpha-interferon alone [134]. HBV DNA became undetectable and liver enzyme profiles became normal in half of the patients.

### C. Mycobacteria: Tuberculosis and Leprosy

#### 1. *Mycobacterium* Tuberculosis

Vaccine therapy for tuberculosis, championed by Koch and widely employed for decades, is undergoing yet another revival (Table 3). Intradermal injections of *Mycobacterium vaccae* have been used to boost immunity to *Mycobacterium tuberculosis* in symptomatic patients [135–137]. The method has been aggressively pursued as cost-effective for developing countries [138,139]. Also, vaccine therapy is seen as perhaps the only alternative for patients infected with multidrug-resistant bacilli [140]. At least five intermediate size trials of the vaccine therapy using heat-killed *M. vaccae* have been reported from countries throughout the world in the last several years. In Romania, the *M. vaccae* vaccine was used as an adjunct to a chemotherapeutic regimen in newly diagnosed cases [141]. Although there were no differences in final outcome, those receiving vaccine therapy showed modestly more rapid improvement. Vaccine therapy was also studied in patients with chemotherapeutic treatment failures [142]. Patients were randomized to receive either *M. vaccae* or saline injections. After 22 months, only 13 of 56 patients receiving vaccine therapy had an unfavorable outcome compared to 26 of 46 patients in the control group. Vaccinated patients were also reported to have better success as measured by chest x-ray and bacteriological cultures. However, there was no significant difference in the number of patients who died in this trial. Two small trials in Argentina,

involving a total of 40 newly diagnosed HIV negative pulmonary tuberculosis patients, were reported to show that vaccine therapy provided added clinical benefit to chemotherapy alone [143]. In this trial, serum levels of IL-4, IL-10, and TNF-alpha fell and levels of INF-gamma rose in vaccine therapy patients compared to placebo-controlled recipients. In Uganda, adjunctive vaccine therapy with heat-killed *M. vaccae* was studied in a placebo-controlled trial among 120 newly diagnosed HIV negative pulmonary tuberculosis patients [144]. Sputum culture conversion to negative and radiographic improvement were more rapid in the vaccinated patients. A larger open label multinational study of adjunctive vaccine therapy with *M. vaccae* was carried out among 337 patients with multidrug-resistant *M. tuberculosis* in Estonia, Iran, Kuwait, New Zealand, Romania, Vietnam, and the United Kingdom [145]. Although there were no placebo-controlled inoculated patients in this study, the authors concluded that the vaccine therapy improved the rate of cure of multidrug-resistant tuberculosis, most effectively in patients with short histories of disease.

## 2. Leprosy

In studies of the immunology of tuberculoid and lepromatous leprosy, Convit in Venezuela observed that patients with lepromatous leprosy did not clear heat-inactivated *Mycobacterium leprae* organisms that were experimentally inoculated intradermally [146,147]. However, these patients did clear inoculated live attenuated bacille Calmette-Guerin (BCG). When heat-killed *M. leprae* organisms were mixed with the live BCG, the *M. leprae* organisms were also cleared. Other studies suggested that *M. leprae* was directly suppressive of a delayed-type hypersensitivity response [148–154]. These experimental observations led to clinical trials of vaccine therapy of leprosy in which mixtures of *M. leprae* and BCG were inoculated into hundreds of patients [155,156]. Although treated patients showed improvements in a number of measures of antileprosy immunity (such as increased antibody titers, increased skin-test reactivity, and increased specific lymphocyte proliferation), clinical benefits were not clear-cut. Combined chemotherapy and vaccine therapy is reported to lead to shorter duration of treatment and faster hospital release [157–159].

Injections of 5 units of purified protein derivative of tuberculin also lead to clearing of *M. leprae* at the site of inoculation, as do injections of other mycobacterial antigen preparations [160–162]. It has been speculated that the widespread use of BCG has been a significant factor in the decline in incidence of leprosy in many countries [163].

Results of at least five clinical studies, all in India, have been reported in the last few years. One product has received authorization from the Drugs Controller of India for industrial manufacture, based on the killed *Mycobacterium "w."* This product has been used as an adjunct to drug therapy in 156 multibacillary leprosy patients [164,165]. Control patients received a placebo injection. Ninety percent of vaccinated patients converted from lepromin skin test negative to positive, compared to only 38% in the placebo group. Clinical scores and bacteriological indices improved more rapidly among the vaccinated patients for the first 3 years. Three

trials have been reported using the “Convit” vaccine consisting of live BCG plus killed *M. leprae*, in various stages of leprosy [166–168]. In all three there is a trend toward favorable results, but in the setting of chemotherapy it is difficult to assess these nonrandomized and not completely controlled studies. One Phase I safety and immunogenicity study was reported in which a vaccine consisting of irradiated *Mycobacterium habana* was used to treat 31 patients with lepromatous leprosy [169]. Vaccination induced lepromin conversion in 100% of the vaccines. However, the vaccine produced small cutaneous ulcerations at the injection site in all patients.

## D. Leishmaniasis

Convit noted the similarities between the clinical and histopathological features of leprosy and cutaneous leishmaniasis and hypothesized that the pathogenesis of the two diseases was similar. Given the apparent success of treatment of leprosy with BCG, Convit and colleagues conducted clinical trials of vaccine therapy for leishmaniasis with inoculations of BCG mixed with killed *Leishmania* promastigotes [170–173]. Although in vitro markers of antileishmanial immunity have not shown marked changes, clinical efficacy in one study was reported to be excellent [174,175]. Other studies with soluble leishmanial antigens have suggested clinical efficacy [176]. Two vaccine therapy clinical studies of cutaneous leishmaniasis have recently been reported. In Venezuela, 43 patients were studied in an effort to find the immunologic correlates of efficacy [177]. The authors detected enhanced antigen-specific IFN-gamma responses to both components of the vaccine, *M. bovis* BCG and *L. amazonensis*. In Brazil, a vaccine composed of killed promastigotes was used as an adjunctive therapy to standard chemotherapy with antimonium salts [178]. Fifty-three patients were randomized to receive the adjunctive vaccine therapy or antimonium salts only. Vaccinated patients showed increased lymphoproliferative responses, but there was no difference in the time for complete healing of the lesions between the two groups.

## V. SUMMARY AND CONCLUSIONS

Vaccine therapy has been an alluring concept since the dawn of microbiology as a laboratory science and Pasteur, Koch, and Wright were all drawn to the idea that it should be possible to manipulate and direct the immune response in ways favorable to the patient. Will vaccine therapy ever live up to its conceptual promise? If effective therapeutic vaccines are to be developed, this will require a more complete understanding of the mechanisms that microbes use to establish and maintain chronic steady-state infections. Thoughtful new vaccine designs may be necessary to counter suppression, reinforce subverted costimulatory signals, or escort antigens in correct conformations to responsive cells. Vaccine therapy may not only be a goal in itself but, following the precedent set by Pasteur, Koch, and Wright, may also be a valuable tool to dissect the host-pathogen relationship so as to understand its crucial facets.

## Vaccination-Based Therapies in Multiple Sclerosis

Jacqueline Shukaliak-Quandt and Roland Martin

National Institutes of Health, Bethesda, Maryland, U.S.A.

### I. INTRODUCTION

Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system (CNS) characterized by extensive leukocytic infiltration and associated demyelination. The end result is invariably damage to myelin and also to oligodendrocytes, with varying degrees of axonal destruction resulting in neurologic impairment [1–3]. While the exact cause of MS is unknown, an immunological component has been suggested based on the examination of lesions showing scattered inflammatory infiltrates (particularly mononuclear cells) [4,5], the positive therapeutic results after immune modulation or immunosuppression [6,7], and the genetic association of disease to the major histocompatibility complex (MHC) or human leukocyte antigen (HLA) in humans, which presents antigen to T cells [8–10]. Also convincing are the striking similarities between disease in humans and an animal model of MS, experimental autoimmune encephalomyelitis (EAE) [11,12], which is generated in several species following immunization with myelin proteins. The T-cell-mediated response that ensues and that can be passively transferred to naive individuals strongly implicates the involvement of these autoantigen-specific T cells in autoimmune disease.

#### A. The Schema of Central Nervous System Autoimmunity: Targets for Therapy

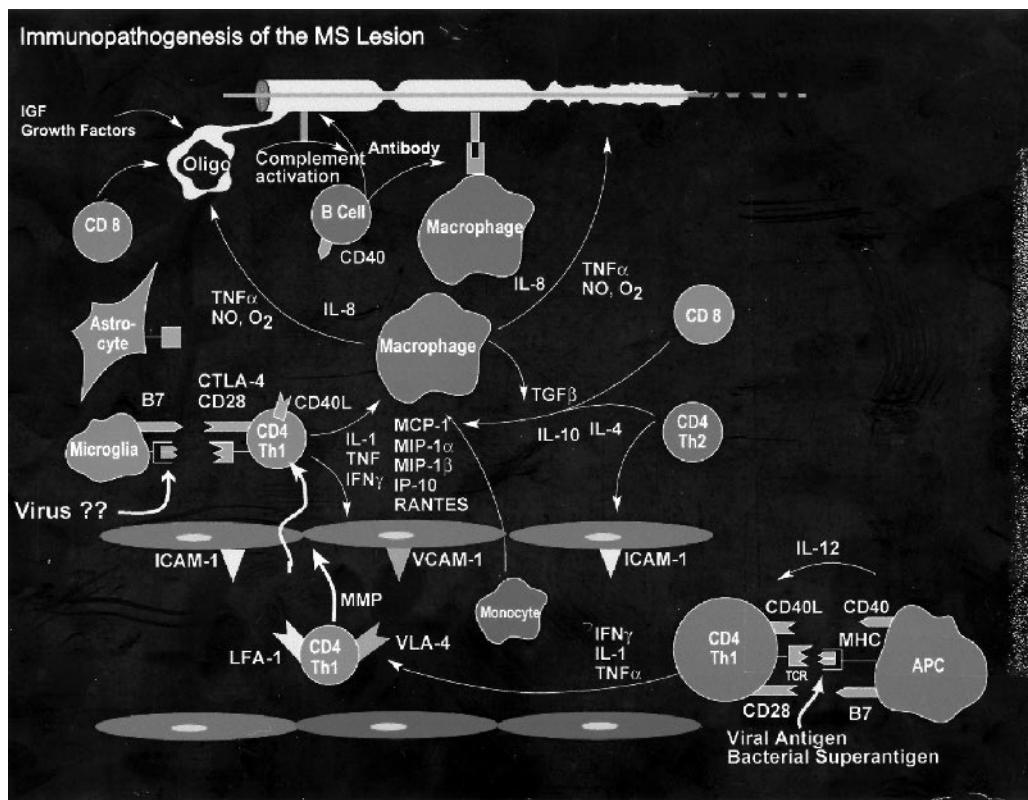

Advances in understanding the immunopathogenesis of MS have given rise to several immunomodulatory therapies. Potential therapies for MS under experimental or practical application to date have focused on several steps of disease pathogenesis (Figure 1). While the precise triggering event that activates autoreactive T cells is unknown, studies using the animal model EAE have shed light on the events following T cell activation. Initial activation likely occurs outside the CNS, as myelin-reactive CD4+ T cells encounter an antigen (bacterial, viral, or otherwise) presented in the context of an antigen-presenting cell (APC) with sufficient costimulation to induce full T cell activation. Activated cells

are able to cross the blood–brain barrier (BBB) through complex interactions involving adhesion molecules, chemokines, and metalloproteinases, and enter the CNS where they encounter the cross-reactive antigen [13]. Both reactivation and subsequent clonal expansion with inflammatory cytokine and chemokine production within the CNS are requirements for disease development in animal models [13,14], and serve to recruit a multitude of immunocompetent cells. Extensive damage and increased permeability at the BBB also allows for the passage of soluble factors including serum proteins, complement, and antibodies that can contribute to the process of demyelination. The recruitment or presence of macrophages/microglia at this stage is the cornerstone of the effector phase of the disease [15] as these cells perpetuate immune-mediated demyelination via phagocytosis with concomitant release of several cytokines, proteases, and toxic nitrogen and oxygen intermediates [16].

The drugs in widest clinical use include immunomodulatory therapies such as the  $\beta$ -interferons and glatiramer acetate (GA). While their mechanism is far from completely characterized, they can inhibit T cell activation, alter levels of various cytokines, or reduce the trafficking of leukocytes across and reduce BBB permeability. However, they are only moderately effective, and at therapeutic doses can cause organ toxicity and complications that can be difficult to manage. They may also impair the activities of all immune cells, including those with regulatory properties. Newer immunomodulatory strategies are continuously being explored in animal models of MS (Table 1) and include the administration of antibodies to inflammatory mediators, systemic administration/gene therapy to deliver suppressive factors, and most recently the application of vaccine-like strategies.

#### B. Vaccines to Combat Autoimmune Disease

The traditional concept of a vaccine is the prophylactic administration of an antigen or attenuated infectious agents in preparedness for subsequent exposure. Typically, the goal is to mount a more rapid and potent humoral and cellular

**Figure 1** Immunopathogenesis of MS. While the precise triggering event activating autoreactive T cells is unknown, studies using the animal model EAE have shed light on the likeliest mechanisms of disease initiation. Most probably, the initial activation occurs outside the CNS, as myelin-reactive CD4+ T cells encounter an antigen presented in the context of an antigen-presenting cell (APC) with sufficient costimulation to induce full T cell activation. Activation may result from the sharing of epitopes between microbes and CNS antigens (molecular mimicry), superantigen-driven nonspecific T cell activation [172], or cytokine-mediated bystander activation. Upon activation, these cells acquire the ability to cross the blood-brain barrier (BBB) localized to the tight, nonfenestrated endothelial cells lining the microvasculature of the brain [173,174]. Through complex interactions involving adhesion molecules, chemokines, and metalloproteinases, T cells enter the CNS where they encounter the specific autoantigen (presumably a neuroantigen). T cell reactivation and subsequent clonal expansion with inflammatory cytokine and chemokine production within the CNS is a requirement for disease development in animal models [13,14], and serve to recruit several immunocompetent cells. Extensive damage and increased permeability at the BBB also allows for the passage of soluble factors including serum proteins and antibodies that can contribute to the process of demyelination. The recruitment or presence of macrophages/microglia at this stage is the cornerstone of the effector phase of the disease [15] as the cells that perpetuate immune-mediated demyelination via phagocytosis with concomitant release of several cytokines, proteases, and toxic oxygen and nitrogen intermediates [16,175]. (Courtesy of H.F. McFarland, NINDS, NIH, Bethesda, Maryland.)

immune response to microbial pathogens. Recently, vaccines have also been explored in the treatment of cancers where they drive a cellular, antigen-specific response. To be effective in autoimmunity, vaccines could be (1) globally modulatory or suppressive, and by eliminating proinflammatory mediators thus reduce some (and possibly all) immune responses for at least a short time, or (2) antigen-specific, and target only antigen-specific T cells thought to mediate disease. Thus the goal of the vaccination in autoimmune diseases is very different from that to combat viral infection or cancer.

The majority of vaccines applied in EAE for immunomodulatory purposes consist of naked DNA encoding cytokines found at high levels in autoimmune disorders and thus

implicated in disease development. Vaccination with cytokine genes induces a breakdown in tolerance and generates self-specific immunity against that gene product in the form of a high affinity, highly specific antibody response at higher levels than natural antibodies. Ideally, these antibodies can then block the accumulation/activity of an overproduced cytokine, thus inhibiting pathogenic effects. Following naked DNA vaccination, EAE was prevented by limiting in vivo responses to MIP-1 $\alpha$  and MCP-1, two chemokines critical in disease progression [17]. Similar protective effects were observed with DNA for TNF- $\alpha$  [18]. While not yet pursued in patients, data suggests that cytokine DNA vaccination could effectively induce anti-self-protective immunity to restrain harmful reactivity. However, the limits of

**Table 1** Antigen-Irrelevant Immunotherapies in EAE and MS

Approach	EAE	MS
<i>Cytokine-based</i>		
IFN- $\beta$	Suppressive	Approved therapy
IFN- $\gamma$	Protective	Worsens
Anti-TNF- $\alpha$	Conflicting	Worsens/failed
TNF- $\alpha$ DNA vaccination	Suppressive	ND
IL-10	Conflicting	Stopped
Retroviral delivery to brain	Suppressive	ND
IL-4	Suppressive	ND
Retroviral delivery to brain	Suppressive	ND
TGF- $\beta$ 2	Suppressive	Negative side effects
<i>Trafficking of Leukocytes</i>		
MIP-1 $\alpha$ DNA vaccination	Protective	ND
MCP-1 DNA vaccination	Protective	ND
Anti-ICAM-1	Suppressive/conflicting	ND
Anti-LFA-1	Suppressive	ND
Anti- $\alpha$ 4	Suppressive/cures	Phase II promising, Phase III planned
Chemokine receptor antagonists	Protective	Phase I in progress
Matrix metalloproteinase inhibitors	Suppressive	ND/planning
<i>Altering costimulation</i>		
Anti-B7-1	Protective	ND
Anti-CD40L (CD154)	Suppressive	Side effects with one antibody; another ongoing
Anti-CTLA-4	Worsens	ND
CTLA-4 Ig	Conflicting	ND (promising in psoriasis)
<i>Immunosuppressive</i>		
Mitoxantrone	Suppressive	Successful, approved
Azathioprine	Suppressive	Suppressive
Cyclophosphamide	Suppressive	Suppressive, side effects
Cyclosporin	Suppressive	Moderately suppressive, side effects

such therapy are clear: Long-term reactivity to inflammatory mediators may not be beneficial, especially when difficulties in directing therapies to the target organ may lend to global administration and subsequent systemic suppression of cytokine responses or reduced leukocyte extravasation. Thus a major goal is developing therapies whose modalities specifically target the activity of pathogenic autoreactive T cells, leaving the remainder of the immune system relatively intact.

### C. Vaccines as Antigen-Specific Therapies

The purpose of this review is to define the goals of and potential for vaccine usage in MS with a focus on antigen-specific therapies (Table 2). Compared to the development of microbial-oriented vaccines, two great challenges exist in developing an antigen-specific vaccine effective in autoimmune diseases. The first of these is determining the precise identity and specificity of the autoantigen in question, and subsequently characterizing the phenotype and role of the autoantigen-specific T cell in mediating disease. While one may consider targeting the autoreactive pathogenic T cells as the

most specific means of treating T-cell-mediated autoimmune diseases, it is important to consider that autoreactive T cells are not uncommon, and give rise to disease only in a minority of individuals. The incredible degeneracy in T cell recognition begs that in any given T cell repertoire, at least some autoreactive T cells escape negative selection during lymphoid development in the thymus. Selection occurs in the thymus as T cells encounter antigen. T cells recognizing self-antigen with high affinity are deleted, yet those with low affinity can escape this negative selection. Antigens from the brain and other “immunoprivileged” organs were originally thought to be sequestered; thus T cells reactive to proteins from these areas could not be selected against, neither in the thymus nor in the periphery, as they had no access to antigen. However, studies have shown that several myelin antigens are indeed expressed in the thymus and that T cells with high affinity for these antigens are indeed negatively selected. While it is postulated that autoreactive cells become activated via “molecular mimicry,” the evidence for its involvement in MS or autoimmune diseases in general is very limited. It has rather been suggested that autoreactive T cells encountering antigen may contribute to T cell survival, mainte-

**Table 2** Antigen-Specific Immunotherapies in EAE and MS

Type of vaccine	Mode of action
<i>DNA Vaccines Delivering</i>	
Autoantigen (protein/peptides) MBP, PLP, MOG	Depletion, anergy of autoreactive T cells
T cell receptor peptides	Depletion of autoreactive T cells, immune deviation
<i>Protein/Peptide Vaccines</i>	
Autoantigens (proteins/peptides) MBP, PLP, MOG	Systemic administration→deletion, anergy Mucosal administration→bystander suppression
Altered peptide ligands (APL) Glatiramer acetate	Bystander suppression Bystander suppression
<i>Cellular Vaccines</i>	
Autoreactive T cells	Idiotypic depletion of autoreactive T cells, Bystander suppression
Spleen cells coupled to autoantigen	Depletion/anergy of autoreactive T cells
Dendritic cells coupled to autoantigen	Depletion/anergy of autoreactive T cells

nance, and possibly also the homeostasis of the immune system, and rarely cause disease [19].

Secondly, the presence of self-reactive cells in healthy individuals suggests that regulatory mechanisms are physiological, and that in affected individuals this balance of “self-tolerance” has gone awry either at the level of regulation or by particularly strong activation. The objective becomes determining what mechanisms have allowed for this break in tolerance that otherwise keep autoreactive T cells at bay, and how to reestablish a balance. Tolerance can arise in the thymus early in life during T cell development (deemed central tolerance), or occur throughout life in the periphery (peripheral tolerance). Given that MS is not diagnosed until typically the third decade of life, the more common therapeutic approaches currently being explored involve attempts to induce peripheral tolerance in patients, i.e., at a time when the central tolerance-generating organ, the thymus, has already undergone its physiological involution. To this end, studies to date have focused on generating antigen-specific peripheral tolerance via one of the following mechanisms:

1. Anergy and T cell receptor (TCR) downmodulation: Eliminating the responsiveness of antigen-specific T cells to antigen.
2. Deletion: Targeting antigen-specific cells for death by attack from the host's immune system or inducing death/apoptosis pathways within the cell itself.
3. Immune deviation: Altering the profile of autoreactive T cells from proinflammatory to nonpathogenic by shifting cytokine patterns.
4. Bystander suppression: Generating cells with specific regulatory properties and the potential to regulate or suppress autoreactive T cells in a shared environment.

#### D. Antigen Specificity and Phenotype of Autoreactive T Cells in Multiple Sclerosis and Experimental Autoimmune Encephalomyelitis—Are They the Same?

The extension of therapies from experimental models to humans is based on similarities in factors including antigens, pathogenic mechanisms, and disease phenotypes between MS and EAE. EAE can be actively induced by immunization with brain or spinal cord homogenate, myelin protein, or peptide in complete Freund's adjuvant (CFA), or passively following the transfer of myelin-reactive CD4+ T cells [20]. Several models exist that vary in species, strain, and the initiating autoantigen. Depending on these factors, the inflammatory response and subsequent demyelination can manifest as an acute, chronic, or relapsing course of paralysis. These models are considered effective tools for studying the immunology of MS as they share a gender bias, genetic associations with MHC class II genes, histopathological correlations, and disease patterns. Although EAE shows clinical similarities to MS, controversy exists over the extrapolation of therapies to the latter, partially because the autoantigen/s in MS has/have not been confirmed. Differences also exist in the incidence of disease: MS spontaneously occurs, whereas EAE must be induced either by active immunization or the transfer of activated autoreactive T cells. As such, EAE models may each only represent certain aspects of the heterogeneous course of MS.

In the search to identify candidate autoantigens in MS, proteins within myelin are popular because myelin sheath degradation is a central event in MS pathogenesis, and many proteins are shared between humans and animal models. Myelin basic protein (MBP) is by far the most characterized and investigated autoantigen in MS and EAE: Classical studies have focused on the human T cell response to MBP

using T cell lines and clones to characterize their phenotype, reactivity (epitope specificity), effector functions, and T cell receptor identity. Immunodominant regions include MBP 83–99 (described in more detail below), MBP 111–129, MBP 145–170, and a few others in both MS patients and healthy controls [21–28]. T cells specific for these are restricted by those HLA-DR molecules most often associated with disease in different ethnic backgrounds (alleles of the DR15, DR4, DR3, and DR6 haplotypes). Interestingly, similar MBP peptides from the middle region [29,30] (MBP 89–101 in SJL mice and Lewis rats; MBP 111–129 in guinea pigs) or C terminus regions (in marmosets or rhesus monkeys) are capable of inducing EAE in several species with a similar association to MHC class II molecules. These studies show strong yet indirect evidence that similarities in peptide binding affinities or as yet unidentified characteristics exist between HLA-DR and MHC class II molecules in humans and mice that allows for sharing of these disease-associated peptides (review Ref. 31).

T cells specific for another myelin antigen, proteolipid protein (PLP), are encephalitogenic in different EAE models, i.e., in SJL mice: PLP 139–151 (immunodominant), PLP 178–191, 56–70, 104–117 (subdominant); Lewis rats: PLP 217–233; Biozzi mice: PLP 56–70. Similar peptides are immunodominant in both healthy control subjects and in MS patients [32–34]. Myelin oligodendroglia glycoprotein (MOG) is another attractive candidate autoantigen, with a unique location at the outer surface of the myelin sheath accessible to antibodies. It exhibits several encephalitogenic T cell epitopes in different rodent strains and primates [35–37], MOG 1–30, 35–55, 94–116. MOG 1–22, 34–56, and 63–87 are immunodominant in humans [38,39], and interestingly MOG 97–108 was recently reported as immunodominant in humanized transgenic mice expressing the HLA-DR4 allele, suggesting that immunodominance can be linked to the same MHC in two different species [40]. In this regard, further studies characterizing encephalitogenic epitopes in transgenic humanized HLA-DR mice could be an effective tool for identifying relevant pathogenic epitopes in humans. Several other myelin and nonmyelin proteins have also been described as target autoantigens, including myelin-associated oligodendrocytic basic protein (MOBP) [41], S100 protein [42], and 2',3'-cyclic nucleotide 3'phosphodiesterase (CNPase) [43], where MOBP and another protein, alpha-B crystallin [44], were found to be both encephalitogenic and immunogenic in humans. Once better characterized, these antigens may also be desirable prospects for antigen-specific therapy.

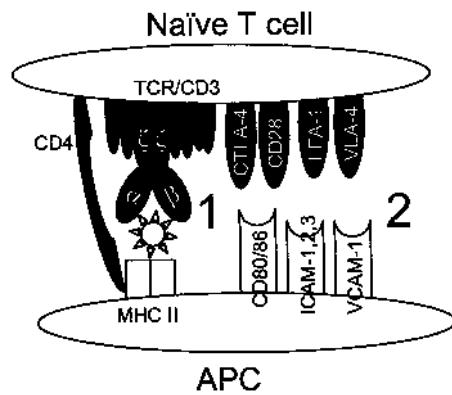

While these studies have focused on the prevalence of single antigens in disease, one must be aware of studies describing the process of determinant- or epitope “spreading,” with the introduction of new autoantigens subsequent to myelin breakdown and damage in the CNS following the initial insult. EAE induced by PLP 139–151 in SJL mice remits and later relapses with a preponderance of T cells reactive to a new epitope, PLP 178–191; a third relapse in turn shows highest reactivity to MBP 84–104 [45]. Given the numerous reactivities to myelin components documented in MS patients and their variance on different MHC backgrounds, and studies describing the existence of epitope

spreading [46], the potential challenges of targeting multiple antigens in a specific manner are obvious.

Cell analysis in EAE has shown that encephalitogenic T cells are typically major histocompatibility (MHC) class-II-restricted CD4+ T helper cells that produce the inflammatory cytokines IFN- $\gamma$ , TNF- $\beta$ , and IL-2. Over the past decade, immunologists have defined the effector functions of T helper cells and grouped them according to their cytokine profile. T-helper 1 or Th1 cells are proinflammatory cells producing IFN- $\gamma$ , TNF- $\alpha$ , or IL-1 $\beta$  and associated with a delayed-type hypersensitivity response. In contrast, Th2 cells produce the immunosuppressive cytokines IL-4, IL-5, IL-13 [47], or IL-10, and are thought to play a greater role in disease suppression. In EAE, MBP- and PLP-specific Th1 clones could induce disease, whereas Th2 clones with the same specificity did not. In fact, mucosally derived MBP-specific Th2 clones were able to suppress MBP- or PLP-induced EAE [48]. In MS, this was paralleled in a study of cytokine secretion by myelin-reactive T cells at defined points throughout the disease course that suggested the profile of these cells changes with disease status. Relapsing-remitting patients tested for PLP reactivity displayed a Th1 profile loosely correlating with an acute attack that was shifted to a mixture of Th0, Th1, and Th2 cytokine expressing clones during disease remission [49]. Such studies suggest that not only the antigenic specificity but also the phenotype and effector function of these cells may be critical in influencing their pathogenic potential. While this Th1/Th2 paradigm has been interesting for studying immune regulation in several models, one must be aware that this distinction is likely oversimplified. For example, T cells producing both Th1 and Th2 cytokines exist in abundance (termed Th0), and it is clear that T cell clones are capable of producing a myriad of these cytokines, often simply in differing proportions depending on the activation stimulus and environment [47].

## E. Activation of Encephalitogenic T Cells

Lymphocytes cannot recognize antigen in a soluble form, rather it must be “presented” to the T cell as a complex with the MHC on the surface of antigen-presenting cells (APC). The specific interactions at this trimolecular complex (Figure 2) [antigen complexed to the MHC and the T cell receptor (TCR)] (primary signals) as well as those between costimulatory molecules located on the T cell and the APC (secondary signals) influence the outcome of T cell antigen recognition. Full activation requires formation of an immunological synapse [50] comprised of the TCR, antigen:MHC, and costimulatory molecules in very close proximity to allow for sustained TCR engagement and subsequent activation. Naive cells that have not previously encountered antigen in the periphery call for a stronger stimulus to become activated, and typically require the primary signal as well as secondary signals to undergo full activation. Cells that have previously encountered antigen in the periphery (memory cells) need a less potent signal to undergo activation. In differentiated memory T cells, a theory of hierarchy exists in the activation of cellular functions, each occurring as the strength of the TCR stimulus increases [51,52]. While cytotoxicity and cytokine secretion appear to be less complex cell

**Figure 2** Formation of the immunological synapse. Two signals are required for the full activation of naïve T cells. The first (1) is the a signal through the formation of the trimolecular complex that consists of the TCR, Ag:MHC complex. Naïve cells also require a costimulatory signal (2) delivered through CD28 and its ligands CD80 (B7.1) or CD86 (B7.2) in addition to adhesion molecules expressed on the T cell and the APC. In contrast, previously activated T cells are less dependent on CD28 signaling and costimulation in subsequent rounds of restimulation. Once activated, cells express CLTA-4 that acts as a negative regulator of activation upon B7 ligation.

functions and thus require a less potent stimulus, proliferation in turn requires “full” activation. Above and beyond these cellular functions, the differential expression of cell surface molecules including cell adhesion molecules and chemokine receptors resulting from partial to full activation also influence the effector function, particularly the trafficking abilities, of these cells [53].

### 1. The Affinity of the T Cell Receptor for Antigen–Major Histocompatibility Complex

A single TCR has been found able to bind thousands of different peptides [54] based on studies using alanine substitutions in TCR ligands [55,56] and more recently using combinatorial peptide library predictions [52]. So what makes one antigen better than the next? Crystallography studies reveal pockets in the surface of the TCR and MHC that vary both in size and electrostatic charge, into which amino acids of potential ligands may fit in a linear conformation. Those ligands that can best align each of their residues both energetically and structurally to both the TCR and MHC, bringing them into the closest possible proximity, would seem biochemically ideal. Structural and MHC binding data based on these electrostatic predictions have supported this theory [57,58]. By sustaining the formation of the trimolecular complex for the longest possible duration, the “ideal” peptide has the greatest potential for full immunological synapse formation, whereas all other peptides can sustain this formation for less time [59]. A distinct correlation exists between the TCR affinity for the peptide:MHC and their related dissociation rate with biological outcome: “Agonists” are ligands that bind with relatively high affinity and

lower dissociation rates and, while an agonist can induce the full range of T cell effector functions described above for “full activation,” partial agonists with substitutions in one or more of the key TCR or MHC contacts are likely to only induce a subset of these T cell functions. “Antagonist” ligands have a high enough binding affinity to compete with agonists for the TCR, but typically cannot induce effector functions, and the binding affinity of null compounds is so low that they simply cannot engage the TCR. Thus the sequence of the antigen and how it influences binding to the TCR is a key component in influencing the extent of T cell activation.

### 2. Anergy Induction

T cell receptor stimuli can also result in T cell unresponsiveness or even cell death depending on the stage of preactivation. Anergy can describe several forms of unresponsiveness, each induced by different means [60]. For a short time after T cell activation, T cells exhibit a state of hyporesponsiveness with decreased  $\text{Ca}^{2+}$  mobilization, reduced IL-2 production, and a diminished response to subsequent antigen exposure. This refractory state is most often associated with down-regulation of the TCR, and accounts for “blindness” or “partial sightedness” of the T cell to antigen. A more favorable definition of anergy would be “a state of long-lasting, partial or total unresponsiveness induced by partial T cell activation.” The most extensively investigated type of anergy is induced in mouse or human T cell clones upon TCR ligation in the absence of full costimulation (i.e., typically the absence of B7 molecules) [60]. Most commonly, it refers to an inability of T cells to produce or respond to proliferative signals [61], and is characterized by an inability to secrete IL-2 by cells otherwise capable of producing IL-2. Importantly, anergy can be partial, as cytotoxic T cells capable of producing IL-2 once rendered anergic no longer produce IL-2, but maintain their cytotoxic potential [62]. Ligation of TCR in the presence of IL-10 also induces IL-2 irreversible unresponsiveness or anergy in T cells [63], giving rise to a unique phenotype. These T cells secrete high levels of IL-10 and are subject to intense investigation for their associated regulatory properties [64]. Importantly, IL-2 can reverse anergy, thus suggesting a potential problem for antigen-specific therapies aimed to anergize autoreactive cells. Infection or any immune response generating IL-2 could reactivate these cells and thus restore their pathogenic potential.

### 3. Activation-Induced Cell Death

Cell death can be the result of activation at the wrong time, i.e., activation-induced cell death (AICD), or stem from cell-mediated immunity, i.e., the lysis of cells targeted with antibodies. AICD is a form of programmed cell death following TCR engagement/T cell activation and physiologically plays a key role in shaping the T cell repertoire during T cell development. Model systems initially studied responses in thymocytes activated with antibodies to CD3, and were recently extended with antibodies against CD3/TCR to mature T lymphocytes in the periphery. Resting T cells are generally resistant to AICD and in vitro require several days of

stimulation before these freshly isolated mature peripheral T cells acquire sensitivity toward AICD. Activated T cells are highly susceptible [65]; thus AICD is thought to be a key means of “turning off” immune responses by limiting the reactivation of T cells. The death receptors Fas/Fas ligand (CD95/CD95L) are key mediators of AICD. A common scenario describes that following stimulation of an activated T cell via the CD3/TCR complex, CD95L mRNA and cell surface expression are rapidly induced. CD95L then binds to CD95 on activated T cells. A complex signaling cascade is initiated, ultimately resulting in apoptosis. The Fas receptor (CD95) is a key initiator of apoptotic death in several cell types but CD4+ T cells are unique in their ability to undergo autocrine (self) and paracrine (fratricide) death induction by stimulating their own Fas receptors or those on neighboring cells with their secreted or membrane-bound Fas upon activation [66–68]. Thus reexposure to antigen too rapidly after previous encounter is a pathway to death and seems an intriguing means to controlling autoimmunity by the selective induction of apoptosis in autoreactive peripheral T cells.

#### 4. Immune Deviation

Several other factors including the type of antigen, dose, frequency, portal of entry, the involvement of the innate immune system, and the genetic makeup of the host can influence the cytokine repertoire and consequently the phenotype of the activated T cell. For example, nasally or orally introduced allergens at low doses in an environment with high levels of the anti-inflammatory cytokines IL-4 or IL-13 generate Th2 effector cells. Alternatively, naive T cells encountering virus at high doses through the skin in the presence of the proinflammatory mediators IFN- $\gamma$  and IL-12 become Th1 effector cells. The local cytokine environment is a key factor in CD4+ T helper response to antigen: IL-12 is the major immunomodulatory cytokine associated with Th1-polarized responses vs. IL-4 for inducing Th2 responses. IL-10, an important immunomodulatory cytokine implicated in tolerance via anergy induction [63], decreases proliferation and Th1 cytokine production with effects on MHC class II dependent antigen presentation [69–72]. Activation status and costimulatory molecule expression also play a role. Engagement of leukocyte-associated antigen (LFA-1) by different plate-bound costimulatory intracellular adhesion molecules (ICAMs) alters the T helper profile: ICAM-1 induced high IL-10 production compared to ICAM-2 or -3, which induced higher TNF- $\alpha$  production [73]. Blocking ICAM-1 or -2 with neutralizing antibodies during T cell/APC interactions resulted in a Th2 phenotype [74]. Initial studies suggested that CD28 engagement by CD80/B7.1 or CD86/B7.2 can induce Th1 vs. Th2 responses respectively, but more likely reflected differences in the expression course of these molecules and relative binding affinities [75,76]. More definitively, CD28/B7 costimulation overall regulates the Th1/Th2 balance. While Th2 differentiation of naive CD4+ T cells is strictly dependent on CD28/B7 costimulation, blockade of this pathway has only minor effects on in vitro IFN- $\gamma$  production (Th1 differentiation) [74,77–79]. The inducible costimulatory molecule (ICOS)

member of the CD28 family that provides a unique costimulatory signal with its ligand B7RP-1 or LICOS. Previously activated memory T cells appear to require ICOS costimulation (ICOS is not expressed on naive T cells), and ICOS stimulation appears to be required for significant IFN- $\gamma$  and IL-10 production, also suggesting a role in T helper cell differentiation [80].

While environment and stimulus can allow for “immune deviation” by alternating potential profiles of naive T cells, similar attempts with differentiated cells have been relatively unsuccessful and are probably prevented by changes in the DNA methylation of cytokine gene loci [81]. Because it is as yet unclear whether terminally differentiated cells can undergo such a shift in their immune profile (i.e., Th1 to Th2 or vice versa), immune deviation may be ineffective at targeting effector or memory cells in autoimmunity.

#### 5. Bystander Suppression and Regulatory T Cells

While anergy, deletion, or ignorance can account for the maintenance of peripheral tolerance, numerous studies in experimental models of organ-specific autoimmune disease convincingly show that specialized T cells exist that are capable of controlling autoimmunity and are an integral part of the T cell repertoire in normal animals. In spontaneous diabetes models [82,83] and in an EAE model of mice transgenic for an MBP-specific TCR [84,85], CD4+ T cells from normal animals inhibit the spontaneous development of disease. Historically, CD8+ T cells were termed cytotoxic/suppressor cells, but were eventually replaced by the Th2 cells described above. Recently, the whole field has rapidly evolved and identified several regulatory T cell types distinct from Th2 cells involved in the suppression/regulation of autoreactive T cells. T regulatory cells (Treg) have been extensively characterized in rodents and more recently in humans as professional regulatory/suppressor cells that actively and dominantly prevent the activation and effector functions of other T cells [86]. One type are named CD4+ CD25+ for their expression of the IL-2 receptor  $\alpha$  chain in mice, (one component of the T cell marker CD25 transiently expressed on activated T cells). These cells are rather homogeneous [87], derive from the thymus [88], and are naturally anergic (nonproliferative) to TCR stimulation. However, TCR stimulation of this cell type is required to inhibit the proliferation of CD4+ or CD8+ T cells through antigen-nonspecific, largely cytokine-independent/contact-dependent mechanisms [89–91]. Murine CD4+ CD25+ Treg cells can inhibit autoimmune diabetes in mice [92] and rats [93], induce tolerance to alloantigens [94–96], impede antitumor immunity [97], and regulate the expansion of other peripheral CD4+ T cells (a mechanism that is IL-10 dependent) [98]. The mechanisms of suppression are ill defined, but thus far suggest the inhibition of responder cell IL-2 production [99] and the downregulation of costimulatory molecules on APC [100]. Notably, CD4+ CD25+ Treg cells represent 5–15% of human and murine CD4+ T cells in the periphery of healthy individuals [86,101,102], and their equivalent frequency in the thymus of humans, rats, and mice [103] suggests an evolutionary conservation of their function.

Studies are continuously attributing new functions to these cells, which seem to vary in their reliance upon cytokine production vs. cell-cell contact.

To date, several reports have described different types of regulatory T cells. Repeated stimulation of naive cord blood cells with immature dendritic cells (DC) was found to generate another type of regulatory cell but with more profound production of the regulatory cytokine IL-10 [104]. In mice and humans, another type of regulatory Tr1 cell arose from continuous antigenic stimulation of naive T cells in the presence of IL-10; these cells showed a low proliferative capacity, but upon stimulation released remarkably high levels of IL-10 that inhibited the expansion of other cells [64], rendering them anergic. Additionally, the mucosal administration of antigen gives rise to Th3 cells, a unique T helper profile characterized by TGF- $\beta$ -associated immunomodulation and associated regulatory properties. Whether or not the above “natural” regulatory cells exist or others can be “induced” in MS patients has yet to be determined, and is an important focus for future studies. For vaccination purposes, the transfer of these cells into mice has shown promise, but the concept of generating these cells for transfer into humans seems not only cumbersome, but challenging because of the large numbers that would be required. Therefore the ability to induce or expand Treg cells *in vivo* as well as *in vitro* could have important implications in autoimmunity. Those Treg cells that exert bystander suppression in a nonantigen-specific manner need not necessarily recognize the target antigen(s) that are the subject of immune attack. Identification of the sites of action of these cells will be paramount in regulatory T cell therapies. Thus the notion of administering a regulatory T cell that upon activation within the target organ would produce a wealth of modulatory cytokines and “dim” the activity of autoreactive T cells at the lesion site is very attractive. As such, regulatory cells, even beyond the Th2 profile, remain a hopeful, “undiscovered country” of therapeutic vaccine potential in MS.

## II. ANTIGEN-SPECIFIC VACCINES

### A. Administration of Autoantigen

In several models of autoimmunity, systemic administration of antigen has been an effective means of establishing antigen-specific T cell tolerance. The creation of mice expressing a transgenic TCR of a single specificity has allowed a unique opportunity to study responses by an otherwise rare population of antigen-specific T cells. Intraperitoneal (i.p.), subcutaneous (s.c.), or intravenous (i.v.) administration of soluble proteins or peptides in high doses were all found to have some effect in inducing tolerance in autoimmune models [105]. Experimental evidence has shown that systemic injection of antigen induces tolerance in several ways. Concurrent with the observation that T cells undergo apoptosis *in vitro* and *in vivo* following exposure to high or repeat-dose antigen, repeated i.v. administration of high-dose soluble MBP deleted peripheral autoreactive T cells and improved the course of EAE [106]. Notably, apoptosis is achieved only if T cells are preactivated and have entered the

S phase of the cell cycle [107], complicating the use of such a therapy in humans where the *in vivo* state of activation of autoreactive cells is not known.

An alternate approach to systemic antigen delivery has been oral or nasal administration of myelin antigens. Mucosal antigen uptake results in a state of unresponsiveness to EAE induction [108]. Success and mechanisms of protection are largely determined by both the antigen administered and the amount/dose, but generally depend on uptake by the gastric mucosa and subsequent processing. Several groups report that oral administration of MBP to mice or rats before disease induction suppresses acute EAE [109–111]. Suppression was shown to be highly specific for the fed antigen [112], and notably myelin administration was ineffective compared to whole MBP [113]. Administration before induction or at the onset of clinical symptoms could suppress chronic relapsing EAE, but multiple doses were required once relapsing disease had been established. At least five mechanisms have been proposed for oral antigen-induced tolerance: immune deviation, deletion, alternate trafficking patterns, active suppression, and anergy. Higher doses favor anergy or deletion of autoantigen-specific cells, whereas lower doses induce regulatory CD4+ T cells that mediate bystander suppression by producing the immunomodulatory cytokines IL-4, IL-10, and TGF- $\beta$  [48]. A recent report describes tolerance induction as a dynamic process, and each mechanism may contribute to tolerance albeit at different times: After a rapid removal of antigen-specific cells from the periphery as soon as 1 hr after oral antigen treatment, cells gradually return for about 1 week, followed by a final depletion that results in the protection of mice from severe EAE [114]. Th2 cytokines (IL-10 in particular) increased but only transiently, and is significant in light of work by Groux et al. [63] describing a role for IL-10 in the generation of peripheral unresponsiveness. Recently, others describe the *in vivo* activation and enrichment of CD4+CD25+ regulatory T cells following oral and i.v. antigen administration, with suppressor function *in vitro* at least partially dependent on IL-10 and TGF- $\beta$  [115,116].

While generally effective in mice, several issues need to be addressed before administration of self-antigen becomes an acceptable approach to prevent/treat MS. The precise role of CD4+ T cells, CD8 T cells, and B cells in mediating MS will have to be clarified better to optimize the therapeutic effect and to avoid unwanted side effects. An obvious danger exists in that cells require activation prior to their deletion via activation-induced cell death [117], activation, which may, if only transiently, worsen disease [118,119]. Antigen administration heavily relies on meeting the challenges of defining pathogenic autoantigens, the spread of the response to different antigens, and sparing regulatory T cell populations that assist in reducing the immune response. Notably, i.p. injection of MOG following active induction of EAE with MOG in marmosets was found to block T cell proliferation to MOG and clinical signs during the treatment period, but upon treatment cessation resulted in a hyperacute form of the disease mediated by autoantibodies and associated with increased anti-MOG antibody levels [120]. Of special concern was demyelination induced in marmosets by priming with MBP and PLP that was associated with

spreading of the response to MOG determinants that generated anti-MOG serum antibodies and subsequent immunoglobulin deposition in CNS white matter lesions [121].

Thus far, only oral administration of MBP has been extended to humans. In a 1-year, double-blind, placebo-controlled study of relapsing-remitting MS patients receiving a daily mixture of bovine MBP and PLP, few side effects or toxicities were observed. Patients generated more MBP- or PLP-specific T cells secreting TGF- $\beta$ 1 compared to placebo-treated controls, without increasing the proportion of Th1/IFN- $\gamma$ -secreting myelin specific cells [122,123], supporting the EAE studies. The results of the trial, although not statistically significant, showed a positive trend with improvement in terms of EDSS and attacks, particularly among males [124]. After a longer period of study, results seemed immunologically desirable and showed a trend for betterment, but positive clinical effects in the placebo-controlled group in a small cohort made for statistical insignificance and the trial was deemed unsuccessful [125]. Lastly, the subsequent failure of a Phase III multicenter placebo-controlled study using oral bovine myelin suggests that oral tolerance in humans is thus far not as successful as in mice.

### 1. Vaccination with DNA Encoding Autoantigenic Peptide

As an alternative to antigen delivered as protein, DNA vaccination has been effective in both infectious disease and experimental cancer vaccines through the delivery of prolonged expression of antigen in ways similar to the systemic administration of antigen. Advantages include the ease of handling, stability, the potential for tissue targeting, and sustained delivery/expression. DNA delivery of autoantigens to treat EAE has met with conflicting results. DNA vaccination with PLP 139–151 in SJL mice [126], MBP 68–85 in Lewis rats [127], and others suppressed disease. However, protection induced by i.m. DNA specific for MBP 68–85 was lost following a single amino acid exchange in position 79. Here protection was unlikely via bystander effects because protection was highly specific for MBP 68–85 and not for a second encephalitogenic sequence, MBP 89–101 [128]. However, difficulties were again observed in the administration of MOG DNA: Mice developed an exacerbated form of EAE when challenged with either MOG or an unrelated encephalitogen, PLP [129]. Further studies are required to determine whether problems relevant to MOG antigen-specific therapies result from induction of T cell without B cell tolerance, knowing that B cells and antibodies are a definitive and possibly unique element of MOG-induced autoimmunity.

### 2. Cellular Delivery of Peptide: Trojan Horses

The delivery of antigens already fixed to antigen-presenting cells has also shown particular promise in several models, and allows for management not only of the antigen delivered but also accompanying costimulatory signals. Antigen-specific tolerance could be induced in established, relapsing-remitting EAE by the transfer of PLP 139–151 coupled to chemically fixed splenocytes [130]. Animals were pro-

tected from further relapse associated with epitope spreading to different myelin antigens. Even tolerance induction prior to disease induction with relapse-associated antigens remarkably reduced relapse rates, albeit after a typical primary attack [131]. Thus tolerance induced via antigen-coupled splenocytes does not result in immune deviation or TGF- $\beta$ -mediated bystander suppression as in other tolerance protocols. In a model of autoimmune myocarditis [132], a similar protocol effected peripheral tolerance in both T and B cells, suggesting even stronger potential for this approach in autoimmunity mediated by both B and T cells. The method of fixing the APCs and thus protecting against *in vivo* stimuli that may alter the nature of their activating potential (i.e., tolerization changing to full activation and subsequent T cell effector function) enhances its promise for immunotherapy. While cancer vaccine strategies have focused on dendritic cells with their potent stimulating properties (nondesirable properties in combating autoimmunity), the tolerogenic properties of immature or IL-10 cultured DC show promise for their use in tolerization protocols in autoimmunity. Dendritic cells loaded with MBP 68–86 conferred resistance to subsequent EAE induction [133]. Interestingly, transfer of DC isolated from MBP 68–86-induced EAE rats (without antigen loading) also afforded protection in naive rats prior to MBP 68–86 immunization [134]. By negating the need for antigen loading, these DCs are also promising for antigen-specific tolerization.

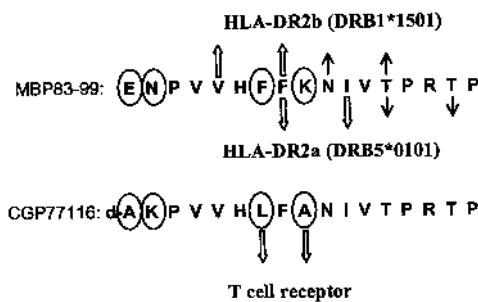

### B. Altered Peptide Ligands

The strength of the signal for T cell activation can determine either full T cell activation (with induction of a Th1 inflammatory response), partial activation (and induction of a Th2 type response), or unresponsiveness/anergy. Thus altering the peptide acts to influence the strength of this signal and thereby also the final effector profile of the T cell. In several animal models, altered peptide ligands (APLs) were created by changing TCR contact residues in immunodominant self-epitopes to impair the strength of the TCR signal. By design, therapeutic mechanisms of APL were postulated to involve MHC blockade [135], TCR antagonism [136], or anergy induction [137] via “impostor” interactions with autoreactive cells at the trimolecular complex. Administration of APL was originally speculated to result in immune deviation of the pathogenic cells *in vivo*, a difficult task *in vitro*. When administered with the wild-type peptide to SJL mice, an APL with two amino acid substitutions at key TCR binding sites of the encephalitogen PLP 139–151 induced PLP-specific Th2 cells that secreted IL-4, IL-10, and protected from disease. While immunization also protected against subsequent disease induction with PLP 178–191, MOG 92–106, or mouse MBP, APL immunization did not prevent the generation of PLP 139–151 specific T cells [138]. EAE protection after the adoptive transfer of Th2/Th0 cytokine producing APL-specific T cell clones suggested instead that the main mechanism of action resides in the delivery of suppressor cytokines [139], where protection was abolished with combinations of neutralizing antibodies to IL-4, IL-10, IL-13, and TGF- $\beta$  [140]. Thus APLs are most likely to afford their greatest protection *in vivo* through the generation of regu-

latory cells with effector cytokine production and bystander suppression rather than antagonism or other mechanisms.

As with other TCR- or antigen-targeted therapies, APL therapy heavily relies on the identification of autoreactive T cell specificities if one is truly interested in targeting the autoreactive cells. In developing potential APLs, one must consider numerous interactions at the tri-molecular complex in light of MHC structural variance and the incredible diversity of TCR recognition. As an example, in vitro studies identified immunodominant epitopes of MBP in the amino acid region of 80–100 [21]. While MBP 83–99 is the immunodominant region of MBP in humans and is also encephalitogenic in two animal models (PL/JxSJL/J F1 mice and Lewis rats), different amino acids are important in each system for MHC and TCR recognition. For example, a proline to alanine substitution in MBP 87–99 (96P→A) APL could treat disease in mice, but not rats. Conversely, MBP 87–99 (91K→A) treated the disease in rats, but not in mice [136].

Studies within the past 2 years have strengthened the pathological relevance of T cells specific for MBP 83–99 and thus described an epitope with considerable promise for APL therapy. The *in vivo* immunolocalization of MBP 85–99 bound to HLA DR2, the HLA molecule highly associated with MS, to the brain tissue of MS patients indicates that MBP 85–99 in the context of HLA-DR2 is present in MS lesions [141]. Transgenic mice carrying a human TCR specific for MBP 83–99 and the human HLA-DR2 allele further revealed the pathogenic potential of these T cells with the spontaneous development of demyelinating disease [142]. In humans, the binding motifs of MBP 83–99 to the HLA-DRB1\*0501 and -DRB5\*0101 alleles of the MS-associated DR2 haplotype were identified (represented in Figure 3), and extensive *in vitro* studies using MS-derived MBP 83–99 specific T cell clones revealed critical TCR contact points

**Figure 3** Schema of MBP 83–99 with HLA-DR2 binding motifs compared to an APL CGP77116. Positions 89F and 91K were identified as important TCR contact sites for the majority of autoreactive MBP 83–99-specific T cell clones *in vitro*; these were modified in the APL along with N terminus regions to increase half life (alterations are highlighted). MHC class II binding motifs of MBP 83–99 to DRB1\*1501 and DRB5\*0101 alleles (coexpressed in the MS-associated HLA-DR2 haplotype) are shown with large arrows (major MHC contacts) and small arrows (minor MHC contacts). (Courtesy of B. Bielekova, NINDS, NIH, Bethesda, Maryland.)

[56,143,144]. In human autoreactive clones from a DR2 MS patient, a TCR-APL (MBP 83–99K→A) was able to induce MBP 85–99 reactive T cells to secrete IL-4 in the absence of IFN- $\gamma$  [145]; yet this cross-reactivity is not predictable and probably specific for individual repertoires [146].

Based on these observations, an APL of human MBP 83–99 in the context of HLA DR2 was developed. The APL CGP77116 was designed with changes at the N-terminus to extend *in vivo* half life and alterations in the presumed TCR contacts F89 and K91 to prevent activation of encephalitogenic T cells. Phase I testing showed good tolerability with a significant expansion of APL-reactive T cells, but a concern of poor immunogenicity suggested a higher dosage might be more beneficial [143]. Two Phase II trials were initiated: one smaller baseline-to-treatment cross-over, open label Phase II study [147] and a larger multicenter, double-blind, placebo-controlled study [148]. Both were terminated before the completion of enrollment and/or dosing: The first as a result of atypical MS exacerbations and the second due to the occurrence of APL-induced systemic hypersensitivity. It was concluded that APL treatment activated autoreactive MBP-specific T cells and caused a flare-up of disease in some patients. A review by Bielekova et al. [147] provides insight into the mechanisms of failures of these two studies, and proposes modifications to dosing, but more importantly to the APL design itself, to reduce the potential for pathogenic T cell activation.

### C. Glatiramer Acetate

Glatiramer acetate (GA or Copolymer 1, Cop 1) is the active ingredient of Copaxone, which was approved by the FDA in 1996 for the treatment of relapsing remitting MS. Initially designed with high homology to MBP and to experimentally induce EAE, the acetate salt of a synthetic copolymer of L-glutamic acid, L-lysine, L-alanine, and L-tyrosine did the opposite. Suppression of EAE was demonstrated in all species studied [149], although different encephalitogenic determinants of MBP are implicated in disease induction in the different species. Although the different mechanisms of action are still being defined, they appear to rely heavily on immunological cross-reactivity with myelin basic protein both at the antibody [150] and the T cell level. *In vitro*, GA can competitively inhibit the immune response to MBP of several MBP-specific murine and human T cell lines and clones different in both MHC restriction and epitope specificity [151,152]. GA demonstrates high binding to different MHC class II haplotypes. Therefore it was suggested that it competes for binding with MBP and other myelin-associated proteins including PLP and MOG, which it can efficiently displace from the MHC binding site [153]. While several reports describe a competition-based or antagonistic mode of action, such competition *in vivo* is unlikely as it would require access to the CNS and substantially larger doses. Perhaps the greatest effect of GA is its ability to generate GA-specific suppressor cells in the peripheral immune system. These IL-4, IL-10, and TGF- $\beta$  secreting (Th2/Th3) cells that are induced both in humans and mice upon GA administration most likely act via “bystander suppression” to inhibit MBP-specific effector lines and thus EAE *in vivo*.

[154]. In addition, cross-reactivity to myelin results in suppressor cytokine release upon exposure to MBP, suggesting a very potent role in mediating/suppressing pathogenic MBP-specific T cell responses *in vivo* at the site of myelin breakdown. Such action is supported by observations that GA-specific T lines are capable of crossing the blood–brain barrier and accumulating in the CNS [155]. Recently, oral administration of GA has been found more effective than oral MBP in suppressing EAE in rats, mice, and in primates [156,157], and has led to further human clinical trials.

GA is very well tolerated. Because of its intrinsic heterogeneity, neutralizing antibodies are not observed, so loss of efficacy attributed to depletion is not a concern. Via mechanisms largely attributable to the induction of suppressor/regulatory cells, GA reduced disease exacerbations by about 30% or delayed disease progression or onset in large Phase III trials [158], and has become one of the treatments for MS today. However, it has little effect in preventing disability accumulation once patients have entered a secondary progressive phase of illness. Like the interferons, the success of GA is thus far limited to patients early in disease, and cannot significantly slow progressive MS. However, the converging observations of increased efficacy following oral administration in mice with an increased incidence of regulatory T cells may increase the therapeutic potential of GA.

#### D. T Cell- or T Cell Receptor Vaccination

Immunologists have long been attracted by the idea that the specificity of cellular and/or humoral immune reactions can be exploited for targeted elimination of antigen-specific T cells, e.g., autoreactive cells. This approach would simulate idiotypic network interactions that are well studied for B cell responses, but clearly less for the cellular immune system. A wealth of evidence suggests that mechanisms act in the peripheral organs to regulate autoantigen-specific T cell responses. Initial studies theorized that pathogenic autoreactive T cells (the “pathogens” in MS) attenuated by irradiation or chemical treatment could be used as vaccines to prevent disease based on the possibility of an idotype anti-idotypic T cell response to TCR-related structures on autoreactive T cells [159,160]. In EAE models, vaccination of naive animals with attenuated autoreactive (and otherwise pathogenic) T cells afforded protection from disease induction, and also induced remission of established T-cell-mediated EAE [159–161]. Protection was specific, long lasting, and attributed to direct killing of the target cells or other inhibitory mechanisms such as cytokine secretion.

The antigen–MHC binding region of the TCR is a heterodimer composed of  $\alpha$  and  $\beta$  glycoprotein chains with variable (V) regions. One of the striking features of experimental autoimmunity is the tendency of autoreactive T cells to possess a limited V gene repertoire in forming functional TCRs specific for defined autoantigens [162]. In many murine autoimmune disease models and in the Lewis rat, autoreactive T cells utilizing the TCR V $\beta$ 8.2 gene segment are instrumental in disease induction [163–165]; thus experiments focused on targeting these cells by vaccination with peptides homologous to regions of their variable chains.

Following vaccination, the induction and expansion of regulatory CD4+ T cells recognizing a portion of the V $\beta$ 8.2 chain was operative in spontaneous recovery from EAE in B10.PL mice [166] and immune deviation from a Th1 to a Th2 profile [167]. Each approach modulated disease when administered before EAE induction, with lesser effects upon later administration.

In other strains of mice, as well as in humans, T cell responses to myelin appear more complex and the TCR usage is not as strict. As a result, studies are divided into those targeting specific TCR peptides and those targeting the myelin-reactive T cell population as a whole. One approach in humans was the induction of clonotypic regulatory networks by immunization with bulk preparations of irradiated MBP-specific T cells [168]; here CD8+ regulatory T cells subsequently depleted myelin-reactive T cells. This pilot clinical trial suggested an excellent safety profile with a moderate clinical improvement in some relapsing–remitting MS patients with a reduced exacerbation rate and EDSS stabilization. However, treatment efficacy must be fully evaluated in controlled studies in the future, and such a study is currently being conducted. In a small cohort of MS patients, a detailed determinant analysis of the human anti-T-cell response was reported and showed circulating T cells specific for human V $\beta$ 5.2 and V $\beta$ 6.1 [169,170].

Protection due to T cell vaccination is likely a result of (1) anti-idiotypic antibody responses, (2) anti-idiotypic T cell regulation by CD8+ T cells [163], or (3) immune deviation through the generation of CD4+ Th2 cell regulatory responses. Following administration of TCR peptides, regulatory cells are generated that produce cytokines or directly kill to suppress/eliminate autoreactive T cells. While promising in animals, caveats do exist. The major disadvantages center on the heterogeneous repertoires of autoreactive T cells possible not only between patients, but also within one patient over time. With the possibility of clonal shift or epitope spreading, the TCR of the target cells could be forever changing, and might preclude the ineffectiveness of this therapy in some murine models. However, the ability of this technique to generate regulatory cells producing anti-inflammatory cytokines such as IL-10 that suppress activation and expansion of MBP-reactive T cells [171] may compensate for shortcomings associated with epitope spreading by limiting disease at earlier stages.

The major concerns with T cell or TCR peptide vaccination approaches are theoretical at this point. The existence of a regulatory, truly idiotypic network of T cells is not well grounded experimentally at this time. Further, the number of individual T cells in our organism, i.e., in the order of  $1 \times 10^{11}$ – $1 \times 10^{12}$  in humans, and even more the number of individual TCR, which is much lower, are far outnumbered by the possible antigens. In this context, it appears teleologically highly wasteful to afford a system of regulation that would produce an equal diversity of regulatory TCR to keep in check those that respond to foreign or self-antigen. In addition, it is now evident that T cells are not as specific as previously thought. Because of these considerations, we deem it unlikely both that a true idiotypic network exists and consequently also that it could be employed for specific immune intervention approaches.

### III. CONCLUSIONS AND FUTURE DIRECTIONS

Our increasing understanding of the pathogenesis of MS will be our most powerful tool in generating novel or increasing the effectiveness of existing MS therapies. The heterogeneity of detectable responses against autoantigens, the potential spread of antigen reactivity, diverse genetic backgrounds, and the diversity of the T cell repertoire have made antigen-specific therapy design challenging at best. Treatment involving the administration of peptides or proteins with any significant homology to myelin antigens appears to require at least some degree of autoantigen-specific T cell activation, whether it be on a pathway to death, anergy, regulatory, or encephalitogenic function. However, if the stimulus with which the autoantigen is delivered can be controlled, such therapies retain their promise. Perhaps the most promising alternative to specific pathogenic T cell targeting looks instead to the generation of a mutually exclusive set of cells with a specificity that allows their activation in a setting of demyelination but with a beneficial effector profile. To this end, mucosal administration of antigens has shown some promise, as have observations using Copaxone and the generation of nonpathogenic T cells mediating strong bystander suppression. Some of the future approaches will be testable in appropriate experimental murine or primate models of MS; however, there will be instances in which the full complexity of the immunotherapy will need to be evaluated in MS patients. This assessment should include a pathogenetically well-based rationale and be performed with an optimal trial design. While driving to eliminate or suppress autoreactive T cells, one must also be reminded of the underlying mechanisms that have allowed for this fundamental break in tolerance. If regulatory responses are truly lacking in MS patients as a means of quieting significant immune responses, therapies aimed at boosting these responses may be less effective. Likewise, what underlying factors have prevented natural regulatory T cells, presumably present in MS patients at least before the onset of disease, from mediating recovery from disease?

The next few years will undoubtedly see an increasing number of trials aimed at both the old and the new. They will include extensions of the existing therapies either by reducing the complexity of antigens, or simply altering their route of administration. Novel vaccination strategies employing genetically modified T cells or other immune populations that can be coupled to delivery of autoantigens or other therapeutic factors are on the horizon. While several approaches to vaccination in MS thus far have not shown remarkable clinical efficacy, a lack of deleterious outcome can be built upon. However, the underlying theme must rely on using vaccines in MS to aim to maximize tolerance, while decreasing the potential for pathogenic immunity.

## Vaccine Therapy for Autoimmune Diabetes

Irun R. Cohen

*The Weizmann Institute of Science, Rehovot, Israel*

### I. TYPE I DIABETES MELLITUS

Type I diabetes is caused by an autoimmune attack, apparently by the combined forces of CD4<sup>+</sup> and CD8<sup>+</sup> T cells, directed to the insulin-producing  $\beta$  cells of the pancreatic islets [1]. Destruction of the  $\beta$  cells can proceed very quickly (within weeks to months) in some patients (mostly children) or very slowly (over years) in others (mostly adults); the reasons for this variable rate of progression are not really known, but variable degrees of autoimmune regulation probably affect the rate of destruction. Type I diabetes was once called "juvenile" diabetes because most cases occurred in young people; but now the incidence is rising and the disease is seen to develop in older persons. Indeed, about 10–15% of persons originally diagnosed as suffering from type II diabetes may actually be undergoing a slowly progressive autoimmune process called latent autoimmune diabetes of the adult (LADA) [2]. Type I diabetes is thus among the most prevalent of autoimmune diseases; a specific therapy would help many people.

The factors that initiate the onset of the autoimmune process are unknown, but susceptibility to type I diabetes is associated with certain HLA class II alleles [1]. Like other prevalent autoimmune diseases, type I diabetes is marked by T-cell reactivity to a collective of self-antigens, and not by autoimmunity to only one self-antigen [3]. Unlike most other autoimmune diseases, autoimmune destruction of  $\beta$  cells produces no symptoms; so type I diabetes is usually diagnosed clinically only by the collapse of glucose homeostasis after the destruction of a critical number of  $\beta$  cells, thought to be about 85% of the normal  $\beta$ -cell mass [1].

### II. PRECLINICAL BACKGROUND

Mice of the NOD strain, particularly the females, spontaneously develop a form of type I diabetes similar in many ways to that seen in humans [4]. My colleagues and I reported the serendipitous observation that the 60-kDa heat shock protein (HSP60) was among the collective of antigens targeted

by the autoimmune reaction responsible for  $\beta$ -cell destruction in NOD mice [5]. HSP60 is hyperexpressed in all stressed cells and not just in  $\beta$  cells [6], so it did not seem likely at the time that autoimmunity to HSP60 could play an exclusive role in the destruction of  $\beta$  cells. Nevertheless, the immunology of HSP60 was intriguing and we wondered whether the molecule might give us a handle on the disease process. We proceeded to identify a target epitope for T cells in the HSP60 molecule composed of amino acids 337–360, which we called peptide p277 (277 was the identification number used by the peptide synthesis unit). We found that  $\beta$ -cell destruction could be stopped in NOD mice by the subcutaneous administration of 100  $\mu$ g of peptide p277 in incomplete Freund's adjuvant (IFA) [7]. However, it was known that diabetes could be prevented by a variety of treatments administered to young NOD mice early in the course of the autoimmune process, including "nonspecific" immune stimulation [8]; hence we tested whether p277 vaccination late in the autoimmune process could still halt  $\beta$ -cell destruction. Indeed, we found that p277 peptide treatment was effective even after the mice were clinically diabetic [9]; residual  $\beta$  cells could indeed be saved by p277 vaccination.

Successful treatment with p277 was associated with a temporary shift of the spontaneous autoimmune response to HSP60 from a destructive Th1 reaction to an anti-inflammatory Th2 reaction [10]. This Th2 shift was accompanied by downregulation of spontaneous autoimmune reactivity to other antigens in the diabetes collective such as insulin and glutamic acid decarboxylase. Immune reactivity to bacterial antigens remained in the Th1 mode in the treated mice; vaccination with p277 did not debilitate the immune system indiscriminately. After some weeks, the Th2 autoimmunity induced by vaccination spontaneously resolved, and the mice appeared to return to a preautoimmune state; the Th1 autoimmunity did not recur. Moreover, animals treated with p277 showed no toxic reactions or immunological deviations from normal. At this point, we felt that therapeutic vaccination with p277 might be of use in human diabetes, and we sought the human connection. We found

that peptide p277 fit the MHC class II binding groove of the HLA susceptibility allele of humans as well as the H2-IA susceptibility allele of NOD mice [11]. Moreover, a significant number of humans, like NOD mice, manifested T-cell autoimmunity to p277 during the development of type I diabetes [12]. It now appeared reasonable to test p277 vaccination in human disease.

There remained two technical problems to solve: IFA could not be used in humans and peptide p277 was chemically unstable. We surveyed several potential vehicles for p277 and discovered that a metabolizable vegetable oil approved for human injection could be used in place of IFA. After experimenting with various amino acid substitutions, we discovered that the p277 peptide could be made stable by substituting the two cysteine residues of the native sequence with valines [9]. The amino acids serine, alanine, or alpha-amino-butyric acid were not effective in substituting for the problematic cysteines (not published). The valine modification was completely cross-reactive with the native p277 peptide; valine-modified p277 does not function as an altered peptide ligand (see below). The valine-modified p277 in vegetable oil is presently called DiaPep277.

We can summarize the background for human trials as follows:

1. Peptide 277 is a target for spontaneous autoimmune T cells in type I diabetes in both NOD mice and human diabetes patients.
2. Therapeutic vaccination using p277 can arrest the progression of  $\beta$ -cell destruction in NOD mice.
3. Preservation of  $\beta$  cells induced by p277 vaccination is associated with temporary activation of a Th2 response to p277 and by lasting downregulation of the Th1 autoimmune reactions associated with type I diabetes.
4. Vaccination with p277 safely leaves intact immune reactions to other antigens not involved in the autoimmune diabetes process.

The question now was whether humans developing type I diabetes would, like NOD mice, respond to p277 vaccination by stopping their  $\beta$ -cell destruction.

### **III. PHASE I TRIALS FOR THERAPEUTIC VACCINES**

Phase I clinical trials are designed to test safety, and not effectiveness. For this reason, Phase I trials traditionally recruit healthy volunteers: persons who would not be expected to benefit from the test treatment, but who still could manifest any adverse effects of the treatment. Consider, however, that exposing a person to a vaccine will leave a mark on the person's immune system. The immune system, like the central nervous system, learns from experience [13]. Both systems continuously organize their repertoires in response to the ongoing interactions of the individual with the individual's internal and external environments. Any immune experience, like any cognitive experience, is formative. Indeed, this cognitive capability of the immune system is what makes vaccination possible; the immune system is

educable [13]. This means that the effects of a vaccine, unlike those of classical pharmaceutical agents, will outlive the catabolism or excretion of the active substance. Hence, any Phase I trial of vaccination will intrude enduringly, if not permanently, in the internal structure of the immune systems of the trial subjects. This consideration led us to disqualify healthy volunteers for a Phase I trial of p277 vaccination.

In place of healthy volunteers, we opened the trial to persons who were already ill with type I diabetes and who had no residual  $\beta$  cells to be saved. We recruited adult male volunteers who had been diagnosed as suffering from type I diabetes for at least 5 years and in whom  $\beta$ -cell function was undetectable: they failed to produce endogenous insulin despite stimulation with intravenous glucagon. We excluded females so as not to expose yet-to-be-born children to the unknown effects of any maternal anti-p277 antibodies transported across the placenta. No adverse reactions to DiaPep277 were noted. The stage was set for a Phase II trial of vaccination.

### **IV. PHASE II TRIALS**

Phase II clinical trials are designed to test effectiveness, as well as toxicity. The proof of clinical effectiveness for a therapeutic vaccine for type I diabetes would have to be the arrest of  $\beta$ -cell destruction. Likewise, aggravation of  $\beta$ -cell destruction would indicate a negative clinical effect. Our studies in NOD mice indicated that the immunological effectiveness of the DiaPep277 vaccine would be manifest in the induction of a specific Th2 response to HSP60 and the p277 epitope. Thus, the end points for the Phase II trial focused on detecting endogenous insulin production as a measure of  $\beta$ -cell survival and on assaying the cytokine profile of T-cell autoimmunity to HSP60 and p277.

Thirty-five consecutive male patients, aged 16–55 years, presenting at the Endocrine Clinic of the Hadassah University Hospital, Jerusalem, with type I diabetes of less than 6 months' duration, who manifested basal C-peptide [14] levels of greater than 0.1 nM, were randomized into two groups. The test group was treated by subcutaneous injections of 1 mg of p277 in the vegetable oil vehicle (DiaPep277) at entry and at 1 and 6 months later, a total of three injections. The control group was treated with three placebo injections of the vegetable oil vehicle without p277. The effect of vaccination on  $\beta$ -cell function was detected by glucagon-stimulated C-peptide production; the amount of C-peptide is the standard indicator of the amount of endogenous insulin produced by a subject [14]. We also measured exogenous insulin requirements. T-cell autoimmunity to HSP60 and to p277 was assayed by cytokine secretion. Thirty-one subjects completed the follow-up period of 10 months and were included in the final analysis [15].

During the 10 months, the placebo-treated control subjects manifested a continuous decline in their stimulated C-peptide levels and a persistent rise in their need for exogenous insulin. In contrast, the subjects treated with DiaPep277 maintained their C-peptide response and manifested a reduced need for exogenous insulin ( $P=0.04$  for both measurements compared to the control group). Immunologically,

the T-cell reactivity to HSP60 and to p277 of the DiaPep277-treated group showed a significantly enhanced Th2 cytokine phenotype. The T-cell responses to bacterial antigens were not modified by the treatment, and no adverse affects were noted [15]. Thus, therapeutic vaccination of new-onset type I diabetes patients with DiaPep277 preserved endogenous insulin production, as forecast by the experimental mouse model [9]. Without unblinding the trial, test and control subjects were treated with a fourth injection at 12 months. The differences between the two groups were even more significant statistically at 12 and 18 months (unpublished).

So much for the clinical results. We shall now consider why therapeutic vaccination should work at all and how we might proceed from there.

## V. ORGANIZED AUTOIMMUNITY

The results of our trials are promising for the future of DiaPep277, but, clearly, much remains to be learned about the optimal way to use this particular therapeutic vaccine. Nevertheless, the present findings by themselves constitute a proof-of-concept: a destructively progressive autoimmune process can still be halted, even at its peak activity, by a few injections of a relatively small amount of a single peptide in a vegetable oil vehicle. The apparent simplicity of this therapeutic vaccination is remarkable: how can a collective of different autoimmune T-cell clones [3] be shifted into a Th2 mode and the disease arrested by such a humble stimulus? Even if it would turn out that repeated vaccine boosts were needed to maintain the benefits of peptide treatment, the obedience of a complex autoimmune process to a simple peptide signal remains a fact.

Note that the effectiveness of therapeutic peptide vaccination contradicts the “forbidden clone” concept of autoimmune disease as taught by the clonal selection theory of the immune system [16]. Indeed, the forbidden clone concept explains neither the standard collectives of autoreactivities that characterize many autoimmune diseases nor the ability of vaccination with a self-peptide to abort the process. Clearly, an autoimmune disease is not the work of a renegade clone, but the expression of the internal organization of the immune system. What is this internal organization and how does it empower the p277 epitope of HSP60 to shut off the autoimmune disease process?

We shall discuss an attribute of HSP60 immunology that might explain the effectiveness of therapeutic vaccination: HSP60 is a dominant self-antigen within the immunological homunculus [13,17,18]. The scope of this chapter does not accommodate a detailed exposition of the immunological homunculus, and our discussion will mention only the essential concepts.

## VI. HSP60 AND THE IMMUNOLOGICAL HOMUNCULUS

The term immunological homunculus encompasses two elements: a set of observations and a theory proposed to explain these observations.

*Empirically*, it is clear that a healthy immune system is biased toward responding to a particular group of self-antigens; HSP60 is paradigmatic. The cord blood of newborn human babies is populated with a high frequency of T cells responsive to an HSP60 variant [19]; about a third of healthy adults express spontaneous anti-HSP60 T-cell activity [12] and anti-HSP60 antibodies; and microbial variants of HSP60 are among the most dominant of immunogens, despite the close similarity of these variants to host self-HSP60 [20]. In short, the healthy immune system is not purged of immune reactivity to the HSP60 self-antigen; on the contrary, the adaptive arm of the system is primed from birth to respond and does respond to self-HSP60. Other dominant self-antigens that are the targets of autoimmunity in healthy subjects include myelin basic protein [21], thyroglobulin [22], insulin [23], p53 [24], and the acetylcholine receptor [25]. The immunological homunculus refers to the totality of this natural autoimmunity.

Other observations, thus far only in animal models, show that existing autoimmunity to HSP60 is controlled by several regulatory mechanisms; one of them appears to be an anti-idiotypic T-cell network directed to a T-cell receptor (TCR) relevant to the particular self-antigen. In NOD mice, for example, the onset of autoimmune inflammation in the islets is accompanied by the activation of these anti-idiotypic regulatory T cells; these T cells recognize the TCR (the idioype) of a particular clone of anti-p277 T cells [26]. The anti-p277 T-cell receptor idioype of this clone is expressed in the TCR repertoires of different NOD mice. In other words, this anti-p277 idioype is a shared idioype [27]. Unfortunately for the mice, the anti-idiotypic response decays spontaneously, and β-cell destruction progresses [26]. The important point is that anti-idiotypic regulation can be rescued: therapeutic vaccination with a TCR peptide or adoptive transfer of lines of anti-idiotypic T cells can arrest the progression of β-cell destruction in most NOD mice [26]. The idioype-vaccinated mice make anti-idiotypic T cells that shut off the disease process. Additional regulatory mechanisms controlling autoimmune T cells include anti-ergotypic T cells [28], CD25<sup>+</sup> T cells [29] and Th2/3 regulatory T cells [30]. These natural regulatory mechanisms are within the immunological homunculus concept. They account for the effectiveness of therapeutic vaccination.

Note that the diabetogenic autoimmunity developing in NOD mice can be halted by administering either of two peptide vaccines: the p277 peptide from the HSP60 molecule or an idiootypic peptide from a TCR clone that recognizes p277. The two vaccines are composed of different peptides, but they may both activate similar regulatory mechanisms. It turns out that the TCR peptide vaccine, which triggers anti-idiotypic T cells, also activates a Th2 shift in autoimmunity to peptide p277 [26]. In other words, arrest of the disease process by either vaccine is marked by a similar Th2 response to the p277 peptide of HSP60. Likewise, vaccination of NOD mice with the p277 peptide sustains the anti-idiotypic T cells as it halts the disease process [26].

*Theoretically*, therefore, the regulation of autoimmunity to HSP60 seems to be built into the NOD immune system, and that regulation can be strengthened by thera-

peutic vaccination. This is the rationale for active vaccination as a means to induce the arrest of autoimmune disease.

It would not be surprising if DiaPep277 treatment strengthens anti-idiotypic T cells as it induces the Th2 shift in human subjects. Humans, of course, are not inbred and homozygous, as are NOD mice. Therefore, it is likely that the T cells in each individual human respond to peptide p277 with unique T-cell receptors; humans, unlike inbred mice, do not express commonly shared T-cell receptor idiotypes. Therefore, we cannot expect to be able to effectively vaccinate different humans with a single T-cell receptor peptide. Each person has his or her own private regulatory networks. Nevertheless, the result of the clinical trial reviewed here does demonstrate that different individuals will respond effectively to vaccination with the *same target peptide vaccine*. There seems to be a uniformity of target antigens among different individuals. Truly, the organization of autoimmunity around HSP60 provides a working definition of the immunological homunculus. The immunological homunculus is not a “little man” inside the immune system; the immunological homunculus is the organization of the natural autoimmune repertoire [13,17].

I borrowed the term *homunculus* from neurology. Neurons in the sensory and motor areas of the brain form a localized anatomical representation of the various organs they innervate; the central nervous system operates on the body using a built-in representation of the body. As can be seen in any neurology textbook, the brain's image of the body is bizarre when traced out on the cerebral cortex because the area of cortex devoted to each organ reflects the function of the organ and not its relative size in the body. For example, the thumb occupies more cortical area than does the whole body truck. By analogy to the central nervous system, the autoimmune clonal repertoire of the immune system creates a functional image of the self [13]. The immune image is a molecular image; the immunological homunculus refers to the sets of naturally autoimmune T cells and B-cells whose antigen receptors form a kind of mirror image of the self-antigens they bind. The immunological image formed by the homunculus, like the image of the neurological homunculus, is bizarre; only some relatively few self-antigens are represented. HSP60 is prominent among them. The function of the immunological homunculus in health is only beginning to be studied, but it seems that some of the autoimmune clones may serve to supply the healthy inflammation needed to maintain the body [31].

## VII. AUTOIMMUNE DISEASE

Homunculus theory proposes that pathogenic autoimmune diseases emerge from natural autoimmunity gone awry [13]. A failure of the natural regulatory mechanisms, such as that seen in NOD mice, unleashes the pathogenic potential of the natural autoimmunity present in the immunological homunculus. True, we do not know how homuncular regulation fails or is weakened, but the immunological homunculus concept does explain the observed order of autoimmune

disease unexplainable by classical clonal selection: the auto-antigen collectives involved in various diseases, the relatively few diseases and their similar immunological expression in different individuals and in different species, and, most importantly, the ability of a simple vaccination to shut off the disease process. Homunculus theory, in short, proposes that both the disease and its regulation are built into the system of each subject.

Obviously, much remains to be discovered about the homunculus. How do the clones responsive to homuncular self-antigens avoid negative selection? What makes self-antigens such as HSP60 so immunogenic? It was recently discovered that the self-HSP60 molecule can act as a “cytokine” to activate antigen-presenting cells through an innate receptor, toll-like receptor (TLR)-4 [32]. Study of the effects of self-molecules on the innate arm of the immune system may provide new insights into both the immunogenicity of some self-antigens and the mechanisms that regulate natural autoimmunity. Indeed, activation of TLR-9 by vaccination with oligonucleotides bearing the CpG bacterial motif can inhibit the development of NOD diabetes [33]. CpG treatment was associated with a shift of HSP60 autoimmunity into a Th2 mode. Thus, the phenotype of autoimmunity is influenced by innate interactions with signal molecules of infectious agents. The self-organization of the immunological homunculus is molded by the totality of the individual's immune experience [13].

## VIII. THE LOGIC OF THERAPEUTIC VACCINATION

Theory leads to practice. Different immunological theories provide rationales for different clinical trial protocols. The forbidden clone theory of autoimmune disease implies its own strategy for therapy; kill or inactivate the forbidden clone and the autoimmune disease will vanish [16]. The homunculus theory of autoimmune disease does not support the strategy of clonal inactivation; on the contrary, the homunculus suggests that once we reactivate natural regulation, the immune system itself will control the autoimmune collective and shut down the disease [13,34]. The two theories recommend opposite approaches: inactivation versus activation. Inactivation of autoimmune T cells by blocking peptides or by toxin conjugates were proposed early on as the solution to autoimmune disease, but the proponents of these approaches are now less assertive. Altered peptide ligands are the latest approach to inactivation therapy, as we shall discuss below.

The apparent success of therapeutic peptide vaccination reviewed here suits well the idea of homuncular activation. In this light, vaccination with a suitable self-antigen or self-peptide would appear to be a natural choice. Each autoimmune disease will need its own particular vaccine, and the challenge will be to find the most effective vaccine for each disease. Multiple sclerosis, for example, might respond to vaccination with a peptide of a myelin antigen [21], myasthenia gravis to a peptide of the acetylcholine receptor [25], lupus to a peptide of p53 [24], and so on. Dose of vaccine and schedule of treatments will be critical factors.

## IX. COMPARATIVE IMMUNOMODULATION

Peptide vaccination is only one of several modalities in clinical trials for autoimmune disease therapy. T-cell vaccination refers to a procedure in which a therapeutic vaccine is prepared using cultures of autoimmune T cells obtained from the individual patient [35]. T-cell vaccination was first discovered to be effective in regulating experimental autoimmune diseases in animal models [26,36]. The rationale for T-cell vaccination, as we discussed above, is to activate natural anti-idiotypic and anti-ergotypic networks using the patient's own autoimmune T-cell clones, suitably attenuated [36]. Several hundreds of multiple sclerosis patients have been treated in various open trials, with encouraging results. However, randomized, placebo-controlled studies are just now being undertaken, and proof of effectiveness awaits the results of these trials [35].

Oral, or mucosal, tolerization is another form of immune therapy that could be viewed as a kind of vaccination. Foodstuffs along with other antigens that enter the body through mucosal surfaces have been shown to induce anti-inflammatory Th2/3 cytokine immune reactions [37]. The idea behind oral tolerance is to exploit this natural property of the mucosae and induce resistance to autoimmune attack by administering target self-antigens via this "immunomodulatory" portal [38]. Despite the success of oral tolerance in animal models, this form of treatment has failed to demonstrate effectiveness in clinical trials [39]. Perhaps the development of suitable monitoring assays will make it possible to adjust the dose and dose schedule of oral immunomodulation to the needs of the individual patient's gut absorption and immune state. Until then, protocols for oral tolerization will continue to suffer from uncertainty.

Altered peptide ligand (APL) therapy is yet another type of specific immunomodulation [40]. APL peptides are modifications of natural self-ligands engineered so that they will interact with specific clones of autoimmune T cells through low-affinity binding. Such interactions have been shown to inactivate or "anergize" the specific T cells [40]. Note, however, that the APL approach is quite the opposite of vaccination. The APL concept fits the classical clonal selection theory that attributes autoimmune diseases to the emergence of forbidden clones of autoimmune lymphocytes. The rational way to treat autoimmune disease, according to that idea, is to rid the body of the renegade lymphocytes, and the APL "anergizer" is the latest version of clonal therapy. To insure that all the "forbidden" T cells are inactivated, APL therapy involves relatively high doses of peptide and frequent and prolonged administration. Vaccination therapies, as we have discussed here, aim to reactivate natural immune regulation [17] using limited vaccination protocols [15]. Natural regulation mechanisms are tuned to natural self-epitopes, and not to APLs. Altered peptide ligands, therefore, are likely to be recognized as independent antigens by additional clones of lymphocytes. Indeed, a trial of APL therapy in multiple sclerosis had to be stopped because of the appearance of allergic reactions [41] and aggravated disease [42]. It is conceivable that APL therapy could be safer and more effective when administered in small amounts, infrequently and with adjuvants.

But then, the APL would no longer be an anergizer, but a true vaccine.

## ACKNOWLEDGMENTS

I am the incumbent of the Mauerberger Chair in Immunology and Director of the Robert Koch Minerva Center for Research in Autoimmune Disease, at the Weizmann Institute of Science, Director of the Center for the Study of Emerging Diseases, Jerusalem, and a consultant for Peptor, LTD, Rehovot, Israel.

## Vaccines for the Treatment of Autoimmune Diseases

David C. Wraith

*University of Bristol, Bristol, England*

### I. BACKGROUND

#### A. Definition of a Vaccine

The term vaccine is defined as follows: "A vaccine is a material originating from a microorganism or other parasite that induces an immunologically mediated resistance to disease" [1]. It is now clear, however, that vaccines can be created for treatment of disorders other than infectious diseases including cancer, allergy, and autoimmune disease. The Mims definition may therefore be simplified to "A vaccine is a material that induces an immunologically mediated resistance to disease."

It is quite straightforward to extrapolate from infectious disease vaccines to cancer vaccines. Many tumors express tumor-specific antigens, and the hope is that these may be used, just as the specific antigens of many infectious agents have been in the past, as the basis for effective vaccines. A paradox arises, however, when we consider vaccines for allergy and autoimmune disease. The aim, in the case of infectious diseases and cancer, is to induce as strong an immune response to the vaccine antigen as possible. In allergy and autoimmune disease, however, the pathology is caused by the immune response itself. Hence, the aim has to be quite the opposite of the conventional infectious disease or cancer vaccine. Here we must aim to dampen down or suppress the disease by desensitizing the individual.

#### B. The Inadequacy of Current Treatments for Autoimmune Diseases

Current therapies for autoimmune diseases are based on treatments that nonspecifically suppress the patient's immune system. These therapies can be quite potent and their use is associated with a range of complications.

1. Continuous suppression of the immune system can allow infectious organisms to colonize the individual. Drastic immune suppression may also disturb

the normal immune surveillance that prevents tumor growth.

2. Chronic autoimmune disease requires long-term immune suppression. Compliance with treatment is difficult to ensure especially when the treatment is associated with obvious side effects.
3. Nonspecific immune suppression can disturb natural immune regulatory processes. Recent evidence demonstrates that drugs such as cyclosporine can interfere with tolerance mechanisms including apoptosis and anergy induction [2,3].
4. Long-term treatment is expensive.

#### C. The Case for Antigen-Specific Immunotherapy of Autoimmune Disease

Autoimmune diseases arise as a consequence of autoimmunity, i.e., an immune response to a self-antigen. Autoimmunity is a common feature of the immune system [4] and can be identified in all individuals whether or not they have disease. Disease is prevented by various central and peripheral mechanisms that lead to the deletion or regulation of autoreactive lymphocytes [5]. Autoimmune disease can therefore be seen as a "breakdown in self-tolerance." The Holy Grail for treatment of autoimmune diseases must be to discover how to reinstate self-tolerance, preferably by making such treatments as specific for the disease as possible.

Autoimmune diseases may be defined either as systemic or organ specific. Among organ-specific diseases, there may be a single antigenic target, such as the acetylcholine receptor in myasthenia gravis [6], or a variety of antigenic targets, as is likely to be the case in multiple sclerosis (MS) [7]. The ideal situation would be to induce antigen-specific tolerance to avoid global immune suppression and hence maintain the immune response to infectious agents. Where several different antigens are involved it will be necessary to induce a bystander mechanism that would direct suppression to the appropriate anatomic site and the range of antigens ex-

pressed at that site. The systemic autoimmune diseases may be more complex to treat by this approach because the pathology is widespread. Nevertheless, recent studies in mice raise the hope that peptide vaccination could suppress autoantibody generation and hence prolong survival in systemic lupus [8].

#### D. Vaccines for Autoimmune Disease: A Paradox

The idea that one can vaccinate to suppress an immune response would appear, at face value, to be a contradiction in terms. Yet, we have known for more than a century that it is possible to suppress immunity by encounter with antigen. It was a French physician, Dakin, who noted that the hypersensitivity reaction to poison ivy could be avoided by eating the forbidden leaves [9]. This early description of "mucosal tolerance" was placed on a more scientific footing by Alexandre Besredka who noted that guinea pigs fed milk became resistant to the anaphylactic reaction induced by intracerebral injection of milk proteins [10]. Subsequently, Merrill Chase demonstrated that antigen feeding had an antigen-specific suppressive effect on subsequent immune challenge [11].

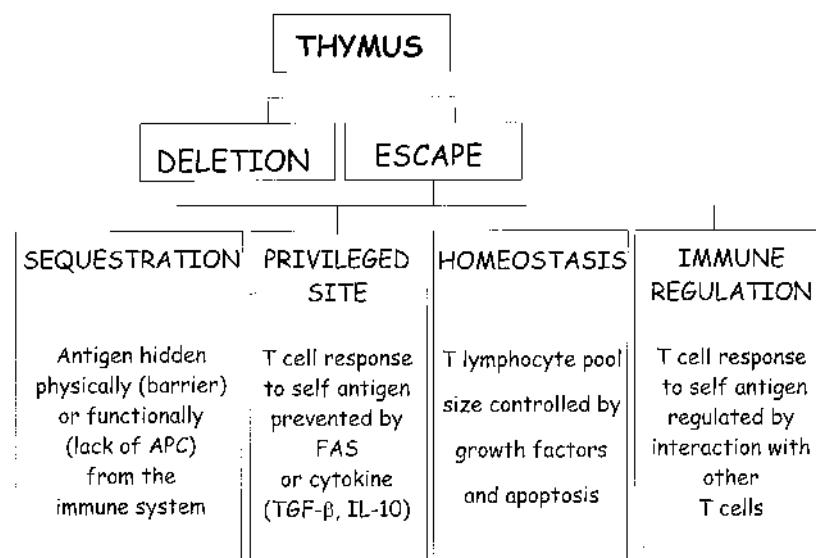

There is an attractive logic inherent in the concept of mucosal tolerance. We accept that the immune system generally tolerates encounter with noninfectious antigens. Think of the bulk of antigens that we must eat and inhale each day. Normally we tolerate this material unless, that is, we suffer from allergy to food or an airborne particle such as pollen or dust mite feces. The question is whether mucosal delivery of a self-antigen would enhance the state of tolerance to that antigen. Here I will introduce some recent advances in our understanding of self-tolerance and discuss

how this is guiding our approach to the design of effective vaccines for the treatment of autoimmune disease.

## II. THE CONCEPT OF IMMUNE REGULATION

Immunological tolerance toward self-antigens is provided by central and peripheral mechanism. These apply to both B and T lymphocytes, although it appears that the mechanisms relating to T cells are especially important. This is because B cells have evolved to continuously mutate their antigen receptor through the process of affinity maturation. B cells are dependent on T cells for both isotype switching and affinity maturation, and it is therefore logical that tolerance to self-antigens should depend largely on T cells. Tolerance is induced in immature T cells as they mature in the thymus by an avidity-dependent process [12,13]. There is clear evidence that central tolerance is incomplete despite the fact that many self-antigens are expressed in the thymus [14]. Thus, T cells specific for antigens such as myelin basic protein (MBP) are commonly found in the peripheral lymphoid tissues of man [15] as well as rodents [16]. It is increasingly clear that such self-reactive cells are under the tight control of various regulatory mechanisms acting on mature lymphocytes [17]. These include homeostatic [18] as well as regulatory mechanisms [19] (Figure 1).

It is now evident that various types of regulatory cells serve to suppress autoimmunity in healthy individuals. One subset of regulatory cells (Treg) develops naturally in the thymus [20]. These cells constitutively express CD25, proliferate poorly in response to antigen, and regulate the growth of neighboring T cells through cell-cell contact. It is now apparent, however, that distinct CD4 positive Treg cells can be induced with antigen. Antigen-induced Treg cells fall into

**Figure 1** Mechanisms of peripheral tolerance among T lymphocytes. Many self-reactive T cells are deleted as they develop in the thymus. Some self-reactive T cells escape deletion in the thymus and appear in peripheral tissues. Autoimmune disease is prevented by a variety of mechanisms ranging from the sequestration of antigen to immune regulation.

**Table 1** The Nature of Induced Regulatory T Lymphocytes

	Th3	Tr1	Tr1/Th10
How raised	Oral antigen	L-10 in vitro	Systemic sol. antigen in vivo
Mechanism	TGF- $\beta$	IL-10	Cell-cell contact, IL-10
Reference	[21]	[29]	[23, 25]

Th3 cells are induced by oral administration of intact antigen and regulate autoimmune disease through the production of TGF- $\beta$ . Tr1 cells may be generated in vitro by repeated stimulation with antigen in the presence of IL-10. IL-10-secreting cells may also be induced in vivo by repeated administration of superantigens or soluble, preferably peptide, antigens.

two categories (Table 1), those induced by oral administration of intact antigen [21] and those induced by repeated administration of either peptide antigens [22] or superantigens [23]. The cells induced by oral administration of intact antigenic proteins include T helper (Th) type 3 (Th3) cells, the helper cells for IgA production, as well as more conventional Th2 cells. Th3 cells produce transforming growth factor beta (TGF- $\beta$ ), the isotype switch factor for IgA. Cells induced by oral administration of antigen suppress autoimmune disease in animal models [24] indicating that TGF- $\beta$  has a direct anti-inflammatory effect on organ-specific autoimmunity. Cells generated by oral or intranasal peptide antigen administration have, on the other hand, been shown to produce interleukin 10 (IL-10) [25,26] rather than TGF- $\beta$  and to resemble cells generated by culture in the presence of this cytokine [27]. The cells generated in culture have been termed T regulatory type 1 (Tr1) cells and have been shown to inhibit both Th1 and Th2 responses and to prevent expansion of naive T cells [28,29]. The fact that Treg cells can be induced by mucosal administration of intact or protein antigen raises the exciting possibility that they could be specifically induced by vaccines to suppress the inflammation associated with autoimmune disease.

### III. WHAT FORM SHOULD THE ANTIGEN TAKE?

#### A. HLA Association

Many autoimmune diseases are associated with a predisposing genotype (Table 2). Among the predisposing genes, the

MHC-associated immune response genes (HLA in man) often show the strongest association. This is not, however, direct and most HLA-associated diseases do not follow a simple Mendelian mode of inheritance, frequently involving several different HLA alleles in addition to non-HLA loci. Nevertheless, association with HLA certainly demonstrates the strongest genetic linkage in diseases such as MS, rheumatoid arthritis, and type I diabetes [30–33]. This raises the hope that specific peptide or protein vaccines could be designed to fit a specific, disease-associated HLA allele.

#### B. The Case for Intact Antigens

Protein antigens are made up of a series of linked epitopes that may be antigenic for T cells from individuals expressing different HLA genes. As mentioned above, HLA association with autoimmune disease is rarely absolute. It is then not likely that a single peptide epitope would be sufficient to induce tolerance in the heterogeneous human population. It was hoped, therefore, that systemic or mucosal administration of whole proteins would effectively induce tolerance and could thus be used for treatment of autoimmune conditions. Even then, there was evidence from experimental animal models of autoimmune disease that more than a single protein would be required. In the experimental model of MS, experimental autoimmune encephalomyelitis (EAE), there was evidence that protein  $x$  would be encephalitogenic in one mouse strain whereas protein  $y$  would cause disease in another mouse strain [34]. There was therefore no reason to believe that a single protein entity would be responsible for

**Table 2** HLA Disease Association in Autoimmune Disease

Disease	HLA allele	Sex ratio (F:M)	Relative risk
Ankylosing spondylitis	B27	0.3	87.4
Type I diabetes	DR3/4 heterozygote	~1	~25
Goodpasture's disease	DR2	~1	15.9
Pemphigus vulgaris	DR4	~1	14.4
Systemic lupus erythematosus	DR3	10–20	5.8
Multiple sclerosis	DR2	10	4.8
Rheumatoid arthritis	DR4	3	4.2
Graves' disease	DR3	4–5	3.7
Hashimoto's thyroiditis	DR5	4–5	3.2
Myasthenia gravis	DR3	4–5	3.7

Many autoimmune diseases display an association with particular HLA genes. Among these associations with class II MHC (HLA DR) molecules are more common.

disease in every single patient suffering from MS. Indeed, there is evidence for T-cell reactivity against a variety of T-cell antigens in MS [7] and further evidence of fluctuation in the nature of the response between antigens during the course of disease [35]. A logical step was therefore to develop tolerance strategies based on the use of mixtures of antigens.

Trials of oral tolerance have involved extracts of myelin in MS, retinal extract for autoimmune uveitis, bovine collagen in rheumatoid arthritis, and insulin in type I diabetes [36]. Unfortunately, none of these treatments provided a dramatic improvement in clinical symptoms. In fact, the uveitis trial indicated that mucosal administration of complex antigens could exacerbate disease. In this trial, patients were treated with either the purified S-antigen or a combination of this antigen with a crude retinal extract [37]. The group receiving the purified S antigen alone appeared to "taper off" their immunosuppressive medication more successfully compared with patients given placebo, whereas all other groups appeared to do worse than did those receiving placebo. This would indicate that the use of complex combinations of antigens should be treated with caution.

Why have clinical trials of oral tolerance been so disappointing? It could well be that oral tolerance to self-antigens is not as easy to generate as first thought. Essentially, there are at least three mechanisms of oral tolerance. The Weiner group has shown that high dose of protein leads to the induction of anergy or deletion in the Lewis rat model of EAE. Low-dose administration, however, generated regulatory cells of the Th2/Th3 phenotype. Our own studies have shown that it is relatively difficult to induce oral tolerance in the H-2<sup>u</sup> mouse model of EAE [38]. Even a low dose of antigen failed to generate tolerance. Further work by Meyer et al. confirmed the difficulty in inducing tolerance in the H-2<sup>u</sup> model. Tolerance was achieved only by feeding vast quantities of protein [39] at levels that could never be achieved in humans on a milligram per kilogram basis. What was more disturbing from the Meyer study was the observation that low-dose oral feeding of self-antigen led to exacerbation of the clinical course of disease. We have to conclude from these studies that the induction of oral tolerance to whole self-antigens is not straightforward. The pioneering work by Weiner [36] and Meyer et al. has revealed a variety of mechanisms by which oral tolerance can be

achieved. At this point, however, it is impossible to predict how oral tolerance with complex mixtures of intact antigens could be achieved safely and reliably in humans. More work is required to investigate dosing effects, the nature of the autoantigen and the use of mucosal adjuvants [40,41] designed to enhance tolerance induction.

### C. The Danger of Antigen-Specific Therapy with Intact Antigen

The obvious danger of administering an intact antigen into an individual prone to autoimmunity is that the treatment might exacerbate disease by (1) priming T cells and (2) mounting an antibody response to the self-protein by activating autoreactive B cells (Table 3). In an experimental model of multiple sclerosis induced by myelin oligodendrocyte glycoprotein (MOG), marmosets tolerized to MOG were protected against acute disease, but after treatment a lethal demyelinating disorder emerged [42]. In these animals, MOG-specific T-cell proliferative responses were transiently suppressed, cytokine production was shifted from a Th1 to a Th2 pattern, and titers of autoantibodies to MOG were enhanced. In this case, immune deviation produced by an apparently tolerogenic immunization schedule led to enhanced immune pathology.

A further danger arises from injection of intact antigens. This is that such soluble antigens can prime cytotoxic T (Tc) cells. Blanas and colleagues demonstrated that oral administration of ovalbumin (Ova) led to the induction of Ova-specific Tc cells [43]. In their model, in which Ova was expressed as a self-antigen in the pancreas, the induction of such Tc cells accelerated the onset of type 1 diabetes. More recently, Hanninen and colleagues have compared different mucosal routes for their ability to induce Tc cells and exacerbate autoimmune diabetes [44]. In their mouse model, delivery of Ova by either oral or nasal routes primed for Ova-specific Tc cells whether the protein was delivered in a high- or low-dose regimen. Ova delivered by either route triggered diabetes in a model in which mice expressed the protein in the pancreas.

The danger of delivering intact self-antigens to the body is therefore twofold. First, there is the possibility that the protein could trigger autoreactive T and B cells leading to the

**Table 3** Potential Danger Associated with Antigen-Specific Therapy

Induction of	Associated danger
Autoreactive B cells and antibodies	Late complications of immune deviation therapy in a nonhuman primate: induction of TH2 cells in marmoset EAE can exacerbate disease by increasing levels of pathogenic antibodies [42]
Autoreactive CD8 "cytotoxic" T cells	Induction of autoimmune diabetes by oral administration of autoantigen: induction of CD8 cytotoxic T cells can trigger disease [43]

Here are two examples of problems arising from the administration of intact protein antigens in therapeutic protocols. In the first, administration of myelin oligodendrocyte glycoprotein led to the induction of a strong Th2 response and pathogenic antibodies. In the second, oral administration of intact protein induced CD8 positive cytotoxic T cells that caused diabetes in an animal model.

production of pathogenic antibodies. Second, intact proteins may prime antigen-specific Tc cells with devastating consequences. We must conclude from the preceding discussion that administration of intact antigens in an autoimmune setting can be highly dangerous.

#### D. The Case for Peptide Antigens

The dangers associated with delivery of intact proteins can be overcome by the use of peptide antigens. The objective here is to use peptides based on the structure of the major class II restricted T-cell epitopes associated with a disease. By inducing tolerance among pathogenic Th cells one would effectively remove help for both pathogenic B and Tc cells. The first advantage of this approach is that peptides are generally poorly immunogenic for B cells (1) because they usually do not retain the three-dimensional conformation of the intact antigen and (2) because well-defined T-cell epitopes rarely contain both the major Th and B-cell determinants required to prime for such a response. The second advantage is that peptide determinants can be selected such that they do not contain known pathogenic Tc epitopes, although knowledge of this is currently limited. Furthermore, there is yet no evidence that the delivery of soluble peptides leads to the induction of autoreactive Tc cells.

#### E. The Pros and Cons of Altered Peptide Ligands

Triggering a T cell is not the same as switching on a light. There are numerous states of activation between resting/inactive and fully activated. Some of these states, whether they represent anergy or an altered state of cytokine production, have been associated with self-tolerance and can be generated by the use of T-cell receptor antagonists. Such antagonists are based on peptide ligands that are altered at residues interacting with the TCR. T-cell antagonism is defined as a specific and dose-dependent downmodulation of agonist-induced T-cell proliferation when both agonist and altered peptide ligand (APL) are presented to the T cell simultaneously [45]. It has been proposed that it might be safer to base antigen-specific treatment of autoimmune disease on the use of such peptides since APL should fail to activate autoreactive T cells and should be inherently safer [46]. Initial studies of APL treatment in well-defined animal models were indeed extremely promising [47–51]. Recently, however, clinical trials of APL treatment have been undertaken in MS and have been less encouraging. A common target for MBP specific T cells in HLA DR2 positive MS patients is an epitope within the 83–99 region. Two trials of peptide therapy with an APL based on MBP 83–99 were recently reported in *Nature Medicine*. The first Phase II trial using this APL had to be curtailed because of side effects [52]. Some patients developed signs of urticaria because of the Th2 response to the APL that developed following repeated administration. In a second open-label trial two patients were reported to have suffered treatment-related exacerbations of MS [53]. This disturbing observation was supported by evidence arising from *in vitro* studies of the patient's lymphocytes. Results from this trial showed (1) that a high dose (50 mg per treatment) of the peptide was highly im-

munogenic and induced APL-specific T cells in each individual, (b) three of eight patients suffered exacerbations, and (c) in two of the three patients the exacerbations were linked to the expansion of APL-specific cells that were able to cross-react with the wild-type MBP 83–99 epitope.

Why should a peptide that behaves as a TCR antagonist *in vitro* cause disease *in vivo* and why only in certain individuals? This most probably reflects the fact that an APL will function as a TCR antagonist for a T-cell clone expressing receptor A but may equally work as an agonist for a distinct clone expressing receptor B. This likelihood had previously been raised through the work of Anderton and colleagues using a well-defined mouse model and the N-terminal nonamer peptide of MBP [54]. This might be expected to be a straightforward model to study because there is limited heterogeneity of TCR usage in the H-2<sup>u</sup> restricted response to this peptide with the majority of T-cell clones expressing similar TCRs [55]. Altered peptide ligands with appropriate substitutions at the primary TCR contact residue were prepared and shown to be effective antagonists of one specific T-cell clone (Tg4). As expected, these APLs failed to induce EAE in the Tg4 TCR-transgenic mouse and yet were found to induce disease in susceptible, nontransgenic H-2<sup>u</sup> strains of mice. This proves that one T cell's antagonist can be the next cell's agonist and emphasizes just how diverse and flexible the TCR repertoire can be, even in a simple mouse model. Extrapolate this to the likely diversity of the TCR repertoire in an outbred population such as man and you have to conclude that the use of TCR antagonists loses its appeal as a therapeutic approach. The remainder of this chapter will therefore concentrate on the use of natural peptides as vaccines for the treatment of autoimmune diseases.

### IV. RULES GOVERNING THE USE OF PEPTIDES FOR THERAPY OF AUTOIMMUNE DISEASE

Various laboratories have now tested peptide therapy as an approach to the prevention and treatment of autoimmune and allergic conditions. The favored route of administration has been mucosal. This is not to say that other routes of administration including intraperitoneal, subcutaneous, and intradermal may not be equally effective for certain peptide antigens. It is believed, however, that the mucosal immune system has evolved to tolerate encounter with antigens when they are not associated with infectious agents (see above). A logical step was therefore to test mucosal delivery of soluble antigens derived from self-antigens or allergens.

#### A. Peptide Therapy Is Effective in a Wide Range of Disease Models

Peptide therapy has proven effective in a wide range of disease models. Fragments of MBP were found to be as effective as the intact protein in prevention of EAE [56]. The 139–151 peptide of PLP has been shown to prevent EAE when administered by either the oral [57] or intranasal [58] route. Furthermore, Liu and colleagues revealed the synergistic effect of different MBP peptides in the rat model of EAE [59].

The nasal route of administration has proven effective for prevention of various models of arthritis. Staines et al. [60], Myers et al. [61], and Chu and Londei [62] have all demonstrated the efficacy of peptides derived from collagen in models of collagen-induced arthritis. Most interestingly, Prakken and colleagues demonstrated that a single peptide, derived from the heat shock protein HSP60 and given by the intranasal route, would protect rats from arthritis induced by either *Mycobacterium* or avridine [63]. Peptides derived from a variety of pancreatic islet antigens have been used to suppress diabetes in the NOD mouse model [64–66] and more recently in man [67]. The fact that a single peptide can prevent arthritis induced by different antigens [63] would imply a bystander suppressive mechanism. This is further supported by observations in diabetes whereby peptides derived from diverse antigens, including glutamate decarboxylase [64], insulin [65], and HSP60 [66], would equally suppress disease in the same animal model. Peptides derived from the S-antigen have been used to prevent experimental autoimmune uveitis [68], peptides from the acetylcholine receptor models of autoimmune myasthenia gravis [69] and peptides from the P2 antigen models of experimental allergic neuritis [70]. A number of groups have also described the use of the peptides to suppress the immune response to allergens. Hoyne and colleagues first described the use of nasal peptides to suppress the immune response to the major house dust mite antigen [71]. More recent work has demonstrated inhibition of mucosal and systemic Th2-type immune responses by intranasal peptide therapy in the Der P1 model [72].

### B. Route of Administration

Some years ago, our laboratory compared oral and intranasal routes of peptide therapy. The nasal route proved far more effective than the oral route for tolerance to the N-terminal peptide of MBP [73]. This peptide is, however, a relatively weak antigen [74], and there is no reason why the oral route should not be equally effective for more potent antigenic epitopes. Others have compared oral and nasal routes for prevention of collagen-induced arthritis. Results have been varied with some groups demonstrating improved efficacy by the nasal route [75] and others observing no significant difference [60]. Furthermore, Jung and colleagues could show no difference between oral and nasal administration of the P2 peptide in a model of experimental autoimmune neuritis [75]. Most probably, the nasal route of administration is more sensitive than the oral route for weaker antigens because they are less likely to be destroyed before they can exert their tolerogenic or suppressive function.

### C. Duration of the Effect of Peptide Therapy

The longevity of suppression mediated by a single dose of tolerogenic peptide was measured in the mouse model [76]. The N-terminal peptide of MBP had been previously shown to induce tolerance in the H-2<sup>u</sup> mouse model of EAE [73]. This peptide was administered intranasally to either euthymic or thymectomized animals. A single dose of peptide induced permanent tolerance in thymectomized animals.

Euthymic animals, however, recovered responsiveness over an 8- to 16-week period. A single dose of intranasal peptide could therefore induce long-lasting thymus-independent, peripheral T-cell unresponsiveness, the recovery of which relied entirely on new T cells being exported from the thymus.

### D. The Mechanism of Peptide Therapy

Several studies have compared the mechanism of tolerance induced by either systemic or mucosal antigen administration. High doses of antigen may induce apoptosis among antigen-specific cells. Critchfield and colleagues were able to detect apoptosis following high-dose administration of antigen in the EAE model [77]. Similarly, Kearney and colleagues described activation-induced cell death as a mechanism involved in antigen-specific tolerance induction [78]. Similarly, several investigators have shown a significant amount of deletion after repeated antigen injection or feeding [79,80]. Deletion of CD-4 T cells in the periphery, however, is never complete and usually leaves a small population of residual T cells.

Although there seems little doubt that some activation-induced cell death occurs in response to antigen in almost any setting, there is now strong evidence that induced tolerance involves alteration in cytokine production. The type of cytokines involved will depend on several conditions: (1) route of administration, (2) genetic background of the recipient, and (3) nature of the antigen. As mentioned above, the response to intact antigen encountered at mucosal surfaces tends to be dominated by Th2 and Th3 cytokines. Most notably, Th3 cells producing TGF-β have been implicated in oral tolerance to intact protein antigen. One might imagine that long peptides would mimic intact protein antigens in their mechanism of tolerance induction. A recent study by Astori and colleagues showed, however, that long peptides based on the structure of phospholipase A2 tended to induce a shift from a Th2 toward a Th1 cytokine profile [81]. Notably, however, IL-10 secretion was not measured in this study.

A detailed study by the Weiner group has compared the administration of either intact antigen or short peptides given orally or intranasally. Despite previous evidence to suggest that administration of protein or peptides in the NOD mouse would drive Th2 responses [64,65] this study showed a clear distinction between protein and peptide. Mucosal administration of intact protein primed for TGF-β, whereas mucosal peptides primed for IL-10-secreting T cells [26].

It appears then that a hierarchy of responses to mucosally administered antigen exists and this depends on the nature of the antigen. The response to intact protein is generally dominated by Th3 cells, whereas long peptides have been reported, in one strain of mouse, to induce Th1 cells. The evidence to date implies that administration of short peptides may induce IL-10-secreting cells. Our own laboratory has provided strong support for the role of IL-10 in peptide-induced tolerance. Studies in the Tg4 TCR transgenic mouse did not provide evidence for apoptosis as a tolerance mechanism following intranasal peptide adminis-

tration [25]. Repeated doses of intranasal peptide nevertheless completely protected the transgenic mice from EAE induction (Table 4). Such treatment also resulted in downregulation of the capacity of antigen-specific CD-4 T cells to proliferate or to produce IL-2, interferon gamma, and IL-4 but increased the production of IL-10. The role of IL-10 in suppression of EAE was confirmed *in vivo* by neutralization of IL-10. This completely restored susceptibility to EAE in mice previously protected by intranasal peptide.

Interleukin-10 has been associated with the induction of long-lasting anergy in human CD-4 T cells [27], and Sundstedt et al. have described superantigen-induced unresponsiveness correlating with the downregulation of IL-4 and upregulation of IL-10 [23]. Furthermore, CD-4 T cells producing high levels of IL-10 but low levels of IL-2 and IL-4 had the capacity to prevent colitis induced in SCID mice by pathogenic CD-4 cells [29]. Moreover, transfected T-cell clones expressing antigen-inducible IL-10 were able both to inhibit the onset of EAE and to treat animals therapeutically after onset of neurological signs of disease [82].

Recent work from our laboratory has shown that it is possible to induce tolerance in H-2<sup>b</sup> mice by intranasal administration of the MOG 35–55 peptide. Tolerance was associated with IL-10 production from spleen cells and could be transferred to naïve recipient mice by adoptive transfer (82a). Most importantly, it was not possible to induce tolerance with intranasal peptide in H-2<sup>b</sup> mice rendered IL-10<sup>-/-</sup> by homologous recombination.

### E. The Function of Regulatory T Cells

The IL-10-producing regulatory T cells described above resemble Tr-1 cells previously described by Groux and colleagues [27]. Tr-1 cells and Th3 cells share one common property although they produce distinct types of cytokine. Both cell types mediate bystander suppression. Bystander suppression was first described by Miller and colleagues in oral tolerance. Thus, Th3 cells specific for antigen A will inhibit responses to antigen B so long as both antigens are presented at the same site [83]. Similar work from our laboratory has shown that peptide-induced regulatory cells specific for an epitope of proteolipid protein would suppress

both PLP- and MBP-induced disease in the H-2<sup>uxs</sup> model of EAE [58]. IL-10 downregulates the antigen-presenting capacity of many antigen-presenting cells, including bone-marrow-derived dendritic cells and Langerhans cells, by downregulating MHC class II and a number of costimulatory molecules, including CD-80, CD-86, and CD-154 [84]. Similarly, TGF-β downregulates MHC class II and prevents upregulation of CD-80 and CD-86 [85,86]. It is likely that both peptide-induced Tr-1 cells and protein-induced Th3 cells mediate bystander suppression by suppressing the function of APC.

### V. FUNCTION OF ANTIGEN-PRESENTING CELLS IN INDUCTION OF REGULATORY T CELLS

Why should short peptides induce Tr-1 cells, long peptides Th1 cells, and intact proteins Th3 cells? It seems likely that B cells play a role in the induction of Th3 responses. The mucosal immune system is designed to produce IgA in response to foreign antigen. It is therefore logical that helper T cells for IgA-secreting B cells should secrete the obligatory cytokine for IgA class switching, namely, TGF-β. Mucosal B cells will be involved in T-B collaboration and would logically respond to intact antigen. It therefore seems appropriate that the immune response to intact antigen at mucosal surfaces should involve Th3 cells providing help for the production of IgA. Peptide antigens, on the other hand, may not fold into a sufficiently stable confirmation for recognition by B cells. Long peptides would nevertheless require antigen processing. It is therefore likely that long peptides are handled by other antigen-presenting cells, including dendritic cells and macrophages. This might explain why mucosal delivery of long peptides fails to induce Th3 cells. Our working hypothesis is that short peptides may be presented to T cells by immature dendritic cells. Short peptides can bind directly to empty MHC at the surface of such cells [87] and hence induce the differentiation of regulatory T cells. Recent reports have shown that CD-4 regulatory T cells, induced by immature dendritic cells, resemble Tr-1 cells in that they secrete high levels of IL-10 but no IL-4 or IL-2 [88,89].

**Table 4** Induction of Tolerance in TCR-Transgenic T Cells Following Intranasal Administration of Peptide

Pretreatment	Proliferation	In vitro response to antigen			
		IFN-γ	IL-2	IL-4	IL-10
PBS IN	+	++	++	-	-
1 × [4Y]IN	+++	++	++	++	++
5 × [4Y]IN	-	-	-	-	++
10 × [4Y]IN	-	-	-	-	++

Transgenic mice expressing the TCR specific for peptide Ac1-9 of MBP were treated with intranasal (IN) peptide (Ac1-9[4Y]) or PBS prior to antigenic challenge with Ac1-9 *in vitro*. Mice received either a single dose of peptide 24 hr or alternatively 5 or 10 doses of peptide every third or fourth day before challenge *in vitro*. Cervical lymph node cells were challenged *in vitro* with Ac1-9 and assessed for proliferation by [<sup>3</sup>H]thymidine incorporation or cytokine production by ELISA.

## VI. EVIDENCE FOR ANTIGEN-SPECIFIC REGULATORY T CELLS IN MAN

Although the oral tolerance trial in MS failed to provide significant evidence of clinical benefit, the laboratory studies associated with this trial demonstrated a clear effect of the treatment. A comparison of cell lines from individuals fed bovine myelin with those from nonfed patients demonstrated a marked increase in the frequency of TGF- $\beta$  secreting lines specific for myelin antigens. This increase was antigen specific and highly significant [90].

Antigen-specific immunotherapy in allergy to bee venom has been associated with downregulation of allergen-specific T-cell proliferation and Th2 cytokine secretion. Recent work by Akdis and colleagues has shown that antigen-specific cells appear anergic and yet continue to secrete IL-10 [91]. Proliferative and cytokine responses to the allergen in question could be reconstituted by neutralization of IL-10 in vitro. Interestingly, the same anergic phenotype was found in T cells derived from healthy beekeepers, all of whom had previously been stung repeatedly [92]. These naturally tolerant individuals showed similar raised levels of IL-10-secreting cells when compared with patients rendered tolerant by specific immunotherapy. Similar observations have arisen from peptide immunotherapy experiments in patients suffering from allergy to cat dander [93]. Inhibition of the late asthmatic reaction to allergen, following peptide therapy, was associated with a decrease in proinflammatory cytokines and a marked increase in IL-10.

Taken together, these observations indicate that antigen-induced regulatory cells similar to those identified in numerous experiments in animal models also exist in man. They can be induced by antigen administration and therefore constitute targets for therapeutic vaccination in man.

## Vaccines to Treat Drug Addiction

Paul R. Pentel and Dan E. Keyler

University of Minnesota Medical School, Minneapolis, Minnesota, U.S.A.

### I. RATIONALE

Drugs of abuse produce their addictive effects by acting on neural pathways in the brain. Currently available medications for drug addiction act by targeting these pathways and altering their response to the addictive drug (Table 1). The challenge posed by this treatment strategy is that the neural pathways that are important in drug abuse are also important in mediating a myriad of other normal functions ranging from cognition to emotion. In altering these pathways to treat drug abuse, medications alter normal functions as well as lead to side effects and limitations on the dose of medication that can be administered.

Vaccines offer an alternative strategy for the treatment of drug abuse in which *the drug itself is the target rather than the brain*. Vaccines directed against these drugs elicit the production of drug-specific antibodies, which bind and sequester drug, and reduce its distribution to the brain. By virtue of acting outside the brain, vaccines appear to circumvent the central nervous system side effects that limit the usefulness of other therapies. The specificity of vaccination in binding only the drug of interest and the generally excellent safety profile of vaccination suggest that side effects outside of the central nervous system should also be minimal. Practical features of vaccination, such as an anticipated long-lasting effect and avoidance of the need for daily medication, could also prove helpful.

The concept of vaccination to treat drug abuse is not new. A vaccine against heroin was studied more than 25 years ago in monkeys [1,2], but further investigation was not pursued because of the development of other promising therapies for heroin addiction at the time. Interest in this area was rekindled in the 1990s with reports that cocaine vaccines could block a variety of cocaine effects in rats [3–6]. Vaccines are currently being investigated for the treatment of cocaine, nicotine, phencyclidine (PCP), and methamphetamine abuse. Only a cocaine vaccine has so far reached Phase I clinical trials, and efficacy studies have not yet been reported. This chapter will consider the mechanistic basis for using vaccines to treat drug addiction and their applica-

tion to specific drugs. Issues regarding the potential clinical use of these vaccines are also discussed.

### II. MECHANISM OF ACTION

The vaccines discussed below act by producing antibodies that bind drugs and alter their tissue distribution or elimination. Both *active* immunization of the animals being studied (herein referred to as vaccination) and *passive* immunization (administration of exogenously produced antibodies) have been studied and will be discussed. An alternative approach involving the generation of catalytic antibodies that act by enhancing drug metabolism has also been applied to cocaine, and will be considered separately.

#### A. Relationship Between Addiction and Drug Concentration in Brain

A hallmark of drug abuse is the high rate with which the drug is self-administered. All addictive drugs serve as positive reinforcers (e.g., are rewarding) in that their effects on the brain increase the frequency of drug seeking and drug self-administration. The extent to which an addictive drug is reinforcing or rewarding is critically dependent on the dose reaching the brain [7]. Below a threshold dose, drug self-administration is not observed. Above that dose, drug self-administration in both animals and humans increases up to a point at which either satiation or adverse effect occurs [8]. An intervention that decreases the amount of drugs reaching the brain might, therefore, reduce or abolish its rewarding properties and lead to a reduction or cessation of self-administration. This is the primary goal of vaccination as a strategy for treating drug addiction.

#### B. Vaccination Effects on Drug Distribution to Brain

When an addictive drug is administered, it enters blood and distributes to tissues throughout the body, including the

**Table 1** Some Medications Currently Available or Under Investigation for the Treatment of Drug Addiction

Medication	Addiction
<i>Receptor agonists</i>	
Nicotine	Tobacco
Methadone, L- $\alpha$ -acetyl methadol (LAAM)	Opiates
<i>Receptor antagonists</i>	
Naltrexone	Opiates
Mecamylamine	Tobacco
<i>Neurotransmitter effect modifiers</i>	
Bupropion, nortriptyline	Tobacco
Desipramine	Cocaine

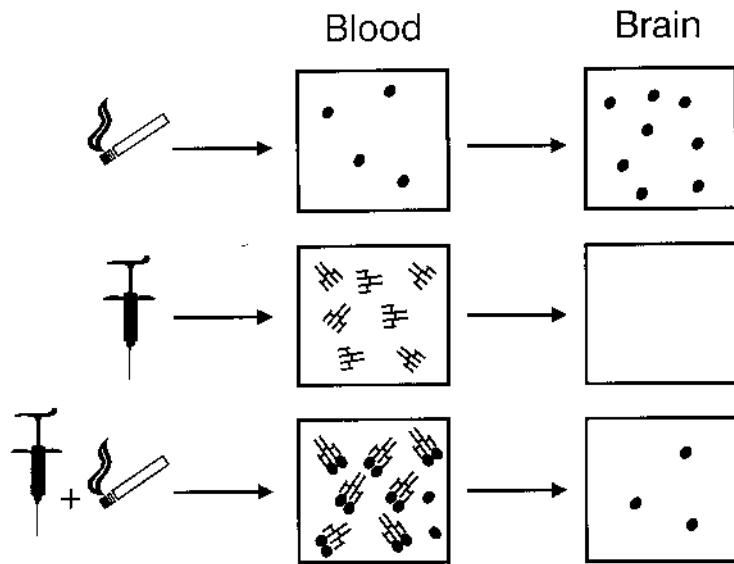

brain (Figure 1). In a vaccinated animal, drug-specific antibody is present in the blood and extracellular fluid. Antibody is largely excluded from the brain by the blood-brain barrier, owing to its large size. Drug-specific antibody presents a potential reservoir for binding drugs outside the central nervous system and before it enters the brain. When a vaccinated animal receives the drug in question, it is bound to antibody and sequestered in the blood and extracellular fluid. If a sufficient binding capacity is available, the concentration of the unbound drug is reduced. Because only unbound drugs can enter the brain, the concentration of the drug in the brain is correspondingly reduced. The binding of

drug by the antibody can also alter its rate of entry and exit from tissues.

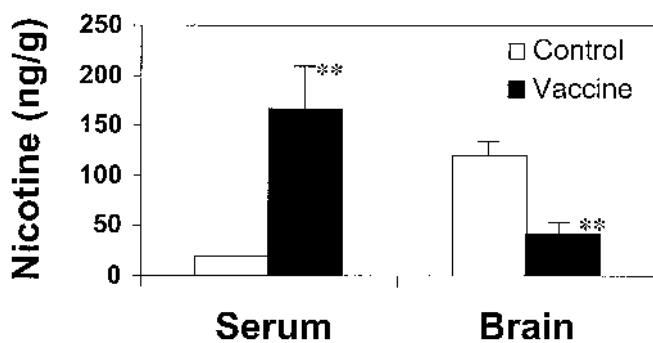

Altered drug distribution is illustrated in Figure 2, in which vaccinated rats received a single nicotine dose equivalent on a weight basis to the nicotine absorbed from two cigarettes by a smoker [9]. The blood nicotine concentration was increased in vaccinated animals, reflecting the binding and sequestration of nicotine in the blood. Brain nicotine concentration was decreased by two-thirds compared to nonvaccinated controls. Brain nicotine concentration was lowest in those animals with the highest nicotine-specific serum antibody titers (Figure 3), suggesting that the ratio of the antibody-binding capacity to the drug dose is an important determinant of efficacy [10]. The increased concentration of nicotine in the blood in vaccinated rats does not result in increased peripheral effects of nicotine because the antibody-bound drug is pharmacologically inactive [9].

### C. Stoichiometry of Drug Binding: How Much Antibody Is Needed to Effectively Bind the Drug?

In the study illustrated in Figure 2, the estimated total body nicotine-specific antibody content of vaccinated rats ( $2.7 \times 10^{-7}$  mol of binding sites) was approximately equal to the moles of nicotine administered. Smokers take in considerably greater nicotine doses throughout the day [11], raising the question of whether the antibodies will become saturated and therefore ineffective in a regular smoker. Surprisingly, the ability of vaccination to reduce drug distribution to the brain persists even when single nicotine doses

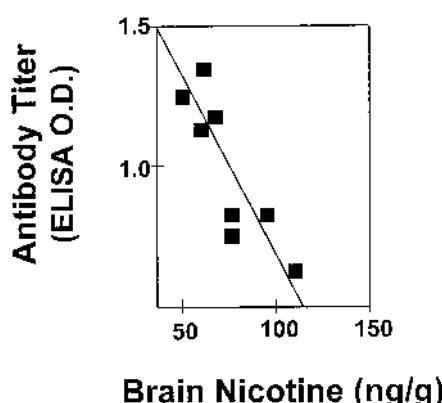

**Figure 1** Effects of vaccination on drug distribution, illustrated for nicotine. Top panel: When a smoker or experimental animal is exposed to nicotine, the drug distributes first to the blood and subsequently to tissues, including the brain. Middle panel: Vaccination elicits nicotine-specific antibodies, which are located largely in the blood and extracellular fluid and which are largely excluded from the brain by the blood-brain barrier, owing to their size. Bottom panel: In a vaccinated animal, nicotine binds to nicotine-specific antibodies in the blood (and extracellular fluid), the unbound nicotine concentration is reduced, and drug distribution to the brain is reduced.

**Figure 2** Vaccination reduces nicotine distribution to the brain. Rats were vaccinated with nicotine immunogen or control immunogen over a period of 7 weeks. One week after the vaccination schedule was completed, 0.03 mg/kg nicotine was administered intravenously. This dose is equivalent on a weight basis to the nicotine absorbed by a smoker from two cigarettes. Serum and brain were sampled 3 min after the injection. The serum nicotine concentration was markedly increased in vaccinated rats due to the binding of nicotine to antibody in the serum. Brain nicotine concentration was reduced by 60%. (From Ref. 9.)

exceed the estimated binding capacity of antibody by up to 67-fold [12], or in the presence of a continuous infusion of nicotine at rates equivalent to two to three packs of cigarettes daily [13]. A similar unexpected efficacy in the face of very large drug doses has also been observed for cocaine [14] and phencyclidine [15] antibodies, and appears to be a general feature of vaccination for drugs of abuse. The basis for this unanticipated pharmacokinetic efficacy is not well understood, but is clearly critical for the successful clinical use of vaccination because both the single and daily doses of most addictive drugs equal or exceed the calculated binding ca-

**Figure 3** Effects of serum antibody titers on nicotine distribution to the brain (protocol as in Figure 2). Brain nicotine concentrations in vaccinated rats were lowest in animals with the highest serum antibody titers (a measure of antibody concentrations). (From Ref. 10.)

**Table 2** Typical Drug Doses Generally Exceed the Anticipated Binding Capacity of Drug-Specific Antibody in a Vaccinated Human

Drug dose	Ratio of drug to estimated binding capacity
<i>Nicotine</i>	
Single dose, 0.015 mg/kg ( $9.3 \times 10^{-8}$ mol/kg)	0.3
Daily dose, 0.3 mg/kg ( $1.9 \times 10^{-6}$ mol/kg)	7
<i>Phencyclidine</i>	
Single dose, 0.14 mg/kg ( $5.6 \times 10^{-7}$ mol/kg)	2.1
Daily dose, 0.7 mg/kg ( $2.8 \times 10^{-6}$ mol/kg)	10
<i>Cocaine</i>	
Single dose, 0.5 mg/kg ( $1.6 \times 10^{-6}$ mol/kg)	6
Daily dose, 5 mg/kg ( $1.6 \times 10^{-5}$ mol/kg)	59
<i>Methamphetamine</i>	
Single dose, 0.1 mg/kg ( $5 \times 10^{-7}$ mol/kg)	1.9
Daily dose, 10 mg/kg ( $5 \times 10^{-5}$ mol/kg)	190

The calculated binding capacity of  $2.7 \times 10^{-7}$  mol/kg is extrapolated from animal studies and assumes that 1% of total antibody (IgG) is specific for the drug in question and that there are two drug-binding sites per molecule of IgG.

Source: Ref. 9.

pacity that can be provided by vaccination (Table 2). Possibly, vaccination reduces nicotine distribution to the brain to a greater extent than to other organs, as has been shown for phencyclidine [15].

#### D. Other Potentially Beneficial Pharmacokinetic Effects of Vaccination

The rate of distribution of drugs to the brain is also an important determinant of its reinforcing potency. For example, inhaled nicotine that reaches the brain in 10–20 sec is far more addictive than nicotine gum, which produces peak levels in 15–30 min [16]. Slowing drug distribution to the brain could make it less reinforcing. Limited data suggest that vaccination may slow nicotine distribution to the brain. The distribution of nicotine to the brain in vaccinated rats is reduced by 64% 1 min after a single nicotine dose, but by only 24% at steady state after a chronic nicotine infusion (unpublished data). Thus vaccination may have its greatest effect on the early distribution of nicotine to the brain, during the time when the reinforcing effects of nicotine are greatest.

The effects of vaccination on drug metabolism differ among drugs. The binding of nicotine by an antibody makes it less available for metabolism and markedly slows its elimination half-life [17]. This could be a detrimental effect in that slower elimination would favor the accumulation of

nicotine and the saturation of an antibody. On the other hand, slowing nicotine metabolism with a metabolic inhibitor has been shown to reduce ad libitum smoking in humans, perhaps by prolonging nicotine's effects and by delaying the onset of craving [18]. Understanding the role of altered nicotine metabolism due to vaccination will require further study. In contrast, cocaine's elimination half-life does not appear to be altered by vaccination [14].

### III. VACCINE FORMULATION AND VACCINATION SCHEDULES

#### A. Overview

There are three principal requirements of vaccines used to treat drug addiction. First, the antibodies elicited by vaccination must have a high-enough affinity to effectively bind the drug. Second, because high ratios of antibody to drug are most effective, a vaccine must elicit and maintain high concentrations of antibody throughout the period of clinical interest. Third, antibodies must be highly specific for the drug of interest. If antibodies cross-react with drug metabolites, those metabolites could compete for binding capacity.

#### B. Linker

Drugs of abuse (molecular weights 150–300) are too small to elicit an immune response. Regular users of tobacco (nicotine) or cocaine do not normally have antibodies against these drugs [19] (A. Fattom, personal communication). Drugs of abuse can be rendered immunogenic by linking the drug itself or a structurally related compound (hapten) to an immunogenic carrier protein to form a complete immunogen. After initial (primary) vaccination, periodical booster doses with the complete immunogen are needed to maintain satisfactory antibody titers: exposure to the drug by itself would not be expected to elicit an anamnestic or booster response. The conjugation or linking of drug to carrier protein has generally been accomplished using five to six atom linkers of various composition [6,9,20]. The binding of linker to carrier protein lysine residues can be accomplished via succinylation. Although some linkers anecdotally seem to produce better immunogens than others, no structural rule has emerged to predict which linkers are most effective. Few published data comparing linkers, linker strategies, or hapteneation ratios (drug/carrier protein molar ratio) are available. A hapteneation ratio of 20:1 was used for conjugating phencyclidine to bovine serum albumin [21].

Linker position is critical to antibody specificity. Linkers that are distant from the predominant sites of drug metabolism (and which do not cover them up) allow the elicited antibodies to recognize parent compounds in preference to metabolites [6,9,20,21]. An alternative strategy has been used for cocaine, which can spontaneously hydrolyze in vitro to one of its major metabolites and potentially allow the metabolite to act as an immunogen. A linker attached at the site of potential hydrolysis was used to stabilize this site, while preserving its structure so that the resulting antibodies were specific for the parent compound [4,22].

#### C. Carrier Protein

A variety of carrier proteins have been used for these vaccines, including bovine albumin [6,21], keyhole limpet hemocyanin [10], cholera toxin B subunit [19], and recombinant *Pseudomonas aeruginosa* exoprotein A [9]. The latter two proteins have the advantage of previous use in vaccines administered to humans.

#### D. Vaccination Schedules

Vaccination schedules in rats have generally involved two to four doses of vaccine over a period of 4–10 weeks. Comparative data are not available to suggest an optimal vaccination schedule. The only human data available are for a cocaine vaccine, which was administered as three monthly injections of 13, 82, or 709 µg of a cholera toxin B subunit conjugate vaccine with alum adjuvant. Maximal antibody titers were reached 1 week after the third injection, titers decreased by about 50% two months later, and were nearly back to baseline 10 months after the final injection [19].

For some clinical applications, it may be desirable to vaccinate individuals before they stop their drug use, in preparation for quitting. Rat studies with nicotine [13], methamphetamine [23], and cocaine [24] vaccines have shown that vaccination during concurrent drug administration is as effective in eliciting drug-specific antibody titers as vaccination in the absence of the drug. Thus vaccination during ongoing drug use seems feasible.

#### E. Antibody Concentrations in Serum

In rats, a cocaine-specific antibody serum concentration of 0.05 mg/mL represents a threshold for efficacy as measured by the suppression of cocaine self-administration [24,25]. This concentration is higher than those achieved in the first clinical trial of a cocaine vaccine (mean 0.003 mg/mL) [19]. Thresholds for other drugs are not known, but serum drug-specific antibody concentrations of 0.1–0.2 mg/mL were effective in altering nicotine pharmacokinetics and effects in rats, and the magnitude of effect was related to antibody titer. Antibody titers in humans given vaccines for infectious diseases are generally lower than those achieved in experimental animals, perhaps in part because only the alum adjuvant and the intramuscular route have been used in humans (rather than Freund's adjuvant administered intraperitoneally or by other routes in animals). Nevertheless, haptene-specific antibody concentrations of up to 0.1 mg/mL in serum have been reported in humans [26,27]. Achieving adequate antibody concentration will be a key issue in determining the efficacy of vaccines for drugs of abuse, and may require additional studies of vaccination strategies.

### IV. SPECIFIC DRUGS

#### A. Nicotine

##### 1. Overview

Cigarette smoking kills 400,000 people each year in the United States (one of five deaths) and 10 times that many

worldwide [28]. New medications and counseling have helped many smokers quit, but the majority of those who try are still unsuccessful [29]. Addiction to nicotine is the primary reason that people smoke [28]. An intervention that could reduce the reinforcing effects of nicotine and render it less addictive is therefore of interest [30].

As discussed above, nicotine distribution to the brain is substantially reduced by vaccination after clinically relevant single doses of nicotine alone or against a background of chronic nicotine dosing. The magnitude of effect is related to antibody titer or concentration in the blood [9,10,13]. In assessing the potential clinical usefulness of vaccination to treat nicotine addiction, key questions are: (a) Does vaccination reduce the reinforcing effects of nicotine? (b) Can beneficial effects be attained with antibody titers that are achievable in humans. (c) Will vaccinated animals or humans try to compensate for reduced nicotine distribution to the brain by simply taking in more nicotine, thereby overcoming the effects of vaccination? Additionally, it is possible that vaccination might affect various aspects of nicotine addiction differentially. Smokers who quit and then relapse to smoking typically do so by starting with a few puffs or a few cigarettes, a relatively small nicotine dose. Vaccination could block the reinforcing effects of those first few puffs and make them less enjoyable, thus making relapse less likely. By contrast, using vaccination to help initiate smoking cessation would involve the larger nicotine dose associated with regular daily smoking. Because the ratio of antibody to drug is important in determining vaccine efficacy, vaccination might be more effective for relapse prevention than for initiating smoking cessation.

## 2. Active Versus Passive Immunization

Studies of vaccine efficacy have used either active immunization (vaccination) of rats prior to nicotine challenge, or passive immunization (the transfer of antibodies produced in rabbits and then administered to rats prior to nicotine challenge). Vaccination of smokers is perhaps more attractive as a potential clinical intervention because it is less expensive and longer-lasting than passive immunization. Passive immunization has been used experimentally primarily as a methodological expedient, a means of controlling antibody dose or producing immediate effects without having to wait for the 1–2 months required for vaccination. However, the rapid onset of effect and the control of dose could also be useful in treating patients, and a clinical role for passive immunization alone or as an adjunct to vaccination is possible [30].

## 3. Vaccines

Two nicotine immunogens have been studied: 6-[carboxymethylureido]nicotine and 3'-[aminomethyl]nicotine [9,20]. Vaccination with either immunogen produces marked effects on nicotine distribution in rats, but the latter vaccine appears somewhat more effective. Both are linked to carrier protein (keyhole limpet hemocyanin or recombinant *Pseudomonas* exoprotein A, respectively) through a five-atom linker placed remote from the major sites of nicotine metabolism, and both show high specificity for nicotine (<3% cross-reactivity

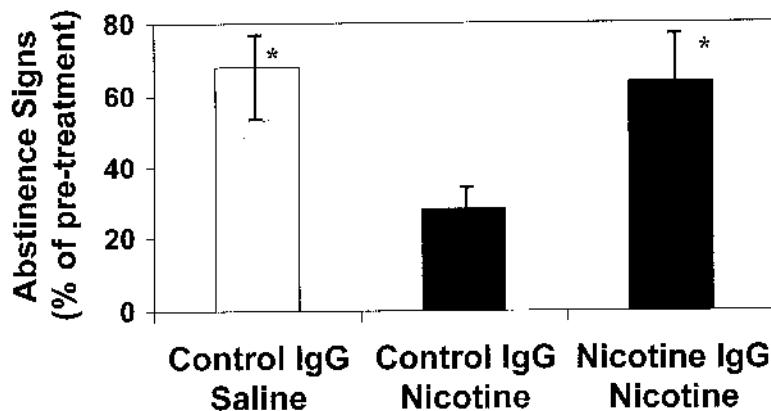

with the major nicotine metabolites cotinine and nicotine-*N*-oxide). Cross-reactivity with acetylcholine, the endogenous ligand for nicotinic receptors, was negligible. The  $K_d$  of elicited antibodies for nicotine has ranged from 20 to 40 nM [9,10,13,20]. Typical serum nicotine concentrations in smokers are higher than the  $K_d$  (50–500 nM), suggesting that the saturation of nicotine-specific antibodies in smokers should be high and most of the binding capacity will be utilized. Serum antibody concentrations in vaccinated rats range from 0.05 to 0.2 mg/mL, or from 0.5% to 2% of the total IgG.

## 4. Efficacy Studies

Passive immunization of rats with nicotine-specific IgG blocked the pressor effect (elevation of blood pressure) from nicotine in a dose-related manner [9]. Because this effect is largely mediated by peripheral autonomic ganglia, these data confirm that nicotine bound to antibody in serum is inactive.

Passive immunization of rats blocked locomotor activation following a single nicotine dose, a nicotine effect mediated in the brain [9]. Passive immunization also affects behaviors in rats that are pertinent to nicotine addiction. Rats can be made dependent on nicotine by a 1-week subcutaneous (s.c.) nicotine infusion, such that the removal of the s.c. pump results in a withdrawal or abstinence syndrome 1 day later [31]. When rats experience nicotine withdrawal, this can be relieved by again administering nicotine. However, if rats experiencing withdrawal are given nicotine-specific IgG, additional nicotine is no longer able to relieve the withdrawal [32] (Figure 4). This paradigm is analogous to a smoker relieving withdrawal symptoms and craving by smoking. Relief of withdrawal is an important reason why people fail to quit smoking: when they are uncomfortable from withdrawal, smoking a cigarette will relieve their discomfort. If it failed to do so, relapse might not occur. Thus vaccination could make relapse to smoking less likely after a quit attempt by virtue of rendering cigarettes less effective for relieving withdrawal. Vaccination also suppresses nicotine-induced dopamine release in the rat nucleus accumbens, providing evidence that an important neurochemical effect associated with nicotine dependence is altered by this intervention (T. Svensson, personal communication).

Rats can be taught to self-administer nicotine by pressing a lever to receive a nicotine dose through an indwelling intravenous (i.v.) cannula. Such a preparation serves as an animal model of smoking. If rats are first vaccinated over several months and then given access to nicotine, the acquisition of nicotine self-administration is impaired. Vaccinated rats, on average, self-administer 40% less nicotine [33]. Vaccination also impairs the reinstatement of nicotine responding, a model of relapse. In this model, rats are taught to self-administer nicotine and then responding is extinguished by substituting saline for nicotine. Responding can be reinitiated by providing a single dose of nicotine as a cue. This reinstatement of responding is blocked when rats are vaccinated during the period of extinction (T. Svensson, personal communication). Taken together with the effects of vaccination on nicotine withdrawal, these data support a

**Figure 4** Passive immunization with Nic-IgG prevents the relief of nicotine withdrawal by nicotine. Rats were made dependent on nicotine with a 1-week infusion of nicotine via a s.c. pump. One day after the pump was removed, controls showed measurable withdrawal signs (left bar). Withdrawal was relieved by a single s.c. dose of nicotine (middle bar). The ability of nicotine to relieve withdrawal was blocked when nicotine-specific IgG was administered just prior to the single nicotine dose (right bar). (From Ref. 32.)

potential therapeutic or preventive role for vaccination. However, each of these behavioral models differs from human smoking behavior in important ways, including route of administration, doses, schedules, and behavioral environments. Further studies using additional models will be useful in assessing the clinical relevance of these findings.

## B. Cocaine

### 1. Overview

Approximately 2 million people in the United States abused cocaine in 1998 [34]. Behavioral interventions are helpful in treating cocaine addiction, but there are currently no approved medications for this disorder [35].

Single and daily cocaine doses are considerably higher than those of nicotine. Even with a single dose, the calculated binding capacity of antibodies in vaccinated animals is greatly exceeded (Table 2). Nevertheless, the studies outlined below demonstrate a considerable efficacy of vaccination in reducing cocaine effects, illustrating the general principle that drug-specific antibodies can alter drug distribution even when the binding capacity is greatly exceeded.

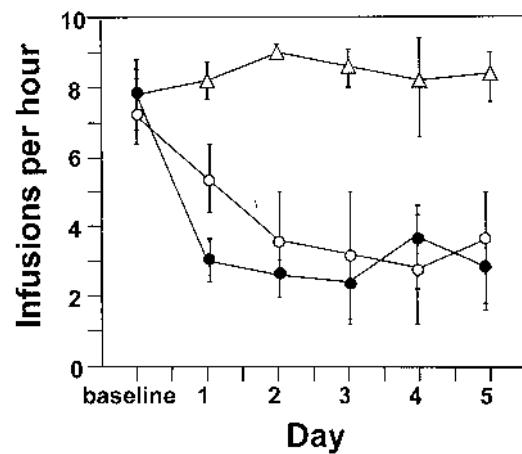

### 2. Vaccines

Linkers for cocaine immunogens have been placed either distant from major sites of metabolism (norcocaine derivatives) [6], or at the methyl ester group to protect it from spontaneous degradation and the generation of the major metabolite benzoyl ecgonine [4,22]. Both strategies elicit antibodies with high specificity for cocaine compared to its metabolites. Serum antibody  $K_d$  for cocaine from a norcocaine derivative vaccine was reported as  $4 \times 10^7$  to  $2 \times 10^9$  M $^{-1}$ . A vaccine has also been developed using an anti-idiotype antibody, which mimics the configuration of the cocaine molecule as the immunogen [36]. It is not clear whether this approach offers any advantage over the use of a conjugate vaccine. Vaccines studied in animals have used

bovine serum albumin or keyhole limpet hemocyanin as carrier proteins. A cocaine vaccine in clinical trials used cholera toxin B subunit as the carrier protein [19].

### 3. Efficacy

Passive immunization with cocaine-specific antibodies reduced early cocaine distribution to the brain in rats by 25–70%, and reduced locomotor activity and stereotypical behavior following a single cocaine dose [4,6]. Vaccination

**Figure 5** Passive immunization blocks cocaine self-administration in rats. Rats were trained to self-administer cocaine as 1 mg/kg i.v. bolus doses during a 2-hr daily session. Control group daily responding is stable over time (triangle). The substitution of saline for cocaine (open circle) resulted in a marked reduction in responding. The infusion of monoclonal anti-cocaine antibodies in rats that continued to receive cocaine (filled circle) resulted in a similar reduction in responding. (From Ref. 6.)

also reduced cocaine self-administration in a variety of models [6,25,37,38]. When animals had access to cocaine for 2 hr/day, cocaine self-administration was immediately reduced to control levels after passive immunization with cocaine-specific monoclonal antibodies (Figure 5). Vaccination also reduced the reacquisition [25] and reinstatement [38] of cocaine self-administration in rats, which had been previously taught to self-administer the drug, a model of relapse prevention. Self-administration in vaccinated animals is closely related to serum antibody concentrations. In rats, a serum antibody concentration of 0.05 mg/mL appears to represent a threshold for efficacy [25]. Surprisingly, increasing the cocaine dose did not reliably overcome the suppression of self-administration. In aggregate, these data provide strong evidence that vaccination reduces cocaine self-administration to a quantitatively important extent and in a manner related to serum antibody concentration.

In contrast to vaccination against nicotine, vaccination does not appear to alter cocaine's elimination half-life [6]. The accumulation of the drug with resulting saturation of antibodies may therefore be less of a problem with cocaine than with nicotine. It is possible that continued rapid cocaine elimination contributes to the high efficacy of vaccination in suppressing ongoing cocaine self-administration. A cocaine vaccine has begun Phase I clinical trials of immunogenicity and safety (see "Vaccine Formulation and Vaccination Schedules" above). No important adverse effects have been found.

### C. Phencyclidine

#### 1. Overview

Phencyclidine is structurally and pharmacologically related to the dissociative anesthetic, ketamine. Abuse is uncommon but important in particular geographical areas. Adverse effects generally consist of acute toxicity from inadvertent overdose and may be severe, but addiction may also occur. Apart from its medical importance, the study of phencyclidine abuse has shed light on the potential role of passive immunization as a treatment strategy.

#### 2. Vaccines

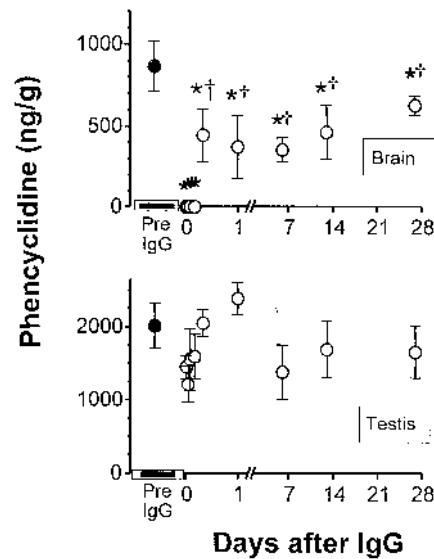

A phencyclidine vaccine consisting of PCP conjugated to bovine serum albumin [21] has been used for the production of monoclonal antibodies. In contrast to vaccines for nicotine or cocaine, which aim to produce highly specific antibodies, the intent of this PCP vaccine was to elicit polyspecific antibodies that would also bind structurally related drugs that might be abused in place of phencyclidine. This was accomplished by placing the linker distant from the structural features that are conserved among the phencyclidine analogues of interest [39,40]. The monoclonal antibody most extensively studied has a  $K_d$  of 1.3 nM for phencyclidine.

#### 3. Efficacy

The passive infusion of monoclonal phencyclidine antibodies or antibody Fab fragment (the 50-kDa antigen-binding fragment of IgG) to rats after acute or chronic phencyclidine

doses markedly reduces the phencyclidine concentration in the brain [15,41]. The protection of the brain is remarkably long-lasting, persisting for a month after a single IgG dose despite continuous infusion of phencyclidine at a daily rate that exceeds the antibody's binding capacity for drug (Figure 6). The protection of another organ (the testes) from phencyclidine distribution was not as persistent, suggesting that the distribution of phencyclidine to the brain is differentially affected. These observations are consistent with those regarding nicotine and cocaine, suggesting that drug distribution to the brain may be affected more than the distribution to other organs, and that protection occurs even when drug dose is substantially larger than the antibody's drug-binding capacity.

Monoclonal phencyclidine antibody also reduces the behavioral toxicity (changes in locomotor activity and posturing) of phencyclidine [39,42]. Like the pharmacokinetic effects, behavioral protection is long-lasting and is observed up to several weeks after a single passive infusion of antibody (M. Owens, personal communication). Phencyclidine antibodies also reverse overt phencyclidine toxicity when they are administered after a toxic phencyclidine dose [39,43]. The

**Figure 6** Phencyclidine-specific IgG produces a long-lasting decrease in brain phencyclidine concentrations. Phencyclidine was administered by continuous s.c. infusion. Monoclonal anti-phencyclidine antibody was administered just once on day 2, after the initial distribution of PCP to tissues. The antibody dose was equimolar to the estimated body burden of PCP at the time. The subsequent PCP infused each day exceeded the antibody-binding capacity for the drug by more than threefold. Brain phencyclidine concentrations remained significantly reduced in the passively immunized rats for up to 1 month. Effects on phencyclidine distribution to the testes were smaller and less persistent. These data support the hypothesis that immunization preferentially reduces drug distribution to the brain. (From Ref. 15.)

considerable monoclonal antibody doses used (up to 0.4g/kg) have shown no adverse effects.

These data support a potential clinical role for passive immunization in the treatment of drug addiction. The ability to control the antibody dose and administer as large a dose as necessary may offer advantages over vaccination, particularly if the titers produced by vaccination are inadequate in some individuals. The ability to produce an immediate effect might also be helpful for initiating therapy when a patient is motivated to quit rather than having to wait months for adequate titers to develop after vaccination. The cost of producing large quantities of antibody is a factor, but improved large-scale methods for the production of monoclonal or recombinant antibodies have made this increasingly feasible.

#### D. Catalytic Antibodies for Cocaine

In contrast to drug-binding antibodies, catalytic antibodies are intended to hasten drug metabolism and thereby blunt the drug's effects. Enhanced metabolism could, if rapid enough, reduce initial drug distribution to the brain and could also prevent the accumulation of drug with repeated dosing. This approach is best suited to drugs that can be inactivated by one-step metabolic processes to an inactive metabolite, such as the hydrolysis of cocaine [44]. It is less well suited to drugs such as nicotine or phencyclidine, which are metabolized through multistep process by cytochrome P450 enzymes.

Cocaine is metabolized in humans primarily to two major metabolites that are not addictive. One of these, ecgonine methyl ester, also appears to be relatively free of toxic effects. Cocaine hydrolysis to ecgonine methyl ester is catalyzed by the plasma enzyme, pseudocholinesterase, and proceeds via a short-lived transition state, which is stabilized by the enzyme. An antibody to this transition state could similarly stabilize the transition state and serve as a catalyst [44]. Because the transition state is short-lived, it cannot be used as an immunogen, but a stable transition state analog used in this manner can elicit antibodies that markedly speed the degradation of cocaine [45–47]. One such monoclonal antibody has been shown to reduce acute cocaine toxicity and cocaine self-administration in rats [37,47]. The relative merits of this approach compared to cocaine-binding antibodies are not yet clear. Conceivably, a combination of binding antibodies to reduce initial cocaine distribution to the brain and catalytic antibodies to prevent cocaine accumulation would be advantageous.

### V. CLINICAL ISSUES

#### A. Importance of Antibody Concentration in Serum

Vaccination is effective only insofar as sufficient antibody is present to bind drugs. For all of the drugs discussed above, antibody dose or concentration is a critical determinant of efficacy. Antibody concentrations elicited in experimental animal studies of drug abuse vaccines (0.05–2% of total IgG) have been higher than those typically elicited in humans after

vaccines for infectious diseases ( $\leq 1\%$  of total IgG, and often much less) [26,27]. Developing suitable immunogens, adjuvants, and vaccination schedules will therefore be important to the success of this approach. Passive immunization, where antibody dose can be controlled, may prove helpful as an adjunct to vaccination.

#### B. Onset and Duration of Effect

Vaccination will likely require multiple injections of immunogen over several months to achieve maximal titers. Vaccination can be initiated while drug use continues, with the cessation of drug use attempted once titers are adequate. Passive immunization may find application when a delay of several months is not clinically acceptable.

#### C. Compensation

It is likely that addicts will be able to overcome the effects of vaccination, if they are determined to do so, by using higher drug doses. Thus vaccination, like all other medications for drug abuse, will be most successful in highly motivated patients. Fortunately, most cigarette smokers want to quit and are unlikely to purposely sabotage their own efforts. Cocaine addicts who enter treatment are also motivated to quit, as illustrated by the substantial abstinence rates achieved with behavioral counseling alone.

#### D. Vaccination as an Adjunct to Behavioral Treatment

As a general rule, drug therapies for addictions are successful only when used in conjunction with behavioral counseling and any necessary psychiatric or social services. It is likely that vaccination, even if effective, will be similar in this regard and should be viewed as an adjunct to counseling.

#### E. Combination of Vaccination with Other Therapies

Because its mechanism of action is distinct, it is possible that vaccination will have additive effects with other medications for drug abuse. It is also possible that vaccination will target some aspects of addiction better than others and will benefit from medications that complement its actions.

#### F. Safety

No important adverse effects have been observed in animals to date with either passive or active immunization for drug addiction. However, such vaccines have not previously been used or tested in humans. It will be important, in particular, to confirm the specificity of the antibodies elicited to assure that they do not bind endogenous compounds.

### VI. SUMMARY

Vaccines to treat drug abuse are being studied for several major classes of addictive drugs. Animal data are encouraging, but none of these vaccines has yet been tested for efficacy

in humans. The main action of vaccines is to elicit antibodies that bind drugs and reduce their distribution to the target organ, the brain. Vaccination reduces or blocks some of the behavioral effects of nicotine, cocaine, or phencyclidine even when drug doses substantially exceed the antibody's drug-binding capacity. Efficacy is closely correlated with antibody titer or concentration in serum, and achieving and maintaining adequate titers will be a major factor determining whether these vaccines are clinically useful. It is likely that addicts can overcome the effects of vaccination by using larger drug doses, so that vaccination will be most effective for individuals who are highly motivated to quit, and when used in conjunction with counseling. Vaccines have proven safe in animals, but their safety in humans is largely untested. The use of vaccination in combination with other medications for drug addiction, to enhance efficacy or achieve a greater spectrum of effects, may be possible.

## Vaccines Against Agents of Bioterrorism

**Theodore J. Cieslak**

*San Antonio Military Pediatric Center, San Antonio, Texas, U.S.A.*

**Mark G. Kortepeter and Edward M. Eitzen, Jr.**

*United States Army Medical Research Institute of Infectious Diseases, Fort Detrick, Maryland, U.S.A.*

Recent events have called enormous attention to the twin threats of biological warfare and bioterrorism. The tragedy of September 11, 2001 and the subsequent outbreak of anthrax cases associated with contaminated mail have made anthrax and smallpox household words. Nonetheless, public health, policy, and law enforcement officials have been planning a defense against potential agents of terrorism for some time now. A component of that defense has included, and is likely to continue to include, immunization. In this chapter, we discuss currently available vaccines against potential agents of biowarfare and bioterrorism. In addition, we discuss prospects for new generation vaccines against these same agents.

In 1999, a group of experts gathered at the Centers for Disease Control and Prevention (CDC) in Atlanta to develop a list of those agents most likely to constitute viable terrorist weapons. These experts soon concluded that, because terrorist's motives were often unclear, it was difficult to ascertain which agents were most likely to be employed. Rather, the group elected to consider which agents, *if employed*, constituted the gravest threats to public health and safety. Moreover, they also took into account current public health preparedness, prioritizing those agents for which a more substantial gap in preparedness was felt to exist. In the end, they divided potential agents of bioterrorism into three categories, with those in category A thought to represent the greatest threats [1]. The list developed at the CDC is provided in Table 1. We discuss here various immunization strategies against anthrax, smallpox, and three of the four remaining agents in category A. The final agent in Category A (actually multiple agents causing viral hemorrhagic fevers, considered collectively) is considered in a separate chapter ("Vaccines for Hantaviruses, Lassa Fever, and Filoviruses"). We also discuss select agents in

category B for which vaccine research appears somewhat promising.

### I. CATEGORY A AGENTS

#### A. Anthrax

Anthrax is caused by infection with the gram-positive spore-forming rod, *Bacillus anthracis*. Although naturally occurring anthrax has become a rarity in the western world, due to changes in animal husbandry practices and, in part, to veterinary vaccination, anthrax has reemerged as the ultimate biological weapon. The ability of the dry spore form of this organism to resist environmental degradation and its behavior as a gas when disseminated in the proper particle size, combined with its rapid lethality, make it an attractive weapon in the eyes of some.

Pasteur first developed an anthrax vaccine (a "duplex vaccine," consisting of two doses prepared by significantly different methods) in 1881. His preparation, the first bacterial vaccine (Jenner's smallpox vaccine predated it by 75 years), was intended for use in cattle and sheep, and arrived just 5 years after anthrax became the first disease for which a microbial etiology was proven by Koch's postulates. Significant modifications to Pasteur's original preparation led to Sterne's live spore vaccine in 1937, and derivatives of this attenuated spore vaccine are used extensively in livestock to this day. A thorough review of the history of early anthrax vaccines has been published [2].

Significant vaccine-associated morbidity makes the use of live spore anthrax vaccines problematic in humans. Nonetheless, a live spore vaccine derived from a Sterne strain of *B. anthracis* has been widely used in humans in Russia and the former Soviet Union [3]. In the 1950s and

**Table 1** Critical Agents for Health Preparedness

Category A	Category B	Category C
Variola virus	<i>Coxiella burnetii</i>	Other biological agents that may emerge as future threats to public health, such as:
<i>Bacillus anthracis</i>	<i>Brucellae</i>	Nipah virus
<i>Yersinia pestis</i>	<i>Burkholderia mallei</i>	Hantaviruses
Botulinum toxin	Alphaviruses	Yellow fever virus
<i>Francisella tularensis</i>	Certain toxins (Ricin, SEB)	Drug-resistant tuberculosis
Filoviruses and Arenaviruses	Food safety threat agents ( <i>Salmonellae</i> , <i>E. coli</i> O157:H7) Water safety threat agents ( <i>Vibrio cholerae</i> , etc.)	Tick-borne encephalitis

Category A—Agents with high public health impact requiring intensive public health preparedness and intervention; Category B—Agents with a somewhat lesser need for public health preparedness.  
(From Ref. 1.)

1960s, development of a new generation of vaccines was made possible by an understanding of the three principal protein virulence factors in *B. anthracis*, namely protective antigen (PA), lethal factor (LF), and edema factor (EF) [4,5]. Pathogenesis of tissue edema and necrosis seen in anthrax cases is attributable to the effects of LF and/or EF, which form the “A” chain of anthrax toxins according to the A–B model of dichain toxins [6]. Protective antigen serves as the “B” chain transport protein, which binds to receptors on target cell membranes and initiates toxin uptake.

Since the appreciation of the role of PA in immunity, vaccines prepared in the United Kingdom in the 1950s and in the United States in the 1960s have employed cell-free filtrates that optimize the content of PA. A vaccine in use in Britain derives from the Sterne strain, and is prepared in a manner very similar to that used in production of the U.S. vaccine. The vaccine currently available for human use in the United States was licensed in 1970, and is derived from strain V770, a PA-rich organism originating from a case of bovine disease. Although the V770-based vaccine [licensed as “Anthrax Vaccine Adsorbed” (AVA)] was used sporadically from 1970 through 1990 to immunize select veterinary personnel, textile workers, and abattoir workers in the United States, it was not until Operations Desert Shield and Desert Storm (ODS/S) in 1990–1991 that widespread and systematic use by the U.S. military spurred a number of controversies surrounding AVA. During ODS/S, approximately 150,000 doses of AVA were administered to U.S. military personnel. The rapid victory achieved during that conflict resulted in very few individuals receiving more than two doses of the usual six-dose series of injections (normally spread over 18 months). Several years later, in 1998, Department of Defense officials resurrected the AVA-associated controversies with a phased program [the Anthrax Vaccine Immunization Program (AVIP)] mandating vaccine for all men and women serving in all branches of the U.S. Armed Forces. In general, these controversies involve questions of: (1) safety, (2) efficacy, and (3) programmatic.

To date, at least 18 studies (summarized in Table 2) have assessed, to varying degrees, the safety of AVA. While many of these studies involve exceedingly small numbers of vaccine recipients, and while several were conducted for reasons

other than a direct assessment of vaccine safety per se, collectively they provide fairly convincing evidence of, at least, the short-term safety of AVA.

The first data available on the safety of AVA comes from the pivotal study of Brachman and colleagues [7] that led to licensure of the vaccine. In this study, published in 1962, employees at four goat-hair processing plants in the northeastern United States during the late 1950s were offered enrollment in a placebo-controlled trial of an anthrax vaccine developed at the U.S. Army’s biological defense facility at Fort Detrick, MD. Among the 379 vaccine recipients involved in this study, approximately 30% experienced mild local reactions (typically 1–2 cm of erythema), while 4% experienced moderate local reactions (defined as erythema >5 cm in diameter). Three individuals developed large local reactions, while two experienced malaise of 24-hr duration. Of note, this study is the sole examination of data performed using only the original Fort Detrick-developed preparation (sometimes referred to as the “Merck Vaccine”).

Shortly after the Brachman study was completed, minor modifications were made to the anthrax vaccine preparation that resulted in a higher concentration of PA and decreased amounts of LF and EF. This modified preparation, sometimes referred to as the “Lansing Vaccine,” is the one that was ultimately licensed by the National Institutes of Health in 1970 [the Food and Drug Administration (FDA) assumed responsibility for vaccine licensure in 1972], and is the one which remains in use today. The fact that the initial safety and efficacy study leading to licensure was performed using a slightly different formulation is a source of some controversy.

Prior to the decision by military officials to mandate immunization against anthrax, further data regarding the safety of anthrax vaccine was available from at least two additional sources. First, the CDC collected data on 6985 persons at risk for occupational exposure [8]. These persons received 16,435 doses of vaccine under an Investigational New Drug (IND) permit during the years between publication of the Brachman study and ultimate vaccine licensure. In addition, investigators at Fort Detrick collected data on at-risk laboratory workers given vaccine over a 26-year period from 1973 to 1999. In their study [9], 1583 persons

received 10,722 doses of vaccine. Although each of these studies showed similar low rates of reaction (moderate reactions in 1–4% and severe reactions in <1%), the former is complicated by the fact that early enrollees received the Merck vaccine while later enrollees received the Lansing preparation and the latter is limited by a passive system for the reporting of vaccine side effects. It was on the basis of the three aforementioned studies that the Department of Defense, in 1998, embarked on its plan to require universal immunization of all U.S. Armed Forces.

Since the AVIP was initially implemented in March of 1998, considerable experience with AVA has accumulated. As of January of 2002, 526,146 service members had received 2,113,155 doses of vaccine [10]. This large number of vaccine recipients has enabled a clearer picture of the problem of vaccine side effects, which have been formally studied in multiple subsets of this total patient population. Most of these studies (Table 2) are, individually, rather small, and would not detect rare untoward vaccine reactions. Moreover, as all of the experience is quite recent, vaccine-related conditions that might conceivably arise years after vaccination would not be detected. Nonetheless, taken together, these studies lead to an emerging picture of a vaccine at least as safe as most conventional vaccines.

In addition to safety, concerns have also been raised regarding the efficacy of AVA in protecting against the bioweapons threat that concerns the military. Such a threat would presumably involve aerosolized anthrax spores and would lead to inhalational anthrax, a disease of significantly different pathology than the cutaneous anthrax that had constituted the more common occupational hazard of textile workers. Although naturally occurring inhalational anthrax is too rare to permit an efficacy trial in humans, vaccine efficacy data is nonetheless available through two separate avenues of research. First, the original Brachman study saw an unexpected five cases of inhalational anthrax occur, although the aim of the study was to examine vaccine efficacy against cutaneous disease. Of these five cases, two occurred in placebo recipients and three occurred in persons who had declined to participate in the study; none occurred in vaccine recipients. While this was not statistically powerful enough to lead to a conclusion regarding efficacy, it is in line with subsequent data collected by the CDC from 1962 to 1974, wherein 24 cases of inhalational anthrax occurred among unvaccinated textile mill employees, while none occurred among employees who had elected vaccination [11].

A second source of efficacy data derives from animal trials involving nonhuman primates. In several small studies conducted at Fort Detrick's U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID), adult rhesus monkeys were given one or two injections of AVA and then challenged with varying doses of aerosolized Ames-strain anthrax spores at varying intervals after immunization. In all, 62 of 65 animals survived challenge, compared with none of the 18 control animals. These studies have recently been summarized [11].

Finally, some controversy surrounds the "programmatics" of the AVIP and of anthrax immunization in general. Undoubtedly, the prospects of immunizing large numbers of individuals against anthrax are made less palat-

able by the unwieldy vaccine schedule. Currently, AVA is licensed as a six-dose series, with doses at 0, 2, and 4 weeks, and 6, 12, and 18 months. Moreover, annual boosters are advised for personnel at ongoing risk of contracting anthrax. In the military especially, given the mobility of its personnel and the attendant difficulties in record keeping, this presents a formidable obstacle. In fact, ongoing studies are examining the feasibility of AVA dose reduction (i.e., eliminating doses of vaccine). A preliminary study [12] comparing recipients of three doses (at 0, 2, and 4 weeks) with those who received only two doses 4 weeks apart demonstrated comparable peak anti-PA IgG antibody titers in both groups. Efforts are underway to expand on this preliminary work in anticipation of a petition to the FDA for dosing adjustment.

Another area of concern deals with vaccine employment strategy. The vaccine was initially licensed for pre-exposure prophylaxis against anthrax in those persons "who may come in contact with animal products." In fact, it was previously noted that "if a person has not previously been immunized against anthrax, injection of this product (AVA) following exposure to anthrax bacilli will not protect against infection [13]." Nonetheless, some authorities now see a potential role for AVA as a postexposure adjuvant to chemoprophylaxis. Such recommendations are based on findings that a percentage of nonhuman primates succumb to experimental inhalational anthrax following withdrawal of antibiotics after a 30-day course. Such studies were recently summarized by the CDC, which noted a "possible benefit of postexposure combination of antibiotics with vaccination [14]." Based on these same studies, the Defense Department has also acknowledged a role for postexposure immunization [15].

Finally, concern surrounds modernization efforts at AVA's manufacturer, the BioPort Corporation (Lansing, MI). BioPort acquired the assets of the Michigan Biologic Products Institute (MBPI) in September of 1998. It was MBPI that had been initially awarded a contract to provide AVA to the Department of Defense. In August of 1999, BioPort applied to the FDA for a license supplement for a renovated vaccine production facility and was asked to cease production of AVA until process validation work could be accomplished to the satisfaction of the FDA. These delays resulted in phased slowdowns of the Defense Department's AVIP in July 2000, November 2000, and June 2001. These slowdowns led to an erosion of confidence among some potential vaccine recipients and their advocates. On January 31, 2002, however, the FDA approved BioPort's Biologics License Application supplement, and full-scale resumption of the AVIP, as of this writing, awaits only the approval of the Secretary of Defense. On March 6, 2002, The National Academy of Sciences, through its Institute of Medicine, concluded that AVA was effective at protecting humans against anthrax "including inhalational anthrax" [16]. Moreover, they also noted that that AVA had a side-effect profile comparable to other vaccines commonly employed in the United States.

Prompted by the safety, efficacy, and programmatic concerns surrounding AVA, however, interest in the development of new anthrax vaccines has increased in recent years. Several approaches have been employed in the search

**Table 2** Studies of Safety of Anthrax Vaccine Adsorbed (AVA)

Study	Subjects	Vaccinees <sup>a</sup>	Purpose of Study	Findings	Reference
Brachman, 1955–1959	Textile Workers; Original licensure study	379 (D)	Pivotal safety and efficacy trial	~30% “mild” reactions; 4% moderate (>5cm) reactions	7
CDC, 1962–1972	Occupationally At-Risk	6985 (M)	Postlicensure monitoring	3–20% mild (<3 cm); 1–3% moderate (3–12 cm) reactions	8
Ft Detrick Multidose, 1944–1971	Laboratory Workers; Hyper-Immunized	97 (M)	Evaluate effects of “hyper-immunization” with large numbers of various vaccines	No unusual disease attributed to receipt of large numbers of vaccines (including AVA)	89
Ft Detrick SIP, 1973–1999	Laboratory Workers	1583 (L)	Cohort safety study (passive surveillance)	3.6% local reactions; ~1% systemic reactions	9
Ft Bragg, 1992–1994	Special Forces Soldiers	495 (L)	Assess safety of AVA booster doses among those immunized during ODSIS	16–28% mild (<5 cm); 4.7–9.3% moderate; 26–45% systemic reactions	90
USAMRIID Dose Reduction, 1998	Adult Volunteers	173 (L)	Pilot study evaluating reduced dosing schedule for AVA	Induration in 3–19% of males, 38–75% of females	12
Canadian Forces Safety Survey, 1998	Military Personnel	576 (L)	Active surveillance for AVA-associated adverse reactions	Mild (<5cm) reactions in 4.4% of doses/12.7% of recipients; moderate in 0.2/0.5%	91
Tripler Survey, 1998–2000	Military Personnel	601 (L)	Self-reporting of reactions to AVA among medical personnel	2.1–2.7% reported systemic symptoms limiting activity	92
U.S. Forces Korea, 1998–1999	Military Personnel	4348 (L)	Self-reporting of reactions to AVA among military personnel	1.9% of recipients reported limitations on work performance	92

VAERS Reports, 1990–2000 Ft Lewis, 2000	All Vaccines (presumably military) ROTC Cadets	1563 (L) 73 (L)	Collection of reports to FDA regarding adverse events Assess reactions among those inadvertently receiving a double dose of AVA	No unexpected findings in side-effect profile of AVA Erythema: 39% in double group vs. 19% in standard.
Langley AFB, 1998–1999	Air Force Personnel	4045 (L)	Study link between AVA and ambulatory diagnoses among SW Asia veterans	Lump: 44/29%; Swelling 50/19% No link between AVA receipt and any specific ambulatory diagnosis
Ft Stewart, 2000–2001	Female Military Personnel	3136 (L)	Evaluate reproductive health among AVA recipient females	No link between AVA receipt and rates of conception, birth, or birth defects
Reproductive Outcomes Study, 1998–2000	Wives of Military Vaccines	68,267 (L)	Evaluate reproductive outcomes of wives & neonates of vaccinees	No increase in hospitalization rates or adverse pregnancy outcomes in wives of vaccinees
USAF Vision Study, 1998–1999	USAF Air Crew Members	(L)	Evaluate causes of visual deterioration	No link between AVA and visual deterioration
Army Aviator Study, 1998–2000	Army Aviators	3356 (L)	Evaluate relationship between AVA and hearing loss	No link between AVA and hearing loss
Defense Medical Surveillance, 1998–2001	Military Personnel	757,540 person-years (L)	Examine hospitalization rates of vaccinated and unvaccinated individuals over time	No increase in rates of hospitalization among vaccinated for all 14 disease categories
Naval Health Research Center, 1998–2000	Military Personnel	(L)	Examine hospitalization rates of vaccinated and unvaccinated individuals over time	Lower hospitalization rates among vaccinated individuals compared to nonvaccinated

for a new anthrax vaccine [17]. First, the PA gene has been cloned into *Bacillus subtilis*, a taxonomic relative of *B. anthracis* lacking virulence for humans, and into other expression vectors. Second, mutant-strain vaccines have been created from the Sterne strain which depend on aromatic compounds not found in human tissue. Finally, purified PA preparations have been combined with various adjuvants. All three approaches have led to the development of experimental vaccines which are protective against aerosolized spore challenge in guinea pigs [18–20]. In particular, a vaccine candidate composed of purified PA combined with monophosphoryl lipid A appears promising. In guinea pigs, this vaccine proved superior in efficacy to the currently available human vaccine. Moreover, lyophilization appeared to have no effect on vaccine potency—a potential advantage over the current preparation, which requires a cold storage chain. Finally, a DNA plasmid vaccine which incorporates the immunogenic and biologically active portion of PA has demonstrated protection in mice against lethal challenge with a preparation of PA + LF [21]. A concise review of the prospects for development of new generation anthrax vaccines has recently been published [22].

## B. Smallpox

Smallpox, a disease limited to humans in the natural setting, was caused by infection with variola virus, a member of the *Orthopoxvirus* genus. A closely related cross-protective Orthopoxvirus, vaccinia, has long been, and remains, the basis of vaccination efforts. The global eradication of endemic smallpox, accomplished in 1977 and formally acknowledged by the World Health Organization (WHO) in 1980, stands as one of the great triumphs of public health. Unfortunately, the subsequent discontinuation of vaccination opened the door for this agent to be used as a weapon of warfare or terrorism. Currently, there exist only two WHO-authorized repositories of the virus: at the CDC in Atlanta and Koltsovo in Russia. However, concerns persist that other clandestine stocks may exist and that these stocks could find their way into the hands of terrorists. Moreover, there are concerns that other orthopoxviruses could be genetically manipulated to produce virulent organisms similar to variola.

Over the years, the numerous, often poorly characterized, strains of vaccinia virus previously employed in vaccination were abandoned under the auspices of the WHO. Ultimately, derivatives of three strains remained available: the Lister–Elstree strain, the EM63 strain (used in the Soviet Union), and the New York City Board of Health (NYC-BOH) strain, an isolate of low pathogenicity [23] used in vaccine production by Wyeth Laboratories. A fourth strain, the “Temple of Heaven” strain, remained in widespread use in the People’s Republic of China. The Wyeth product, Dryvax®, is currently available through the CDC, which has approximately 15.4 million doses on hand [24]. It is administered by scarification with a bifurcated needle dipped in vaccine; further guidelines for its use are published [25]. The effectiveness of vaccinia vaccine is attested to by its success in smallpox eradication; however, future availability of the vaccine has, until recently, been a concern. Wyeth

discontinued the manufacture of Dryvax® in 1982, the existing doses are undergoing a gradual loss of potency, and all will ultimately expire. Moreover, recent testing of the product diluent revealed that the phenol level did not meet specifications. Therefore a new diluent (lacking brilliant green) has been manufactured and the vaccine must thus be administered under the CDC’s IND with informed consent.

In light of these issues, three different approaches have been taken to improve the country’s preparedness for an outbreak of smallpox. First, collaborative work has been undertaken by investigators at USAMRIID and the CDC to develop a nonhuman primate model for smallpox in order to test new compounds (such as cidofovir) for therapeutic efficacy. Second, clinical trials have been conducted at several universities in cooperation with the National Institute of Allergy and Infectious Diseases to evaluate whether the existing Dryvax stocks could be diluted 5-, 10-, or 100-fold and still produce an effective “take.” This would provide an immediate method of expanding the existing vaccine stockpile. In a pilot study using 20 subjects per group, previously unimmunized individuals given undiluted vaccine and vaccine diluted 10- or 100-fold, 95%, 70%, and 15%, respectively, had evidence of a take [26]. The results of a larger follow-up study with 5- and 10-fold dilutions were more promising, with 232/234 (99.1%) being successfully vaccinated with a 5-fold dilution and 330/340 (97.1%) successfully vaccinated with a 10-fold dilution [27]. The mean titer of the diluted vaccine in the 10-fold dilution arm was  $10^{7.0}$  PFU compared with  $10^{6.5}$  PFU/mL in the pilot study, indicating that a titer of approximately  $10^{7.0}$  PFU/mL is needed for a higher take rate. The third approach has been to launch a large-scale effort to produce a new cell-culture-derived vaccine. Investigators at USAMRIID first developed a new vaccine at the request of the Defense Department. This cell culture preparation derives from a Connaught (NYCBOH) vaccine strain in use until the early 1970s, and recently underwent Phase II testing in human volunteers. In this study, vaccinees receiving the cell culture vaccine intradermally, with subsequent development of cutaneous pox lesions, had immune responses comparable to those receiving Dryvax® by scarification. Those recipients who failed to develop pox lesions, or who received intramuscular vaccine, experienced humoral immune responses inferior to those elicited in the Dryvax® group [28]. From this study, it is clear that administration by scarification remains necessary. An expanded trial, comparing Dryvax® and the cell-culture-derived preparation, both administered by scarification, has been completed and is pending publication. There are two additional cell-culture-derived products being evaluated. The master virus and cell banks from the USAMRIID preparation were subsequently rederived and an IND request for the new product filed by the Defense Department’s Joint Vaccine Acquisition Program (JVAP) in March, 2002. The first clinical trial of this product is scheduled to begin in the near future. A second cell-culture-derived product was manufactured by Acambis Corporation, under contract with the CDC to produce 155 million doses. This product is a plaque-purified clone from Dryvax. A Phase I trial has been executed but final results are still pending. This product, like the JVAP product, is propagated in MRC5 cells.

Fortuitously, in March, 2002, Aventis Pharmaceuticals [29] revealed that they had discovered 85 million doses of frozen liquid smallpox vaccine produced in the late 1950s. Therefore, the existing U.S. stockpile of vaccine has jumped from 15 million to 100 million doses even without dilution of existing stocks or new cell-cultured vaccine production. The recently discovered product appears to be potent and clinical studies are planned.

### C. Plague

Plague is caused by infection with *Yersinia pestis*, a bipolar-staining gram-negative facultative intracellular bacillus. Human plague occurs rarely in the western world, but remains endemic in India, Burma, Vietnam, Madagascar, and elsewhere. Of the three typical presentations of illness—bubonic, pneumonic, and septicemic plague—bubonic continues to be the most common, and until recently, vaccine development efforts targeted this form of the disease.

In 1897, Haffkine [30] developed a “plague prophylactic fluid,” which was a killed vaccine preparation used to combat the disease in India, where it was hyperendemic. Although the preparation was apparently efficacious in preventing the bubonic form of the disease, clinicians rejected it because of the high rate of adverse reactions [31] caused by the injection of up to 12 mL of vaccine. (It was erroneously believed that doses sufficient to cause systemic febrile reactions were necessary to induce protective immunity.) Prior to World War II, a new-generation, formalin-killed modification of the original Haffkine vaccine was prepared from *Y. pestis* strain 195/P, a virulent clinical isolate from India. Ultimately, the National Research Council Committee on Medical Research recommended the use of such killed vaccines in military personnel. During World War II, approximately 12,000 troops were immunized with a two-dose vaccine series of Plague Vaccine, USP, an Army version of the formalin-killed preparation. Despite potential exposures from deployments into areas of high endemicity, none of the soldiers contracted plague, providing circumstantial evidence of efficacy [31].

Only eight cases of plague were reported among U.S. service members during the Vietnam War, where the vaccine was routinely administered. The success of the vaccine is attested to by comparing rates of the disease among the U.S. personnel and the unvaccinated South Vietnamese civilian population. U.S. personnel had a rate of approximately 1 case per million person-years of exposure [32], compared with a 330-fold greater incidence of plague among the unvaccinated South Vietnamese civilian population [33]. The relatively high incidence among U.S. troops of murine typhus, another disease transmitted in Vietnam by the same vector, *Xenopsylla cheopis*, implies that the U.S. troops likely had exposure to plague, despite the low disease rates [34].

Even though the plague vaccine appears to protect soldiers against endemic plague, the preparation most recently used is not considered protective against infection by the aerosol route [35,36], which is the route of most concern in the context of a biological attack. In addition, local reaction rates to the plague vaccine are high, with reaction

rates increasing with successive doses. Hence the initial dose is 1.0 mL, but the second and third doses of the primary series (at 1–3 and 5–6 months, respectively) are reduced to 0.2 mL [35]. In addition, 20% of vaccine recipients reported systemic reactions [37]. Moreover, 7% of vaccinees failed to respond serologically, while many others required the full three-dose series to achieve hemagglutination titers similar to those protective in mice [38]. Finally, the short duration of immunity elicited by this vaccine necessitated booster doses as often as every 6 months [35]. These difficulties, as well as supply and manufacturing problems and limited commercial demand outside the military, led to a discontinuation of production in 1999. The fact that no licensed plague vaccine is currently available, and that previous vaccines were not effective against plague transmitted by aerosol, drives an interest in new generation vaccines.

One theory guiding the search for an improved vaccine suggests that mucosal immunity in the tracheobronchial tree may be important in the defense against pneumonic plague [39]. Oral immunization of vervets with a live-attenuated *Y. pestis* vaccine, EV76, afforded some protection against inhalational challenge [40]. However, EV76 and similar live plague vaccines produced a significant number of side effects when administered subcutaneously to humans. Moreover, approximately 1% of mice given EV76 succumbed to fatal infection [41].

A more recent approach to vaccine development involves the use of recombinant subunit vaccines. The F1 (“fraction 1”) and V (“virulence”) antigens of *Y. pestis* have both been shown to be individually immunogenic. Moreover, their protective effects in combination appear additive [42]. Furthermore, although antibody against F1 alone protects against plague, F1 is not critical for virulence, and virulent F1-negative *Y. pestis* strains have been described [43], adding theoretical support to the case for a multiantigen vaccine. Single-dose immunization with a subunit vaccine containing F1 and V antigens has been shown to protect mice against pneumonic disease [44]. Studies are ongoing to evaluate these vaccine candidates further.

### D. Tularemia

Tularemia, a plague-like illness, is caused by infection with the gram-negative coccobacillus, *Francisella tularensis*. Two biotypes of *F. tularensis* are known; *F. tularensis tularensis*, the causative agent of “Type A” tularemia, is found only in temperate areas of North America. It is an organism of extraordinarily high virulence, with as few as 10 cells representing the rabbit lethal dose ( $LD_{50}$ ) and human infectious dose ( $ID_{50}$ ). *Francisella tularensis palearctica*, the agent of “Type B” tularemia, on the other hand, is a low-virulence organism found in Europe and the former Soviet Union. The rabbit  $LD_{50}$  of this organism is of the order of 10 million cells. These differences have potential implications in vaccine development, although immunity against one biotype appears to be cross-protective. Current tularemia vaccines derive, by and large, from seed stocks of the “live vaccine strain” (LVS), which, in turn derives from “strain 15,” biotype *palearctica*, an organism attenuated by repeated subculture. The fact that *F. tularensis* occupied a prominent

position in the Cold War-era biological arsenals of both the United States and the Soviet Union is made more intriguing, considering that "strain 15" was given to U.S. investigators in 1956 by colleagues at the USSR's Gamaleya Institute. An LVS-based investigational vaccine has been sporadically used in the United States since that time to immunize laboratory workers in select settings. Multiple studies attest to its efficacy in preventing inhalational tularemia among human volunteers [45,46].

Despite their apparent efficacy, several considerations limit the potential employment of LVS-based vaccines [47]. First, knowledge of factors responsible for virulence in *F. tularensis* remains incomplete. Second, concerns persist regarding the genetic stability of the vaccine strain, namely that LVS might revert to a more virulent or, alternatively, a less protective, state. Precedent for the latter exists among *F. tularensis* vaccine strains previously employed in the Soviet Union. Third, LVS preparations consist of two colony types, only one of which appears immunogenic. Combined, these factors dictate that each new lot of tularemia vaccine is evaluated for immunogenicity prior to use [48]. Moreover, any LVS immunization strategy is potentially hampered by the need to administer the vaccine by scarification, wherein a 0.1-mL dose is applied to the skin, which is then punctured by 16 stabs of a bifurcated needle. These microbiologic and clinical concerns, the ill-defined nature of the vaccine strain, and cases of clinical tularemia among vaccinees receiving larger inocula would seem to argue for the need for an improved vaccine.

However, the search for new tularemia vaccine candidates is hampered by uncertainty over the nature of antigens required for protective cell-mediated immunity and a failure of killed vaccines to produce such immunity. In fact, few significant developments have occurred in the search for improved tularemia vaccines over the past half-century. In addition to the problems of antigenic characterization, this is likely due, in part, to the rather low incidence of endemic tularemia in the west, as well as to the lesser perceived threat posed by weaponized tularemia when compared, for example, to weaponized anthrax, smallpox, or plague. In fact, the JVAP has taken on responsibility for shepherding the current LVS vaccine through to FDA licensure.

## E. Botulism

Botulism is caused by exposure to any of seven related neurotoxins (types A–G) produced by the obligately anaerobic gram-positive bacterium, *Clostridium botulinum*. While only toxin types A, B, and E appear to be significant causes of naturally occurring botulism, other toxin types have the potential to produce disease. Although a licensed antitoxin designed to treat endemic disease thus contains antibody against only types A, B, and E, defense planners anticipate that vaccines against an intentional botulism release should optimally induce immunity against a broader array of toxin types.

The relatively low incidence of naturally occurring botulism has hindered vaccine development, and no licensed product exists today. A pentavalent (types A–E) toxoid, prepared by combining separate aliquots of the five inacti-

vated toxins was originally produced by Parke-Davis. A second, less-reactogenic, pentavalent product, with a decrease in the amount of residual formaldehyde, but otherwise little changed from the original, has been produced for the U.S. Army by the Michigan Biologic Products Institute. Several thousand volunteers and at-risk laboratory workers have received this toxoid on an investigational basis. The vaccine regimen consists of a three-dose series, involving 0.5-mL subcutaneous doses at 0, 2, and 12 weeks, with annual boosters, a strategy hampered by an increasing rate of local reactions to each subsequent booster. A separate inactivated monovalent type F vaccine of similar construct has also been available on a very limited investigational basis.

Local reactions to current investigational preparations, coupled with cold-storage requirements, less than desirable antibody titers to types B and D toxin, and high cost, have spurred efforts to develop improved botulinum toxoids. Several avenues of research appear to hold promise in this regard. First, recombinant technology has been used to express a fragment of the heavy chain of type A toxin in *Escherichia coli* [49]. Mice immunized with this preparation are protected against intraperitoneal challenge with type A botulinum toxin. Second, a Venezuelan Equine Encephalitis (VEE) virus replicon vector has been employed to produce toxin antigens *in vivo* [50] (see also section on VEE). Finally, *C. botulinum* carboxy-terminal-fragment-coding genes have been synthesized and the nontoxic gene products expressed in yeast [51]. The resultant product induces immunity against high-level challenge in both mice and nonhuman primates.

## II. SELECT CATEGORY B AGENTS

### A. Brucellosis

Brucellosis is caused by infection with one of several species of the genus *Brucella*, a group of gram-negative facultative intracellular coccobacillary bacteria. Brucellosis is a major veterinary problem in many areas of the world and naturally occurring human brucellosis is not uncommon in some locales, especially in the Middle East. In addition, despite its long incubation period and low lethality, many experts consider brucellosis, because of its extraordinary infectivity, a viable terrorist threat.

Veterinary vaccines against brucellosis have long been studied and widely employed. The vaccination of livestock to reduce enzootic disease load, in combination with the slaughter of infected animals, is largely responsible for the declining incidence of human brucellosis in the United States. In fact, the decline of human brucellosis cases reported to the Centers for Disease Control has paralleled the control of *Brucella abortus* infections in cattle [52]. Most veterinary vaccines in use until recently derived from *B. abortus* strain 19, an attenuated organism with stable virulence, or from Rev 1, a live, virulence-stable *B. melitensis* strain. In 1996, a new generation vaccine, derived from strain RB51, a stable mutant of *B. abortus*, was conditionally licensed for use in cattle. This mutant strain, which lacks a polysaccharide O-chain, fails to induce antibody detectable

by current veterinary screening assays. Bovine brucellosis eradication campaigns make use of such antibody detection to detect infection and institute quarantine procedures among cattle herds. RB51 has the advantage of not interfering with such campaigns.

Although live *Brucella* vaccines have been employed in humans at various times and in various developing nations [53], none are licensed in most of the Western world, including the United States. Most preparations studied in humans in the past derived from *B. abortus* strain 19, reflecting the cross-immunity among *Brucella* species, and diminished human virulence of *B. abortus* when compared with other species. Despite their relatively low virulence, however, administration of either live preparation to humans is hampered by frequent hypersensitivity reactions and by a modest but notable incidence of clinical infection. Such problems were noted in the former Soviet Union, where human vaccination is still widely employed, and in a U.S. trial of strain 19 and Rev 1 vaccines conducted 35 years ago [54]. More recently, human infections have resulted from inadvertent exposure to veterinary RB51 vaccines as well [55].

Several attempts have been made to develop fractional component vaccines derived from various *Brucella* strains. An acetic-acid extract of a variant of strain 19 *B. abortus*, yielding a complex known as "brucellosis protective antigen," was tested in the USSR [56]; immunity elicited in guinea pigs failed to persist. A "phenol-insoluble fraction" vaccine consisting primarily of delipidated strain 19 components protected mice and guinea pigs from challenge, and has been used on a small scale in humans [57]. While this latter preparation was apparently efficacious at protecting high-risk recipients, immunity was not lasting, and boosting appeared necessary every 2 years. Moreover, any strategy for immunization (and especially for reimmunization) was further complicated by the need for skin testing of potential recipients, as skin-test-positive patients react strongly to vaccine. More recently, the outer membrane protein (OMP) of *Neisseria meningitidis* has been shown to be a useful adjuvant to intranasal *B. melitensis* immunization in mice and guinea pigs [58], and a mucosal vaccine combining OMP with purified lipopolysaccharide of *B. melitensis* is under study.

## B. Q-Fever

Q-fever is caused by infection with *Coxiella burnetii*, a pleomorphic gram-negative coccobacillary organism. Like brucellosis, Q-fever has a long incubation period but an extraordinary degree of infectivity. In fact, a single bacterial cell likely represents a human ID<sub>50</sub>. This high degree of infectivity, combined with a resistance to heat and dessication, explain the consideration given Q-fever as a potential weapon.

Effective vaccines against *C. burnetii* have existed for over half a century. The Smadel vaccine [59] was a highly immunogenic, formalin-inactivated preparation derived from the Henzerling strain of *C. burnetii*. The history of this and related early vaccines has been reviewed [60]. Although apparently effective, early vaccines occasionally resulted in significant morbidity, with sterile abscess and sinus forma-

tion frequently occurring at inoculation sites [61]. Q-fever vaccines with improved immunogenicity followed the discovery of the phenomenon of phase variation among *C. burnetii*. The organism is pathogenic and immunogenic in its Phase I form, but reverts to an avirulent, nonimmunogenic Phase II form after serial passage in yolk sac cultures. Awareness of this phase shift permitted the manufacture of more potent vaccines formulated entirely of Phase I organisms.

A formalin-inactivated, purified, Henzerling strain, Phase I whole-cell Q-fever vaccine has been licensed for many years in Australia as Q-Vax®. While Q-Vax® has been shown to be highly efficacious at preventing clinical Q-fever in humans [62], concerns exist regarding the potential for severe local reactions in patients with pre-existing immunity to *C. burnetii*. Use of a skin test, consisting of 0.1 mL of vaccine (intradermally administered), to identify these patients, can reduce the incidence of local reactions, but adds to the cost and complexity of immunization efforts. An analogous vaccine, administered in a one-time 0.5-mL subcutaneous dose, has been used on an investigational basis for many years in the United States.

The morbidity and skin testing requirements associated with whole cell vaccines might be eliminated with the development of a chloroform–methanol residue (CMR) preparation. The CMR vaccine contains Phase I antigens, and in animal studies, is less reactogenic than Q-Vax®, with comparable efficacy [63]. In humans, CMR vaccine was safe and immunogenic in nonimmune volunteers [64] and is currently being examined for reactogenicity in Q-fever immune individuals.

## C. Venezuelan Equine Encephalitis

Venezuelan Equine Encephalitis (VEE) is caused by infection with the new-world alphavirus of the same name. Despite a natural transmission cycle requiring a mosquito vector, the disease is nonetheless transmissible artificially via aerosol, accounting for its inclusion among the list of terrorist and warfare threats.

A live-attenuated vaccine against Venezuelan Equine Encephalitis, TC-83 (so called because of its 83 passages in cell culture) was first developed in 1961 [65,66]. Evidence for the efficacy of this vaccine is largely anecdotal, relying on an observed marked decline in laboratory-acquired VEE infections among vaccine recipients. Despite its apparent efficacy, however, TC-83 vaccination is complicated by a high systemic reaction rate [65]. Moreover, a substantial number of primary TC-83 vaccine recipients fail to mount an adequate serologic response [67]. A tissue culture of TC-83 vaccine, inactivated with formalin, led to a less reactogenic preparation, C-84 [68]. Unfortunately, however, when given alone, this preparation afforded inadequate protection against aerosol challenge in hamsters [69]. Moreover, in human volunteers, one or two doses of C-84 alone (as compared to a dose of TC-83 with and without C-84 boosting) led to a particularly deficient IgA antibody response [70]. It has been postulated that IgA is the dominant immunologic entity responsible for protection against VEE. In practice, select laboratory workers are now given C-84 as a booster immunization following priming with TC-83 [67].

Driven by the high systemic reaction rate and incomplete protection afforded by TC-83, new approaches to immunization against VEE are actively being explored. One strategy involves a recombinant attenuated VEE vaccine, V3526, which features mutations at two loci. These mutations minimize the risk of reversion to virulence and result in a vaccine potentially less reactogenic than TC-83. In preliminary studies, V3526 protected mice against intranasal challenge with fully virulent VEE virus [71]. A second strategy involves incorporation of TC-83 virus, inactivated by radiation, into DL-lactide-co-glycolide microspheres. In one study [72], mice immunized with this microsphere preparation experienced greater protection against systemic challenge than those immunized with free virus.

Of interest, a considerable amount of ongoing work with VEE virus involves its potential use as a vector for the delivery of other recombinant vaccines. These vaccine vectors, or replicons, are developed by substituting genes coding for a protein of interest (for example, an immunizing epitope of a different virus or bacteria) for those coding for VEE structural proteins. The result is a viral genome that encodes its own replicases and transcriptases, enabling the synthesis of abundant quantities of mRNA coding for the protein of interest. The replicon genomes can be encapsidated into virus-like particles by cotransfected replicon RNA along with helper RNAs coding the VEE nucleocapsid and capsid proteins. These virus-like particles contain the recombinant RNA genome. Following inoculation, the particles are taken up by immune effector cells; heterologous antigens are expressed, and protective immunity results. Because the replicon genome lacks the genes for VEE structural proteins, no viral progeny are produced. Consequently, the infection is limited to one cycle; viremia does not develop, and immunity to VEE structural proteins does not develop [73]. This approach has been successful in immunizing rodents against Ebola and Marburg viruses [74], as well as against type A botulinum toxin [50] and many other agents. Replicons could theoretically be developed to encode multiple antigens, conferring immunity against numerous pathogens. Because immunity to VEE structural proteins does not result, VEE replicons could theoretically be used repeatedly for booster immunizations, or for sequential immunizations against numerous pathogens, without being inactivated by host immunity. This offers a potential advantage over vaccinia- and adenovirus-vectored recombinant vaccines [75].

Currently, laboratories employing VEE vaccines to protect those studying the virus or utilizing VEE virus as a vector in replicon work offer an initial 0.5-mL subcutaneous dose of TC-83, followed 28 days later by an assessment of plaque-reduction neutralization titers. Recipients with titers <1:20 are given a 0.5-mL subcutaneous dose of C-84. Typically, subsequent titer checks would be performed annually on recipients at ongoing risk; C-84 boosters would be administered when titers fall below 1:20.

VEE is only one of a group of alphaviruses occasionally mentioned in a bioweapons context. However, despite the fact that they tend to cause more severe disease in humans, the closely related agents of Eastern (EEE) and Western (WEE) Equine Encephalitis, are generally felt to represent less of a threat than VEE. This is principally due to the high

proportion of asymptomatic infections associated with these viruses. Whereas the disease to infection ratio of VEE is on the order of 1:1, that of EEE [76] is 1:23 and of WEE [77], 1:1150. Nonetheless, investigational inactivated vaccines have been developed against EEE and WEE, employing technology analogous to that used in the production of C-84. Similarly, a live vaccine candidate against the Old World alphavirus, Chikungunya, has been developed and evaluated in Phase II human trials [78]. Currently, usage of these vaccines is limited to a small number of laboratory investigators working with the viruses. The Department of Defense's JVAP has contract options for the development of a trivalent VEE/EEE/WEE vaccine.

#### D. Staphylococcal Enterotoxin B Intoxication

Staphylococcal enterotoxin B (SEB) is one of several pyrogenic exotoxins produced by *Staphylococcus aureus*. A familiar cause of naturally occurring food-borne disease, SEB (and other staphylococcal enterotoxins) might be employed by terrorists to contaminate food and water. In addition, however, SEB lends itself to aerosolization, producing a systemic febrile illness accompanied by pulmonary symptoms when encountered via this route. In a recent report [79], a laboratory accident resulted in nine workers developing inhalational SEB disease. Fever was prominent in all subjects, reaching as high as 106°F. All had cough, in most cases accompanied by dyspnea and chest pain.

No SEB vaccine is currently available for human administration, although several approaches to immunization against SEB intoxication have been explored. Formaldehyde-inactivated SEB toxoid, prepared as an alum precipitate, has been incorporated into microspheres and proteosomes. Microspheres containing SEB toxoid administered intramuscularly with an intratracheal booster protect rhesus monkeys against aerosol challenge [80]. In another approach, mutations were induced in the SEB molecule which render it nontoxic yet leave its three-dimensional antigenic structure intact. Using such a preparation with three-point mutations, investigators demonstrated immunogenicity in rhesus monkeys without apparent toxicity [81]. More recently, this attenuated SEB protein has been expressed in *E. coli* and the resultant recombinant product shown to protect mice against SEB intoxication when administered nasally or orally. Moreover, protection was afforded against both inhalational and parenteral (intraperitoneal) challenge [82].

#### E. Ricin Intoxication

Ricin is a toxic glycoprotein derived from the castor bean. Its ease of extraction from the by-products of castor oil production and its worldwide availability combine to make it an attractive candidate agent to would-be terrorists and bio-criminals. Moreover, ricin is extremely toxic by oral, respiratory, and percutaneous routes, further enhancing its potential attractiveness. In fact, ricin has been used percutaneously in multiple assassination attempts [83].

There is no effective human vaccine against ricin intoxication. Both a formalin-inactivated toxoid [84] and a degly-

cosylated A-chain subunit vaccine [85] have been shown capable of protecting mice against aerosol challenge. Encapsulation of toxoid in Poly(lactide-co-glycolide) microspheres resulted in mouse protection following both intramuscular [86] and oral [87] administration. A separate preparation of toxoid encapsulated within liposomes was likewise effective at protecting mice when administered intratracheally [88].

It seems clear in the aftermath of September 11 that terrorism concerns are likely to remain with us for some time. Paramount among these threats in the eyes of many planners, the biological threat has been likened to the "poor man's atomic bomb." Effective strategies must be developed to combat this threat. Immunizations are likely to play a prominent role in any comprehensive defense strategy. As our understanding of the heretofore largely obscure pathogens that constitute viable threats increases, effective vaccines against these pathogens will likely become a reality.

*VaxGen, Brisbane, California, U.S.A.*

### I. DIFFERENT VACCINE TYPES AND THEIR MAJOR PRODUCTION STEPS

The major vaccines licensed and used in the United States, by manufacturer, and their primary manufacturing technology are shown in Appendix A. Similar vaccines are on the market in many other countries. Table 1 divides the most commonly used vaccines into product classes and summarizes the basic techniques involved in their bulk manufacture, with examples of each. Section II outlines the basic production process and defines in more detail what is involved in each of these steps.

### II. MANUFACTURING PHASES AND CRITICAL ISSUES FOR EACH

The access to manufacturing capacity includes:

- The receipt and control of raw materials to be used in the production process
- The production of purified bulk antigen from various expression systems or directly from live, possibly attenuated strains of the agents
- Aseptic filling and final packaging of stable proteins or live infectious agents
- Analytical capacity to evaluate the products using standard biochemical or physiochemical methods or specialized biological tests
- Appropriate storage and distribution

These steps will be considered in more detail below. The entire process may take from 1 to 2 years to manufacture and release a vaccine [1], although production can be fast-tracked, for example, for biodefense products or the annual

formulation of influenza vaccines. This is illustrated in Figure 1. Production flowcharts to illustrate the process for oral polio vaccine and for *Haemophilus influenzae* type b conjugate vaccine (tetanus conjugate) are included in Appendix B.

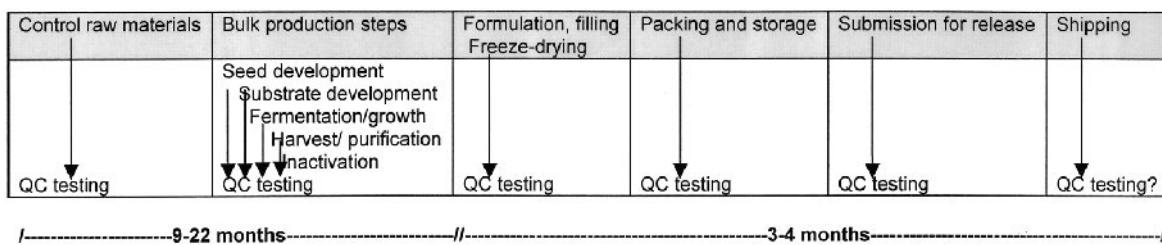

#### A. Raw Materials

All raw materials must come from reliable sources and be shown to meet specifications. Most manufacturers use supplier qualification coupled with some quarantine release tests to assure the quality of the raw materials. Raw materials must be kept under quarantine until released from the Quality Control department. However, the primary raw materials for biological products, seeds, cells, and biological fluids, are subject to intense documentation and testing measures, which will be covered more thoroughly in Section II.B. Recently, there has been particular concern with some specific raw materials commonly used for vaccine production.

- Bovine material, most commonly fetal calf serum, is used in growth media for most cell culture-produced viral vaccines. To avoid the potential risk of transmission of bovine spongiform encephalopathy (BSE), any bovine materials must be sourced from geographic locations shown to be BSE-free and from parts of the animal shown to be at low risk for transmitting BSE. For new vaccines, avoiding bovine material is an objective, and serum-free media have now been developed.
- Human albumin has been used in formulating many vaccines, but the trend is to replace it with other products or to eliminate it.

**Table 1** Process of Bulk Manufacture for Selected Vaccine Types

Vaccine type	Process	Examples
Attenuated microbial cells	Growth and purification of microbial cells adapted or engineered to delete pathogenicity, retaining immunogenicity. Steps include fermentation and purification	BCG, oral typhoid, oral cholera
Killed microbial cells	Growth, inactivation, and purification of microbial cells. Steps include fermentation, inactivation, and purification	Whole cell pertussis, anthrax, cholera/typhoid
Live attenuated viruses	Growth of cells (from cell banks of continuous cells or primary cells from animal/egg tissue), infection with attenuated virus, isolation, and purification of virus. Cells are propagated in bioreactors, roller bottles, hollow fiber, cell cubes, flasks, or microcarrier culture with various types of feeding. The medium is generally entirely synthetic but may contain blood proteins to enhance growth. Cells are infected with the vaccine virus; removal of cell or cell debris by centrifugation or ultrafiltration methodology; purification of virus if required, concentration	Yellow fever, measles-mumps-rubella, OPV, varicella
Killed viruses	Growth of cells (from cell banks of continuous cells or primary cells from animal/egg tissue), infection with virus, isolation, inactivation, and purification of virus. Cells are propagated in bioreactors, roller bottles, hollow fiber, cell cubes, flasks, or microcarrier culture with various types of feeding. The medium is generally entirely synthetic, but may contain blood proteins to enhance growth. Cells are infected with the vaccine virus; removal of cell or cell debris by centrifugation or ultrafiltration methodology; purification of virus if required, concentration; inactivation may occur before or after purification, testing for inactivation	IPV, rabies, hepatitis A, Japanese encephalitis B, influenza
Purified polysaccharides	Growth of bacterial culture, extraction, and purification of capsular polysaccharides by centrifugation or filtration; chemical extraction and, in some cases, chromatography; chemical characterization of the polysaccharide; concentration and, in some cases, drying of bulk	Meningitis polysaccharide (ACW135Y), pneumococcal polysaccharides
Conjugated polysaccharides	Growth of bacterial culture, extraction, and purification of capsular polysaccharides, preparation and purification of carrier protein. Chemical modification of polysaccharide; linker if required; chemical processing of carrier if required; conjugation; separation of conjugated from unconjugated species by chromatography; concentration of bulk conjugate if required	Meningitis C, Hib conjugate, pneumococcal 7-valent conjugate
Purified protein, excreted or cell-associated	Growth of bacteria, yeast, or cell culture where cells are expressing a recombinant protein, cell lysis (for cell-associated proteins), isolation and purification of the protein by ultrafiltration methodology; protein purification by chromatography, concentration, buffer exchange, sterile filtration	Hepatitis B (recombinant or plasma-derived), bacterial toxoids, acellular pertussis, split influenza
Live microbial vector	Fermentation in defined media; recovery of whole microbial cells by centrifugation/washing or ultrafiltration methodology	BCG-vectored HIV, Salmonella vectors
Live viral vectors	Growth of cells, infection with genetically engineered replicating nonpathogenic viruses containing added gene of interest, isolation, and purification of virus. Cell culturing in bioreactors, roller bottles, hollow fiber, cell cubes, flasks, or microcarrier culture with various types of feeding; virus infection; cell controls; removal of cell or cell debris by centrifugation or ultrafiltration methodology; purification of virus if required	MVA, canary pox, adeno, AAV vectors for an assortment of antigens
DNA vaccine	Extraction and purification of plasmid DNA from bacterial cells containing desired gene in the plasmid. Fermentation in defined media; recovery of whole microbial cells by centrifugation/washing or ultrafiltration methodology; cell lysis and removal of cell debris (filtration, centrifugation, or expanded bed chromatography); removal of host impurities, RNA, genomic DNA, proteins and endotoxins (salting out, PEG precipitation); concentration (ultrafiltration methodology, PEG precipitation); purification of plasmid DNA by IEC and/or SEC; concentration and buffer exchange; sterile filtration of final bulk	HIV candidates in DNA plasmids, other candidates

**Figure 1** Time frames for major bulk production steps.

- Manufacturers are seeking substitutes for aluminum salts used as adjuvants because of possible injection site reactions, but aluminum remains the best-documented adjuvant.
- The most commonly used preservative, thimerosal, contains mercury, and its use has been required to be minimized in many countries, making the manufacture of multidose vials of vaccine impossible in those countries. Phenoxyethanol is the second preservative widely used having bacteriocidal or bacteriostatic properties, but is less potent than thimerosal.

## B. Bulk Manufacture

Production should occur in dedicated laboratory suites as per current Good Manufacturing Practices (cGMP) guidelines. It is recommended that laboratory areas for generating “clean” (prior to infection with the seed vaccine virus) cultures be segregated from production areas; this can be accomplished by physical barriers and pressurized air locks to prevent cross-contamination. Segregation of upstream (production) and downstream (purification) areas, although recommended, may not be always practical given the design and cost considerations. Release of viruses or bacteria into the environment is a concern for both air and effluents.

### 1. Viral Seed Preparation

Master Viral Banks (MVB) are generally used to initiate manufacture of viral vaccines and viral vectors. Virus seed stocks generated by amplifying the virus/vector in a compatible cell line are typically used to generate the MVB. The use of plaque-purified seed virus stocks aids in reducing the number of defective viral particles in the MVB.

### 2. Bacterial Fermentation

Fermentation generally refers to the process of growing bacteria in large-volume closed systems. In some cases, fermentation technology has been used for eukaryotic cell culture. This will be covered in Section II.B.3. To develop vaccines based on bacteria, the principle of a Master Seed Bank is used as well. The bacterial seed is obtained with a well-documented history and is stored in an appropriate manner. To initiate culture, aliquots of the bacteria are first grown in a small volume, and the culture is incubated at in-

creasingly larger volumes until the volume of the final production scale fermenter is reached. Modern fermenters control and document environmental variables such as temperature, oxygen pressure, and pH, enabling standardized production methods to be used. Because these systems are computer-driven, their validation is not trivial.

### 3. Cell Culture

The history of cell lines should include good documentation of their origin and their passage histories. This documentation should include the number of passages since origination, storage, and cell culture conditions. A Master Cell Bank (MCB) is produced according to cGMP guidelines and consists of frozen vials of a cell line (generally kept in liquid nitrogen) manufactured at as low a passage number as reasonably possible. Continuous cell lines are usually cloned from a single cell before a MCB is generated to assure purity of the cell line. The term MCB is used to designate stock cultures from which a second set of vials is usually generated; this second set of vials is termed the Working Cell Bank (WCB). The WCB is then extensively tested. Tests on human cell banks include those for microbial contaminants, tumorigenicity, identification, adventitious and endogenous viruses, and specific viruses. Frozen vials of the cell line chosen for production are used for culture buildup. The cell expansion can occur in standard tissue culture plasticware, shaker/spinner flasks, Roller Bottles, Nunc™ Cell Factories, CellCube™ systems, and, in some cases, even in stirred tank bioreactors. The expansion can progress from tissue culture flasks to 1–10 L spinner cultures and for large-scale production to 50–10,000 L bioreactor systems. Unlike fermentation, mammalian cell culture split ratios range from 1:2 to a maximum of 1:10.

When large-scale production is desired, vials of MCB are used to generate the WCB at the appropriate cell density and at the desired life span of the cell line. Since vials of the WCB are typically used for commercial production, it is recommended that the WCB be generated only after all aspects of cell culture have been worked out and no changes to cell culture medium or inoculation density are expected.

### 4. Animals and Eggs

When animal systems or eggs (chick or duck embryos) are used, they should be from controlled herds or flocks and should be routinely tested to assure freedom from contam-

inating microorganisms that could impact the vaccines (specific pathogen-free—SPF).

### 5. Harvest

The mode and the method of harvest depend on the product being grown. Generally, a synthetic medium different from that used during cell growth is used during virus growth containing no biological or protein products. For lytic viruses, the virus can be intracellular or lysed into the cell culture medium. For viruses secreted into the cell culture medium, rather than harvesting the entire culture, the cell culture supernatant is collected at different time points during production. Perfusion systems where the spent culture supernatant is continuously harvested are popular. Depending on the type of virus, harvest may continue for a few days. Optimization of virus titer is critical during this step.

### 6. Purification

Once the production culture has been harvested, the antigen typically needs to be concentrated and purified. For extracellular viruses or for bacteria, the product is typically only concentrated using standard techniques such as centrifugation or ultrafiltration and often no purification step is performed. For intracellular viruses, clarification is first performed to separate the cells from the culture medium. This clarification is performed via centrifugation in small-scale systems and ultrafiltration when larger volumes are involved. The cells are then lysed to release the virus. Cell lysis can be achieved by intermittently freezing and thawing, using chemical disruption (with the help of a surfactant) or by mechanical lysis using a microfluidization system or sonication.

For large-scale production systems, the virus can be concentrated using ultrafiltration methods. Several ultrafiltration systems are available such as hollow fiber or plate and frame systems. In some cases, viruses are purified by cesium chloride gradient systems or by column chromatography for larger systems.

In the case of protein or polysaccharide antigens, these must be purified from the appropriate starting material, cell lysate, purified organism, or biological fluid, using column chromatography, ultrafiltration, or centrifugation procedures, as defined above. A sterile filtration step follows to ensure the sterility of the bulk antigen.

### 7. Inactivation

Inactivation of purified virus or bacterial antigens is generally done chemically using reagents such as formaldehyde or peroxide, combined in some cases with heat. Inactivation parameters must be standardized and validated to ensure that the process completely and consistently inactivates the antigen. A sterile filtration step on the bulk concentrated antigen is generally applicable before or after inactivation.

## C. Formulation and Filling

A high level of control is needed to assure a consistent product including the amount of antigen, stabilizers, adju-

vants, pH, volume, etc. The acceptable limits of variation in each of these factors are ultimately related to the safety and the efficacy demonstrated in clinical studies. The sterile process must be tightly controlled for these three steps: formulation, filling, and freeze-drying. This is the most sterile part of the entire production process because most vaccines, especially those based on whole organisms or those incorporating adjuvants such as alum, cannot be terminally sterilized, in contrast to the majority of drugs and large-volume parenteral solutions. The length of time that the filling process (for example, over the course of several hours or several days) can continue must be validated. In general, not more than 16 hr are allowed for filling operations in order to clean and prepare the room for the following day.

The definition of a lot, “doses that are at the same risk of contamination,” depends on the size of the filling process. For some products, the filled vials are then lyophilized for better long-term stability.

## D. Packing

Packaging of a vaccine product may vary depending on the market. All packaging operations must also be under strict control, and the processes must be documented.

## E. Testing

It is critical that biological materials used to generate products for human use are properly qualified. Qualification can include testing for identity, presence of any adventitious viruses, microbial contamination, and mycoplasma. Safety assessments are also necessary and routine to demonstrate that the product itself remains safe. This has traditionally been performed by demonstration of lack of reversion of an attenuated virus product to a virulent state or of an inactivated bacteria or toxoid to toxicity. Figure 1 schematically indicates the multiple steps in the production process where testing is done. All tests must be standardized and validated to ensure that the test results actually reflect the presence or absence of the quality being tested for.

## F. Submission for Lot Release to Regulatory Authorities

Besides testing and quality assurance procedures being performed by the manufacturer on a lot-by-lot basis, the regulatory authorities must also release the products. In some cases, this is done on bulk products, and, in other cases, on the final container vaccine. The manufacturer must program into the production process the time for lot release by the relevant regulatory authorities before the product can be shipped.

## G. Storage and Shipping

Storage and shipping are also subject to documentation and validation. The temperatures, storage, and shipping conditions must be such that the product is stable, and these conditions must be reproducible. Generally, vaccines are

stored and shipped using a “cold chain” to maintain temperatures close to or below freezing, depending on the product. Manufacturers often use temperature-monitoring devices to ensure that these temperatures are maintained, and real-time data on the shipping process must be obtained to ensure the integrity of the process. For products that cannot sustain freezing, it is critical to closely monitor the cold chain, as inadvertent freezing can damage the integrity of the vaccine.

### III. FACILITIES DESIGN, MAINTENANCE, AND USE

There are two general types of production facilities: pilot lots for the manufacture of clinical trial material and the commercial manufacturing facility for large-scale production. Even if the large-scale production facility is used for the manufacture of clinical trial lots, it is rare that this is done at the same scale as for commercial production. Thus all processes must be established and documented to ensure consistency of the product, and these facilities and operations must all be established, operated, and maintained to assure regulatory compliance and approval of the produced product. Validation at each scale has to be established by preclinical or clinical data, depending on the changes introduced.

One of the critical strategic issues facing any developer of vaccines for human use is how to minimize the risks attendant in scaling up from pilot production to commercial operations. Often, there are technical, procedural, and/or equipment differences between the production of a few hundred or thousand doses to support clinical trials and the tens or hundreds of millions of doses that may be necessary to supply the U.S. or global markets. Some companies have elected to build, equip, and validate facilities capable of commercial-scale manufacture midway through clinical development to minimize the risk of product changes prior to entering time-consuming and expensive Phase 3 field trials. While this strategy may be the most direct and quickest route to achieving license and market launch, it can be financially devastating. Commercial manufacturing facilities can easily cost \$100–600 million by the time approval is received. Product failures or even delays in the timing of product approvals can turn this investment into financial ruin. Strategies used to avoid such exposure include the use of pilot manufacturing facilities or contract manufacture organizations. The U.S. Food and Drug Administration (FDA) has provided specific guidance to manufacturers regarding the use of both contract manufacturing arrangements [2] and the use of pilot manufacturing facilities [3]. The use of consistent manufacturing technologies between small- and large-scale facilities and modest (<10-fold) differences in production scale are most probable of success. When larger scale-up strategies are necessary to manage risk or due to resource constraints, the use of consistent technologies is highly desirable. Where differences in product are unavoidable, it may be necessary to do bridging clinical studies to demonstrate that the product from the final commercial manufacturing facility is acceptably consistent with that used in the clinical studies supporting licensure.

For the longer term, investing in new manufacturing equipment or facilities is also not a simple exercise and can take anywhere between 2 years for a new packaging line (studying, ordering, installing, and validating), 5 years for a new facility, and 7 years for a new site, assuming no major complications. In practical terms for the vaccine manufacturer, this means having to take a major financial risk without knowing whether the candidate product will receive regulatory approval and market acceptance. These time and cost elements have become even more critical given the fact that manufacturing capacities have been saturated for the last few years.

As reported in the J.P. Morgan H&Q report “The State of Biologics Manufacturing” [4], the manufacturing capacity for bulk biological products is not projected to meet the demand brought by new product introductions. Due to the long life cycle of approved biologics, and the rapid evolution of manufacturing technologies, there is virtually no churning or turnover of manufacturing capacity for obsolete products into capacity to support new product introductions. The traditional vaccine business used a “one product/one building” approach for capacity into the mid-1980s. However, with the dramatic escalation in facility cost, the long lead time for facility readiness, the introduction of recombinant expression systems for vaccine antigens, and the desired flexibility for late-stage clinical manufacturing and launch plants, a multiproduct concept has evolved and matured. The multiproduct facility concept has allowed for the development of a contract manufacturing organization (CMO) industry to share risk and to provide expertise and flexible capacity to meet short-term needs (see Ref. 2 for FDA guidance on this). The economics for CMOs to establish new capacity has been less supported through growth of the market overall rather than the needs of a single product.

Multinational vaccine companies, smaller biotechnology companies developing vaccines, and even CMOs have looked conservatively at the risk/reward scenario of preinvestment in capacity prior to product approval and balked. Very recently, this has changed as evidenced by the announcements of major new investments by several CMOs, e.g., BioReliance Corporation’s investment in larger-scale viral therapeutic manufacture (including vaccines), DSM Biologics’s announced commitment to invest in engineering a large-scale expansion in Quebec, Cambrex’s announcement to invest \$18,000,000 in capacity expansion for biological product contract production, VaxGen, Inc.’s construction of a manufacturing facility in California, and announcement of a significant strategic partnership for commissioning of a large-scale (47,000 L) contract biological production facility in South Korea.

Access to manufacturing capacity thus poses a gap that may place timely approval of products at risk. The manufacturing of more traditional vaccines such as the anthrax vaccine by BioPort has demonstrated the continuing challenges to meet ever-stricter regulatory standards, with challenges to financial return and a very limited capability for immediate response to a dramatic increase in market demand. Therefore the development of new vaccines not only requires good science, efficient development, and application of current technologies, but also the long-term commitment

to invest in the physical capacity to deliver these new products to a healthcare system in need of cost-effective preventative medicines.

#### **IV. BASIC COMPONENTS OF GOOD MANUFACTURING PRACTICE**

Compliance with the principles and guidelines of Good Manufacturing Practice (GMP) is a statutory requirement. The Good Manufacturing Practice regulations govern that part of quality assurance that ensures medicinal products are consistently produced and controlled to the quality standards appropriate to their intended use. Simply stated, production operations must follow clearly defined procedures. The general aspects of GMP are covered in more detail below. In addition, GMP requires evidence of prevention of cross-contamination in production, the performance of validation studies supporting the facilities, systems, processes, and equipment, control of starting materials, control of packaging materials, and handling of finished products. All aspects of these measures and methods of control are specifically defined by local regulations.

It is the primary responsibility of the Regulatory Affairs/Quality Assurance department in a manufacturing facility to ensure that all manufacturing operations performed for clinical production of human vaccines are in compliance with current GMP guidelines and follow all regulatory and safety procedures. Some specific responsibilities of this department could include review of standard operating procedures (SOPs) and batch/production records, investigation into any procedural or operational error and deviations from SOPs and/or batch/production records, system inspections/audits, validation of facilities, equipment, and testing procedures, and regular cGMP training to personnel.

##### **A. Facilities**

Facility design should provide for unidirectional flow of materials, product, and personnel. Production suites should be on separate heat, vacuum, and air conditioning (HVAC) systems that provide classified, preferably HEPA-filtered air. Airflows need to be balanced within the production areas to maintain the classification. There should be designated "clean" corridors for entry into production areas. Personnel are then made to gown in pressurized entry air locks before accessing the production suites. Exit from production areas should also be through dedicated air locks, where degowning can occur prior to exiting to the return corridor. If possible, separate personnel and equipment air locks should provide access to the production areas. Standard operating procedures should describe the use of all facilities, and all systems must be validated to ensure that they function to specifications. Containment of microorganisms must also be achieved to avoid their release into the environment. Biological wastes require special equipment for decontamination prior to release.

##### **B. Equipment**

Equipment used in production should be installed, operated, and maintained as per cGMP guidelines. Where appropriate, Installation/Operational/Performance Qualification Protocols (IQ/OQ/PQ), calibration, and validation studies need to be designed and executed. As appropriate, all equipment should be maintained on current calibration and preventive maintenance scheduled and performed as recommended by the manufacturers.

##### **C. Documentation**

All operations in GMP manufacturing whether dealing with facility, equipment, material usage, manufacturing, or product release have to be performed as outlined in the SOPs. This ensures that the manufacture of clinical material is performed in strict accordance with established manufacturing, regulatory, and safety procedures. Any deviation from SOPs has to be reported and its effect on the clinical product has to be documented. Standard operating procedures are critical documents and usually maintained by Document Control, a separate functioning department. Document Control is usually responsible for organizing, distributing, and revising SOPs as appropriate. Each SOP is uniquely identified and usually stored in both electronic and paper formats.

Production or batch records are used to document all manufacturing operations that are performed in the production of human vaccines. These records are established in accordance with appropriate SOPs and are distributed and controlled by the Document Control Department. Any deviations from manufacturing operations outlined in the SOPs are documented in the appropriate batch records. Batch records are especially important when it becomes necessary to revisit the manufacturing operations if some inconsistency or deficiency is discovered in the clinical product.

Validation is another important function performed by the Quality Assurance group in a manufacturing facility. Validation is the demonstration that a piece of equipment, process, or test performs according to specification so that the data or the products generated are credible. Validation protocols must be maintained on file as part of the documented record of a production process. Process and quality control validation are becoming more important to confirm the robustness of the methods employed. For a biological product, consistent quality is ensured by strict process application during manufacturing operations.

##### **D. Materials Receipt and Quarantine**

The primary responsibility of the Materials Management Group is to ensure that all materials (raw, in-process, and final) are properly received, uniquely identified, stored, released, documented, and inventoried. Generally, incoming products are released by the Quality Control Department from quarantine once tested or the accompanying documentation is reviewed. Standard operating procedures will describe how the receipt and quarantine process is implemented.

### E. Animal House and Laboratory Testing

The Quality Control group is responsible for environmental monitoring and testing of all materials (raw, in-process, and final). Testing is performed before release to manufacturing and before release of final product. Environmental monitoring includes monitoring of plant water systems, depending on whether any or all of the following sources—city water, potable water, water for injection, etc.—are used, tracking and trending particulates in manufacturing areas, and microbial identification of environmental isolates. The animal house is for holding and, in some cases, breeding of animals used for test purposes or in cases where vaccines are produced in animal tissues (for example, Japanese Encephalitis B vaccine produced in suckling mouse brain). The animal house is subject to similar kinds of environmental monitoring and control, as well as restricted access, as the production areas. All work done in the animal house and in the quality control laboratories is covered by SOPs, and all tests must be validated.

### F. Human Resources

cGMP requirements dictate that personnel performing manufacturing operations are adequately qualified and trained. Apart from having to pass physical and laboratory examinations, newly hired personnel are required to undergo intensive training in operational techniques, personal and product hygiene, before being cleared for work. These training sessions are required to be repeated on an annual or semi-annual basis. The Manufacturing department should be organized to have an adequate number of trained and qualified personnel to execute all GMP operations satisfactorily.

## V. STEPS IN PRODUCT LICENSURE

For timing for product licensure, 10 years is now considered as a minimum as shown in Figure 2. In the United States, vaccines are regulated as biological products. A single set of basic regulatory approval criteria applies to vaccines, regardless of the technology used to produce the vaccine (see Ref. 5). General regulations for product manufacture are covered in the parts of the U.S. Code of Federal Regulations (CFR), and other guidelines and points to consider are tabulated in Appendix C. Specific products are not covered by guidelines, but rather the license application contains the production and testing methods that will be in use. Similar procedures are in use in other parts of the world, and Appendix C summarizes some of the relevant documentation.

### A. Facilities License

In many countries, the production facility is approved as well as the product as part of the licensing process. Until recently, the United States separately licensed the vaccine (PLA or Product License Application) and the production facility in which it was manufactured (ELA or Establishment License Application). In the United States, these are now combined in a Biologics License Application (BLA). In either case, the proposed manufacturing facility undergoes a prelicensing inspection by experts in GMP and in the particular type of product to be produced, which reviews the entire production process as well as the equipment, utility (HVAC) systems, human resources, and production records of specific batches or lots of product.

### B. Product License

When a potential candidate vaccine is ready to move toward the licensing pathway, the process for manufacturing the vaccine at a research scale or for clinical study must be developed into a process that is appropriate for the manufacture of large-scale commercial material (scale-up). This includes all steps of bulk production, purification, and testing. Thus all steps in the process as well as the facility must be validated, demonstrating consistency of manufacture from lot to lot. The licensing file will contain all the information related to the production of the product including documentation, a preclinical package that includes especially data on safety testing in animals, as well as results of all other quality control tests, and documentation of the consistency of production. This file is used as a basis for approval of testing in humans. All human trial results, along with the above information, comprise the license application file.

### C. Phases of Clinical Trials

The clinical development of vaccines is generally carried out in four phases. Initial Phase 1 studies are intended to evaluate safety and are generally performed in a small number of healthy adults; Phase 2 studies usually include dose-ranging studies and may provide an early indication of efficacy. On the basis of Phase 1 and 2 trials, the manufacturer might choose to scale-up the production facility in preparation for Phase 3 trials, which provide the pivotal efficacy and safety data that are required for licensure. Phase 1 and 2 studies should provide the support for product dose and study the immune response and biological activity, while Phase 3 studies are larger trials to establish efficacy in the target population at the expected dose range and formula-

<b>Discovery and preclinical</b>	<b>Clinical study and consistency lots</b>			<b>File review</b>
	<b>Phase 1</b>	<b>Phase 2</b>	<b>Phase 3</b>	
			<b>Lot preparation phase 3</b>	
			<b>File preparation</b>	
	<b>1-1.5 years</b>	<b>1-1.5 years</b>	<b>0.5-1.5 years</b>	<b>1 year</b>
<b>2.5 years</b>			<b>6-8 years</b>	<b>2 years</b>

**Figure 2** Vaccine development phases and time frames (adapted from Ref. 1).

tion. Serological correlates of efficacy are developed, if possible, in this phase, which may include hundreds to tens of thousands of subjects. Where possible, Phase 3 trials should be randomized, double-blinded, and placebo-controlled. Illustrative time frames are indicated in Figure 2.

#### D. Postlicensure Activities

Postlicensing, the manufacturer is still required to work with the regulatory authority in a number of areas to continue to assure the safety, potency, and consistent quality of the product. This may include monitoring of the product by lot release testing and monitoring of the production facility through periodic facility inspections, which continue as long as the manufacturer holds the license to the product. Phase 4 studies are generally large-scale postmarketing studies conducted to obtain additional data on adverse events focusing primarily on events that may occur at a very low frequency. In addition, significant adverse events occurring in routine use of the product must be reported to the regulatory authority and must be analyzed to determine if they are an indication of compromised product safety. Finally, any changes to the production of the product must be covered by SOPs and validation documentation and must be reported to the regulatory authority. Significant changes must be approved prior to their implementation. Variations may be classified into the following three categories:

- Type IA variations that for biologicals are limited to administrative modifications. These variations are submitted as notifications and are not reviewed by the authority.
- Type IB, considered as minor variations that do not modify the quality, safety, and efficacy of the product. The authority starts a 30-day evaluation and, in practice, the timescale for such variations lies between 35 and 95 days.
- Type II, major variations that require extensive data submission. For biologicals, any modification to the manufacturing process, for example, falls within this category. In practice, the approval of Type II variations is granted after 155–250 days.
- In addition to modifications within the scope of these three types, major changes to the product (e.g., new Master Cell Bank, additional dosage forms) require a full registration dossier to be submitted. The assessment may then take up to 1 year.

#### VI. THE SPECIAL CASE OF COMBINATION VACCINES

Combination vaccines, many of which are based on additions to the diphtheria, tetanus, and pertussis (DTP) combination, are becoming very popular as a means to reduce

injections and to minimize delivery issues even if they may be more expensive than the separate products [6]. They are being used in both the industrialized world and the developing countries, in both public and private sectors, and are being produced by a range of manufacturers, both multinational and local. They present a special issue in manufacture, as the producer must make and control up to seven antigens at the same time and have them ready for formulation: any delay in any of the components impacts the final product. Allocation issues can become very important and often antigens can become limiting.

Combination vaccines pose special issues in GMP compliance as the new use of an established antigen will require a new review of its manufacture and control protocols that may no longer meet licensing requirements. Often, each antigen must be relicensed for use in the production of the combination product, and the relicense may require renovation of production facilities or changes in process. Combination vaccines also pose special issues in regulation because of the complications to quality control of each component while in combination and the difficulties of attributing adverse events to an individual component. Finally, if serological correlates of immunity do not exist, the combination may need extensive clinical efficacy trials for licensing.

#### VII. THE FUTURE

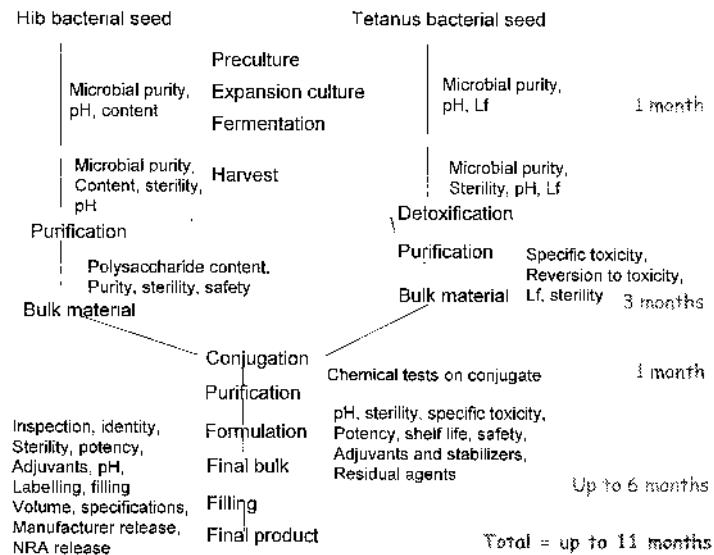

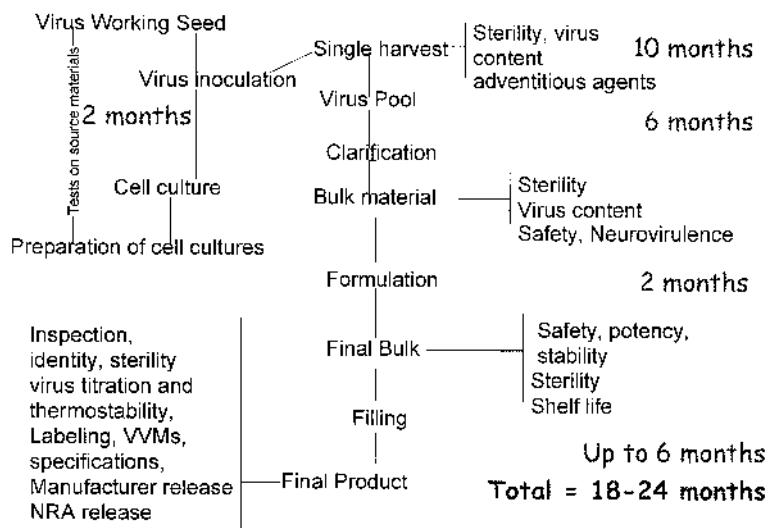

Given the experience of the past, it is clear that the future will hold new technological developments for vaccine production in the form of new vaccine types, such as multiple antigen peptide vaccines, virus-like particles, and transgenic plant vaccines, and new delivery platforms, including aerosol and transcutaneous delivery systems. All of these innovations will bring with them the need for assuring their safety and consistency; thus process and testing validation criteria and cGMP compliance will become even more demanding.

**Appendix A** Vaccines Licensed by the U.S. Center for Biologics Evaluation and Research and Marketed in the United States

Manufacturer of record	Product description	Primary manufacturing technology
Aventis Pasteur Inc.	Diphtheria and tetanus toxoids and acellular pertussis vaccines	Bacterial fermentation, extracted, toxoided proteins
	Influenza virus vaccine	Killed virus grown in embryonated eggs
	Meningococcal polysaccharide vaccines (ACYW135)	Bacterial fermentation, extracted capsular polysaccharide
	Yellow fever vaccine	Live virus grown in embryonated eggs
	<i>Haemophilus influenzae</i> type b conjugate vaccine	Bacterial fermentation,
	Poliovirus vaccine inactivated	protein-polysaccharide conjugate
	Rabies vaccine	Killed virus grown in mammalian cell culture
	Typhoid Vi polysaccharide vaccine	Killed virus grown in mammalian cell culture
Merck and Co., Inc.	<i>Haemophilus influenzae</i> type b conjugate vaccine	Bacterial fermentation, extracted
	Hepatitis A vaccine inactivated	capsular polysaccharide
	Hepatitis B vaccine (recombinant)	Bacterial fermentation, protein-polysaccharide conjugate
	Measles, mumps, and rubella live virus vaccines	Killed virus grown in mammalian cell culture
	23-Valent pneumococcal polysaccharide vaccine	Recombinant protein expressed in yeast
	Varicella virus vaccine live	Avian/avian/mammalian cell culture
	<i>Haemophilus influenzae</i> type b conjugate vaccine	Bacterial fermentation, extracted capsular polysaccharide
	Influenza virus vaccine	Virus grown in mammalian cell culture
Wyeth Pharmaceuticals	7-Valent pneumococcal conjugate vaccine	Bacterial fermentation, protein-polysaccharide conjugate
	23-Valent pneumococcal polysaccharide vaccine	Killed virus grown in embryonated eggs
	Diphtheria and tetanus toxoids and acellular pertussis vaccines	Bacterial fermentation, extracted capsular polysaccharide
	Hepatitis A vaccine inactivated	Bacterial fermentation (pathogenic)
	Hepatitis B vaccine (recombinant)	Killed virus grown in mammalian cell culture
	Hepatitis A + B	Recombinant protein expressed in yeast
	DTaP-IPV-Hepatitis B	Hepatitis A and B vaccines combined (see above)
		Combination of products of bacterial fermentation (inactivated), killed virus, and recombinant proteins
GlaxoSmithKline Biologicals	Influenza virus vaccine	Killed virus grown in embryonated eggs
	Rabies vaccine	Killed virus grown in avian cell culture
	Tetanus and diphtheria toxoids	Bacterial fermentation (pathogenic)
PowderJect Pharmaceuticals Plc Chiron Corporation University of Massachusetts Biologic Laboratory BioPort Corporation Berna Biotech	Anthrax vaccine adsorbed	Bacterial fermentation, soluble filtrate
	Typhoid vaccine live oral Ty21a	Live attenuated bacteria, bacterial fermentation
		Killed virus, isolated from the brain of intracerebrally infected mice
Biken	Japanese encephalitis virus vaccine inactivated

## APPENDIX C. GUIDELINES RELEVANT TO LARGE-SCALE VACCINE MANUFACTURE

WHO Guidelines (see Refs. 7 and 8)

- A WHO guide to good manufacturing practice requirements, Part 1: Standard operating procedures and master formulae. Ordering code: WHO/VSQ/97.01
- A WHO guide to good manufacturing practice requirements, Part 2: Validation. Ordering code: WHO/VSQ/97.02
- Guide for inspection of manufacturers of biological products. Ordering code: WHO/VSQ/97.03 [1170]
- Guidelines on clinical evaluation of vaccines: regulatory expectations. Adopted 2001, TRS, in press, Annex 1
- Guidelines for assuring the quality of DNA vaccines. Adopted 1996, TRS No 878, Annex 3
- Guidelines for the production and quality control of synthetic peptide vaccines. Adopted 1997, TRS No 889, Annex 1
- Requirements for the use of animal cells as in vitro substrates for the production of biologicals. Revised 1996, TRS No 878, Annex 1
- Good Manufacturing Practices for biological products. Adopted 1991, TRS No 822, Annex 1
- Guidelines for national authorities on quality assurance for biological products. TRS No 822, Annex 2
- Biological products prepared by recombinant DNA technology. TRS No 814, Annex 3
- General requirements for the sterility of biological substances. Revised 1973, TRS No 530, Annex 4; Amendment 1995, TRS No 872, Annex 3

FDA Guidelines (see also Ref. 5)

- Points to Consider in the Manufacture and Testing of Monoclonal Antibody Products for Human Use (1997)
- Guidance for Industry for the Evaluation of Combination Vaccines for Preventable Diseases: Production, Testing, and Clinical Studies (1997)
- Content and Format of Chemistry, Manufacturing, and Controls (CMC) Information and Establishment Description Information for a Vaccine or Related Product (1999)
- IND Meetings for Human Drugs and Biologics—Chemistry, Manufacturing, and Controls Information (2001)
- 21 CFR 25 Environmental Impact Considerations
- 21 CFR 210 Current good manufacturing practice in manufacturing, processing, packing, or holding of drugs; general

- 21 CFR 211 Current good manufacturing practice for finished pharmaceuticals
- 21 CFR 600 Biological products: general
- 21 CFR 610 General biological products standards

ICH Guidelines (see Ref. 9)

- Quality of Biotechnological Products: Viral Safety Evaluation of Biotechnology Products Derived from Cell Lines of Human or Animal Origin
- ICH Stability Guideline
- Derivation and Characterisation of Cell Substrates Used for Production of Biotechnological/Biological Products
- Analysis of the Expression Construct in Cells Used for Production of r-DNA Derived Protein Products

EMEA Guidelines (see Ref. 10)

- CPMP/BWP/2289/01 Points to Consider on the Development of Live Attenuated Influenza Vaccines
- CPMP/BWP/2517/00 Points to Consider on the Reduction, Elimination, or Substitution of Thiomersal in Vaccines
- CPMP/BWP/3354/99 Note for Guidance on the Production and Quality Control of Animal Immunoglobins and Immunosera for Human Use
- CPMP/BWP/2490/00 Note for Guidance on Cell Culture Inactivated Influenza Vaccines—Annex to Note for Guidance on Harmonisation of Requirements for Influenza Vaccines CPMP/BWP/214/96
- CPMP/BWP/3207/00 Note for Guidance on Comparability of Medicinal Products Containing Biotechnology-Derived Proteins as Drug Substance
- EMEA/410/01 Rev. 1 Note for Guidance on Minimising the Risk of Transmitting Animal Spongiform Encephalopathy Agents via Human and Veterinary Medicinal Products
- CPMP/BWP/3088/99 Note for Guidance on the Quality, Preclinical and Clinical Aspects of Gene Transfer Medicinal Products
- CPMP/BWP/328/99 Development Pharmaceutics for Biotechnological and Biological Products—Annex to Note for Guidance on Development Pharmaceutics (CPMP/QWP/155/96)
- CPMP/BWP/477/97 Note for Guidance on Pharmaceutical and Biological Aspects of Combined Vaccines
- CPMP/BWP/268/95 Note for Guidance on Virus Validation Studies: The Design, Contribution, and Interpretation of Studies validating the Inactivation and Removal of Viruses

## Heterogeneity of Pediatric Immunization Schedules in Industrialized Countries

**James D. Campbell**

*University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.*

**Margaret Burgess**

*Children's Hospital at Westmead, Westmead, New South Wales, Australia*

### I. INTRODUCTION

Many factors influence the selection of vaccines that are administered to infants and toddlers in a particular country and the immunization schedule that is followed. These include epidemiological (e.g., past and present burden and prevalence of specific infectious diseases), economic (e.g., relative cost of vaccines, including various combination vaccines), sociological (e.g., the public perception of the risk and severity of specific infectious diseases and of the safety and efficacy of specific vaccines), logistics (e.g., population dispersion, mobility, and access to health services), immunological (e.g., differences in the immune responses to specific vaccine antigens depending on age and spacing of doses), and historical factors. For infant immunizations, the national schedule for diphtheria/pertussis/tetanus (DPT) vaccine largely drives the overall infant immunization schedule. Interestingly, in most of the developing world, the Expanded Program on Immunization (as described by Bruce Aylward et al. in the chapter entitled "Reaching Every Child—Achieving Equity in Global Immunization") administers infant DPT immunizations according to only two main schedules. In the least developed countries, where the risk of pertussis in early life is a particular danger, doses of DPT are administered at 6, 10, and 14 weeks of age. Because of economic and logistical constraints in these countries, a booster immunization in the second year of life is generally not practiced. In contrast, in many newly developing and middle-income countries, where the incidence of pertussis is lower and immunization coverage is higher, such as in Latin America and parts of Asia, infant DPT immunizations are typically administered at 2, 4, and 6 months of age; these countries usually also give boosters in the second year of life (often at 18 months of age). Thus, among the nonindustrialized countries there exists an extraordi-

nary degree of harmonization of pediatric immunization schedules with most countries following one of two schedules, although the array of specific vaccines administered at these times varies greatly (largely driven by economic considerations).

In contrast, among the industrialized countries of the world one finds a remarkable heterogeneity of infant and toddler immunization schedules. This is particularly notable in Europe where neighboring countries of similar wealth and epidemiologic situation (with respect to the incidence of infections such as pertussis, diphtheria, *Haemophilus influenzae* type b, and hepatitis B) often use distinct immunization schedules. Table 1 provides some examples, limiting the comparison to DTP. Multiple distinct schedules are readily apparent. Spain and Portugal follow an infant and toddler schedule similar to that used in North America and most of Latin America (although the specific array of vaccines differs in individual countries). Ireland also immunizes its infants at 2, 4, and 6 months of age but does not give a booster to toddlers in the second year of life. Across the Irish Sea, in the United Kingdom, a completely distinct schedule is followed as infants are immunized at 2, 3, and 4 months of age; in the U.K., no booster is given to toddlers although one is given somewhat later to preschool children. Crossing the English Channel one finds that France, Belgium, Germany, and Luxembourg also immunize their infants at 2, 3, and 4 months of age, but these countries show heterogeneity in the age when a booster is administered.

The Scandinavian countries (Denmark, Norway, Sweden, and Iceland) and Italy immunize infants at 3 and 5 months with a third dose at 11–12 months of age. Meanwhile, Austria, Finland, and the Netherlands give their infants primary immunization at 3, 4, and 5 months of age with a booster at either 11 (Netherlands), 13–15 (Austria), or 20 (Finland) months.

**Table 1** Examples of the Heterogeneity Among the DPT Immunization Schedules Practiced in Various Industrialized Countries

Country	1.5 mo	2 mo	3 mo	4 mo	5 mo	6 mo	7 mo	8 mo	11 mo	12 mo	13–15 mo	15–18 mo	20 mo
United States	DaPT	DaPT	DaPT	DaPT	DaPT	DaPT	DaPT	DaPT	DaPT	DaPT	DaPT	DaPT	DaPT

aP = acellular pertussis vaccine; wP = whole-cell pertussis vaccine.

**Table 2** Recommended Immunizations During the First 18 Months of Life, U.S.A.

Birth	1 mo	2 mo	4 mo	6 mo	12 mo	15 mo	18 mo
HBV1 <sup>a</sup>							
	HBV2			HBV3			
	DaPT	DaPT		DaPT			DaPT <sup>b</sup>
	Hib	Hib		Hib <sup>c</sup>	Hib		
	IPV	IPV		IPV			
	Pneumo	Pneumo		Pneumo			Measles/mumps/rubella1 Varicella Pneumo

<sup>a</sup> All infants should receive the first dose of HBV in the perinatal period and before hospital discharge. However, the first dose may also be given by age 2 months if the infant's mother is HB surface antigen-negative. Only monovalent vaccine can be used for the birth dose. Either monovalent or combination vaccine can be used to complete the series. Four doses may be given if a birth dose was administered. The second dose of HBV must be given at least 4 weeks after the first dose, except for combination vaccines, which cannot be administered before age 6 weeks. The third dose should be given at least 16 weeks after the first dose and at least 8 weeks after the second dose. The last dose in the vaccination series (third or fourth dose) should not be administered before 6 months age.

<sup>b</sup> The fourth dose of DaPT may be given as early as 12 months of age as long as at least 6 months have passed since the third dose.

<sup>c</sup> If PRP-OMP was given as the Hib conjugate in either monovalent or combination formulation, a third dose at age 6 months does not have to be given.

## II. COMBINATION VACCINES

The different industrialized countries utilize an array of DTP-based combination vaccines, which include combinations of four vaccines (e.g., DaPT plus hepatitis B [HBV] or *Haemophilus influenzae* type b conjugate [Hib] or inactivated polio vaccine [IPV]), five vaccines (e.g., DaPT plus Hib and IPV; DaPT plus HBV and IPV; DwPT plus HBV and Hib), or six vaccines (DaPT plus HBV, Hib and IPV). (For more on infant combination vaccines see the chapter by Margaret Rennels on this subject.)

## III. CONCOMITANT VACCINES

Depending on the industrialized country, various additional noncombination vaccines are concomitantly administered at the same visits when DPT is given. In a few countries oral polio vaccine is still given. Several countries routinely recommend seven-valent pneumococcal conjugate vaccine along with the first doses of DPT. A few (e.g., United Kingdom) give meningococcal C conjugate, and Japan gives

Japanese B encephalitis vaccine. As an example to illustrate the complexity of an immunization schedule in an industrialized country, the 2003 schedule for U.S. children 0–18 months of age is shown in Table 2.

## IV. CONSEQUENCES OF HETEROGENEITY

The staggering array of distinct infant immunization schedules practiced by the industrialized countries (Table 1) affects the price and supply of vaccines. As new vaccines become developed with the intention that they will enter the infant/toddler immunization schedule, their safety and immunogenicity must be shown for each distinct schedule and in conjunction with the concomitant vaccines ordinarily administered at those visits. The greater the array of immunization schedules, the more separate regimens must be validated. A perusal of the examples shown in Table 1 suggests that with a relatively few modifications in just a few countries the number of regimens can be reduced. Undoubtedly, this will be difficult to achieve and will take time. Nevertheless, it is a worthy objective.

# Index

Acellular pertussis vaccine (*see* *Bordetella pertussis*, vaccine; Combination vaccines)

description of generic types  
  conjugate vaccines, 17  
DNA vaccines (genetic immunization), 13  
epitope-based vaccines, 14  
live attenuated, 12  
subunit vaccines, 11  
transgenic plants, 12  
vector vaccines, 12, 283  
virus-like particles (VLPs), 283  
experimental challenge studies, 6, 20, 134  
good manufacturing practice (GMP), 84  
licensure, 122, 134  
  Vaccines and Related Biological Products Advisory Committee (VRBPAC), 122, 124  
live vector vaccines (*see* Antigen delivery systems, live)  
manufacture, 119  
  aseptic filling, 1081  
  bacterial fermentation, 1083

[Vaccines]

- batch/production records, 1086
- biological waste, 1086
- contract manufacturing organization, 1085
- control of raw materials, 1081
- current Good Manufacturing Practices (GMP), 84, 117, 131
- definition of lot, 1084
- Document Control, 1086
- environmental monitoring, 1097
- filling, 1084
- harvest, 1084
- Installation/Operation/Performance Qualification Protocols (IQ/OQ/PQ), 1086
- large-scale production facility, 1085
- Master Cell Bank (MCB), 1083
- Master Seed Bank, 1083
- Master Viral Banks (MVB), 1083
- phenoxyethanol, 1083
- pilot lots, 1085
- product consistency, 1085
- quality assurance, 1086
- quality control, 84, 1081
- segregated production areas, 1083
- standard operating procedures (SOPs), 1086
- storage, 1081, 1084
- thimerosal, 85
- ultrafiltration, 1084
- vaccine product classes, 1081
- validated tests, 1084
- Working Cell Bank (WCB), 1083
- mature vaccines, 59
- measles-mumps-rubella-varicella (MMRV), 417
- metabolic burden of expressing foreign antigens, 354
- mucosal (*see* Adjuvant, mucosal; Mucosal immunization)
- multiple epitope vaccines, 188, 189, 190
- plasmid-based expression of foreign antigens, 354
- plasmid maintenance systems, 355
- segregation of expression plasmids, 355
- proprietary pediatric, 59
- production (*see* Vaccine, manufacture)
- reactogenicity (*see* Vaccine, safety and Vaccine, adverse events)
- recombinant (*see under* individual vaccine)
- regulatory issues, 414
- safety
- adverse events (adverse effects), 123, 127, 130, 131, 133–137, 283
- animal models, 132
- Bovine Spongiform Encephalopathy, 132
- causality assessment, 137
- Guillain-Barré syndrome (after Swine flu vaccine), 8, 136
- impact on vaccine supply, 131
- molecular mimicry, 204
- MMR and autism, 138
- National Childhood Vaccine Injury Act, 130, 138
- risk assessment, 137
- risk management, 138

[Vaccines]

- thimerosal and neurodevelopmental disorders, 85, 138
- vaccine-attributable autoimmune adverse effects, Guillain-Barré syndrome after Swine flu vaccine, 8, 136, 206
- idiopathic thrombocytopenia after MMR, 206
- vaccine-related (but unsubstantiated) allegations of autoimmune adverse effects
- arthritis after Lyme disease vaccine, 209
- multiple sclerosis after hepatitis B vaccine, 207
- type 1 diabetes after infant DPT immunization, 208
- Vaccine Adverse Event Reporting System, 130, 135
- Vaccine Safety Data Link, 136
- side effect (*see* Vaccine, safety, or Vaccine, reactogenicity or Vaccine, safety, adverse reaction)
- string-of-epitopes constructs, 186, 189
- supply, 105, 131
- therapy (*see* Vaccine Therapy)
- WHO Vaccine Safety Advisory Committee, 98
- Vaccines and related Biological Products Advisory Committee, 134
- Vaccine and vaccination economics, 57
- cost benefit analyses (CBA), 108
- cost-benefit (CB) ratio, 108
- cost effectiveness analysis (CEA), 90, 108
- cost-utility analysis (CUA), 109
- demand, 60, 67
- developing country market, 67
- development costs, 62
- direct costs of health events, 111
- disability adjusted life years (DALYs), 109

- procurement, 59
- production scale-up, 62, 63, 66
- profit, 59, 62

- [Vaccine and vaccination economics]  
public-private partnerships, 72  
“pull” and “push” finance mechanisms, 69–72  
co-payments, 71  
differential pricing, 58, 59, 71  
direct financing, 70  
market assurances, 71  
prizes and tournaments, 71  
tax credits, 71, 72  
quality adjusted life years (QALYs), 109  
“return on investment” (ROI), 62, 67  
revenue, 58, 59, 61, 62  
risk, 62, 65, 67, 69  
scale, 64, 65  
supply, 61–62  
technology transfer, 85  
tiered pricing, 58, 75, 85  
unit costs, 63  
Vaccine Fund, 69  
variable cost, 63  
willingness to pay, 61  
years of potential life lost (YPLL), 109
- Vaccine therapy  
autoimmune diabetes, 1041  
DNA viruses, 1016  
drug addiction, 1957  
cocaine, 1062  
nicotine, 1060–1062  
phencyclidine, 1063  
rationale, 1057  
history, 1011  
hepatitis B, 1014  
Koch, Robert, 1011  
Pasteur, Louis, 1011  
rabies, 1013  
smallpox, 1012  
Wright, Almorth, 1012
- HIV, 1014
- Leishmania*, 1019
- Mycobacteria*, 1018
- strategies,  
postexposure prophylaxis, 1011, 1012–1014  
treatment or reduction of recurrences, 1011  
true prophylaxis, 1011
- vaccinotherapy, 1011
- Vaccinia virus  
modified virus Ankara, 381, 382  
recombinant vaccinia virus for expression of foreign  
antigens/proteins, 313–318  
bovine leukemia virus, 315  
*Chlamydia*, 840  
costimulatory molecules, 316  
cytokines, 316  
cytomegalovirus (CMV), 315  
foot and mouth disease virus, 316  
hepatitis B, 315  
Herpes Simplex virus, 315  
human immunodeficiency virus (HIV), 316, 318  
influenza virus, 315–316  
*Plasmodium*, 316
- [Vaccinia virus]  
prior immunity to vaccinia vector, 316  
rabies, 315, 317  
respiratory syncytial virus (RSV), 315–316  
rinderpest, 317  
simian immunodeficiency virus (SIV), 315, 318  
vesicular stomatitis virus, 317
- Varicella zoster virus  
vaccine, 76  
vaccine therapy, 1016
- Variola virus (*see* Smallpox Virus)
- Variolation, 1
- Vector, live for vaccine delivery (*see* Antigen delivery system, live)
- Venezuelan equine encephalitis virus  
vaccines  
inactivated viruses, 1075  
formalin-inactivated C-84 vaccine, 1075  
irradiated TC-83 in polylactide-polyglycolide  
microspheres, 1076  
live attenuated strains, 1075  
TC-83, 1075  
recombinant strain V3526, 1076  
prime-boost strategy (TC-83 followed by C-84), 1076
- VEE replicons, 1076  
recombinant VEE replicons encoding foreign  
antigens, 337–340, 1076
- Vesicular stomatitis virus (VSV)  
recombinant vaccinia expressing VSV antigen, 317  
recombinant VSV replicon expressing foreign antigens,  
342–343
- Vibrio cholerae*  
antigens and virulence factors, 513–516  
characteristics of, 499  
cholera toxin (*see* Cholera toxin)  
clinical disease, 499–500  
epidemiology, 599, 506  
HAP, 514  
immunity to, 500–502, 511, 513  
LPS, 501, 514  
MSHA, 501, 513  
serogroups, 499  
TCP, 510–502, 513  
treatment, 500  
vaccines  
clinical trials, 502–507, 512–515  
history, 4  
inactivated oral, 499–509  
BS-WC (O1) (Dukarol), 502–507  
cross-protection against enterotoxigenic *E. coli*,  
504  
vaccination schedule, 508  
WC (O1), 507  
WC (O139), 507  
inactivated parenteral, 474, 475, 500  
live attenuated, 511–517  
395N1 (O1), 512  
638 (O1), 514  
Bengal 3 (O139), 515  
CVD 103-HgR (O1), 19, 25, 512–513

- [*Vibrio cholerae*]  
 CVD 101 (O1), 512  
 CVD 111 (O1), 514  
 CVD 112 (O139), 514–515  
 IEM101 (O1), 514  
 JBK 70 (O1), 512  
 Peru-15 (O1), 515  
 O1 polysaccharide conjugate vaccine, 474  
 immunogenicity, 475  
 O139 polysaccharide conjugate vaccine, 475  
 serogroups of, 499  
 transgenic plant, 307, 308  
 vector for heterologous antigen expression, 515
- Viral hemorrhagic fever (*see individual viruses*)
- Virus-like particles, 263  
 definition, 283  
 expression systems, 283  
 Ebola virus, 283, 284  
 Norwalk Virus VLPs, 285, 286  
 papillomavirus VLPs, 284  
 rotavirus VLPs, 287
- West Nile virus  
 clinical syndromes, 562  
 disease burden, 562  
 encephalitis, 562  
 vaccines  
   chimeric derivative of 17D yellow fever vaccine, 569  
   efficacy challenge study in horses, 569  
   neutralizing antibodies in horses, 569  
 DNA vaccine, 562  
 inactivated viruses  
   formalin-inactivated vaccine for horses, 562  
 vector (*Culex* mosquitoes), 562
- Whooping cough (*see Bordetella pertussis*)
- World Health Organization (WHO)  
 Expanded Programme on Immunization (EPI), 89, 90, 95, 97, 98, 393, 1093  
 Vaccine Safety Advisory Committee, 98  
 WHO/UNICEF Product Information Sheets (PIS), 90
- World Summit for Children, 94, 97, 148
- Wright, Almroth  
 heat inactivated phenol-preserved parenteral typhoid vaccine, 4  
 vaccine therapy, 1012
- Yellow fever virus  
 clinical illness, 562  
 disease burden, 562  
 flaviviruses, 338–340, 559  
 organization of genome, 559  
 replication of virus, 559  
 vaccine, attenuated strain 17D,  
   adverse reactions, 562  
   contraindications, 562  
   duration of immunity, 562  
   history, 4, 562  
   neutralizing antibodies, 562  
 recombinant strain 17D expressing foreign antigens, 338, 340, 565–569  
 substrain 17DD, 562  
 viremia (vaccinemia), 562
- ChimeriVax™ (17D chimeras with other flaviviruses)  
 chimera with dengue viruses, 567–569  
 chimera with Japanese B encephalitis virus, 565–567  
 chimera with West Nile Virus, 567  
 vector, *Aedes aegypti* mosquitoes, 562
- Yersinia pestis*  
 aerosol transmission, 1073  
 category A bioterror/biowarfare agent, 1073  
 protective antigens  
   Fraction 1 (F1), 1073  
   virulence (V), 1073
- vaccines  
 attenuated strains, 1073  
 attenuated strain EVC, 1073  
 Haffkine's inactivated whole cell vaccine, 1073  
 Plague Vaccine, USP, 1073  
 Protoeosome F1-V vaccine, 276  
 recombinant subunit vaccines, 1073
- Zoster (*see Varicella-Zoster Virus*)

## **ABOUT THE EDITORS**

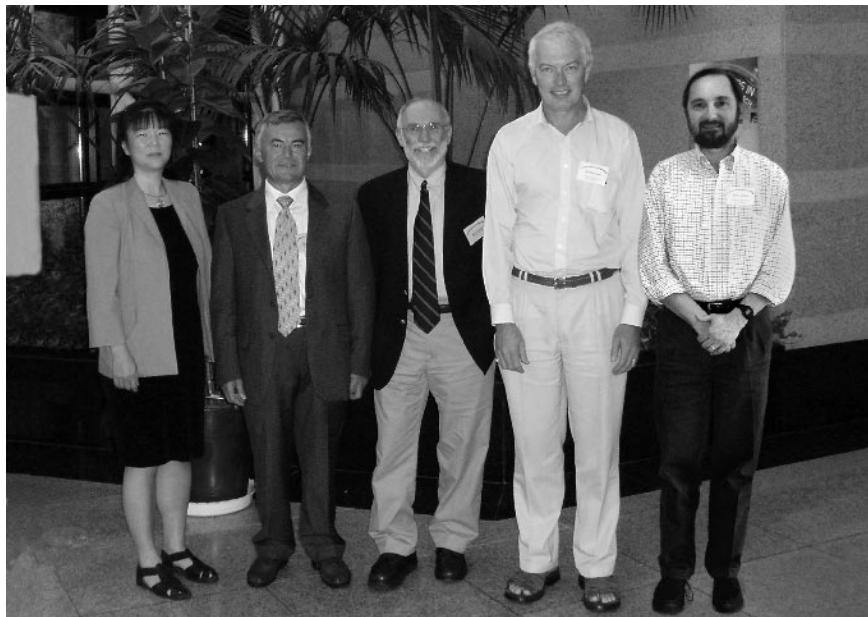

MYRON M. LEVINE is Director of the Center for Vaccine Development, Professor of Medicine, and Head of the Division of Geographic Medicine, as well as Professor of Pediatrics and Head of the Division of Infectious Diseases and Tropical Pediatrics, University of Maryland School of Medicine, Baltimore. He received the M.D. degree (1967) from the Medical College of Virginia, Richmond, and the D.T.P.H. degree (1974) from the London School of Hygiene and Tropical Medicine, England.

JAMES B. KAPER is Associate Director for Laboratory Research at the Center for Vaccine Development, and Professor of Medicine, Microbiology and Immunology, University of Maryland School of Medicine, Baltimore. He received the Ph.D. degree (1979) from the University of Maryland at College Park.

RINO RAPPOLI is Vice President for Vaccines Research, Chiron S.r.l., Siena, Italy. He received the Ph.D. degree (1976) from the University of Siena, Italy.

MARGARET A. LIU is Visiting Professor at the Karolinska Institute, Stockholm, Sweden, and Vice-Chairman of Transgene, Inc., Strasbourg, France. She was formerly Senior Advisor for Vaccinology, Bill & Melinda Gates Foundation, Seattle, Washington. She received the M.D. degree (1981) from Harvard Medical School, Boston, Massachusetts.

MICHAEL F. GOOD is Director, Queensland Institute of Medical Research, Australia. He is a former Director of the Cooperative Research Centre for Vaccine Technology. He received the M.D. degree from the University of Queensland, Australia, and the Ph.D. degree from the Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia.

Left to right: Margaret A. Liu, M.D., Transgene, Inc.; Rino Rappoli, Ph.D., Chiron S.r.l.; Myron M. Levine, M.D., D.T.P.H., University of Maryland School of Medicine; Michael F. Good, M.D., Ph.D., Queensland Institute of Medical Research; James B. Kaper, Ph.D., University of Maryland School of Medicine.
