### I. INTRODUCTION

In recent years, there has been increasing interest in immunization approaches that seek to generate protective immunity through effector T cell induction. An improved capacity to induce such T cells would facilitate the development of vaccines against a variety of intracellular pathogens including malaria, HIV/AIDS, and tuberculosis, three of the most important infectious diseases of the developing world. Also, a capacity to induce high-level persistent T cell responses could revolutionize the field of therapeutic vaccines and allow the development of immunotherapeutics for persistent viral infections such as hepatitis C virus and HIV and malignancies such as melanoma and breast cancer. Although vaccination studies aimed at inducing cellular immunity have often focused on CD8<sup>+</sup> cytotoxic T cells as the main effector cells, it is becoming clear that CD4<sup>+</sup> effector T cells may be of value in several diseases.

Numerous studies of subunit vaccines with the widely used alum adjuvant have shown that nonparticulate antigens with alum generally induce few or no CD8<sup>+</sup> T cells, leading to the assessment of a wide variety of alternative vaccine delivery systems for CTL induction. These have included peptides with a variety of adjuvants, lipopeptides, particulate vaccines such as recombinant Ty-virus-like particles, DNA vaccines, and viral and bacterial vectors. Although all of these approaches have succeeded in inducing CD8 T cell re-

sponses, often, the magnitude of the induced responses and their durability has been insufficient to induce useful levels of protection.

In this chapter, we shall review an increasingly widely used approach to inducing high-level effector T cell responses that requires the sequential use of two different vaccines both encoding the same epitopes or antigen. Such heterologous prime-boost immunization [1–3] can be employed with a variety of the so-called priming vaccines and a more limited variety of boosting vaccines. However, because there is now the most extensive preclinical and clinical experience with DNA as a priming agent and the recombinant viral vector, modified virus Ankara, as a boosting agent, this particular prime-boost combination will be the focus of this chapter.

We shall initially review the background to the discovery of the immunogenicity and efficacy of this heterologous prime-boost immunization approach. Then we shall give some examples and characteristics of this immunization approach in small animal models and discuss the likely underlying mechanisms. Next, available data from nonhuman primate studies will be reviewed before summarizing recent clinical data suggesting that marked synergy is also observed with the use of this prime-boost approach in humans. Recent clinical data showing good safety of this approach and unprecedented levels of effector T cell induction suggest that further development of such strategies

should contribute to the development of new therapeutic as well as prophylactic vaccines.

## II. BACKGROUND STUDIES

The development of improved means of inducing strong T cell responses has advanced in parallel with, and been facilitated by, new immunoassays allowing more sensitive measures of specific T cell numbers and function. The original assay for CD8 T cells was the chromium release assay which, although providing an assay of effector function, has limited sensitivity and requires radiolabeling of target cells and usually many days of expansion of T cells in vitro culture to allow their detection. Although precursor frequencies were measurable using chromium release assays along with limiting dilution methods, these often underestimate the overall effector frequency [4]. Newer assays such as the ex vivo ELISPOT assays of cytokines [5,6] allow quantification of lower numbers of T cells and have a much greater measurement range, so that 10–1000-fold changes in immunogenicity can be measured. The  $\gamma$ -interferon ELISPOT assay in particular has become widely used to enumerate induced CD4 and CD8 T cell in both preclinical and clinical studies [7,8]. Flowcytometric methods of enumerating specific cells in the presence and the absence of antigens allow the characterization of the induced response using intracellular staining of cytokines and other mediators [9]. Finally, the introduction of fluorescently labeled MHC-peptide tetramer reagents has provided an elegant and sensitive method of both staining and sorting specific vaccine-induced T cells [10].

The discovery and widespread adoption of DNA vaccination in the 1990s are described elsewhere in this volume. The ease of generation of plasmids and their ability to induce both humoral and cellular immune responses in small animals led to numerous studies of DNA vaccines and, subsequently, to attempts to improve their immunogenicity and protective efficacy. Heterologous prime-boost immunization may thus be seen as one of the many means that have been employed in attempts to improve the performance of DNA vaccines.

However, heterologous prime-boost immunization approaches also build on 15–20 years of experience with using recombinant viral vectors, particularly recombinant poxviruses as candidate vaccines. Recombinant vaccinia viruses were generated in the early 1980s and shown to be capable of inducing protective T cell responses in small animals [11,12]. In 1988, Taylor et al. [13] showed that a recombinant avipoxvirus, fowlpox, was able to induce humoral and cellular immune responses in mammals, although the avipoxviruses cannot replicate in mammalian cells. Subsequently, large numbers of recombinant canarypox vectors have been evaluated in phase I/II clinical trials for several diseases including HIV, but, generally, these failed to generate strong effector T cell responses in most vaccines [14]. Recombinant nonreplicating orthopoxviruses such as modified vaccinia virus Ankara (MVA) [15] and NYVAC [16] may be more immunogenic. MVA was generated from the virulent replicating CVA strain of vaccinia virus by Mayr [17] by over 500 passages in chick embryo fibroblasts and

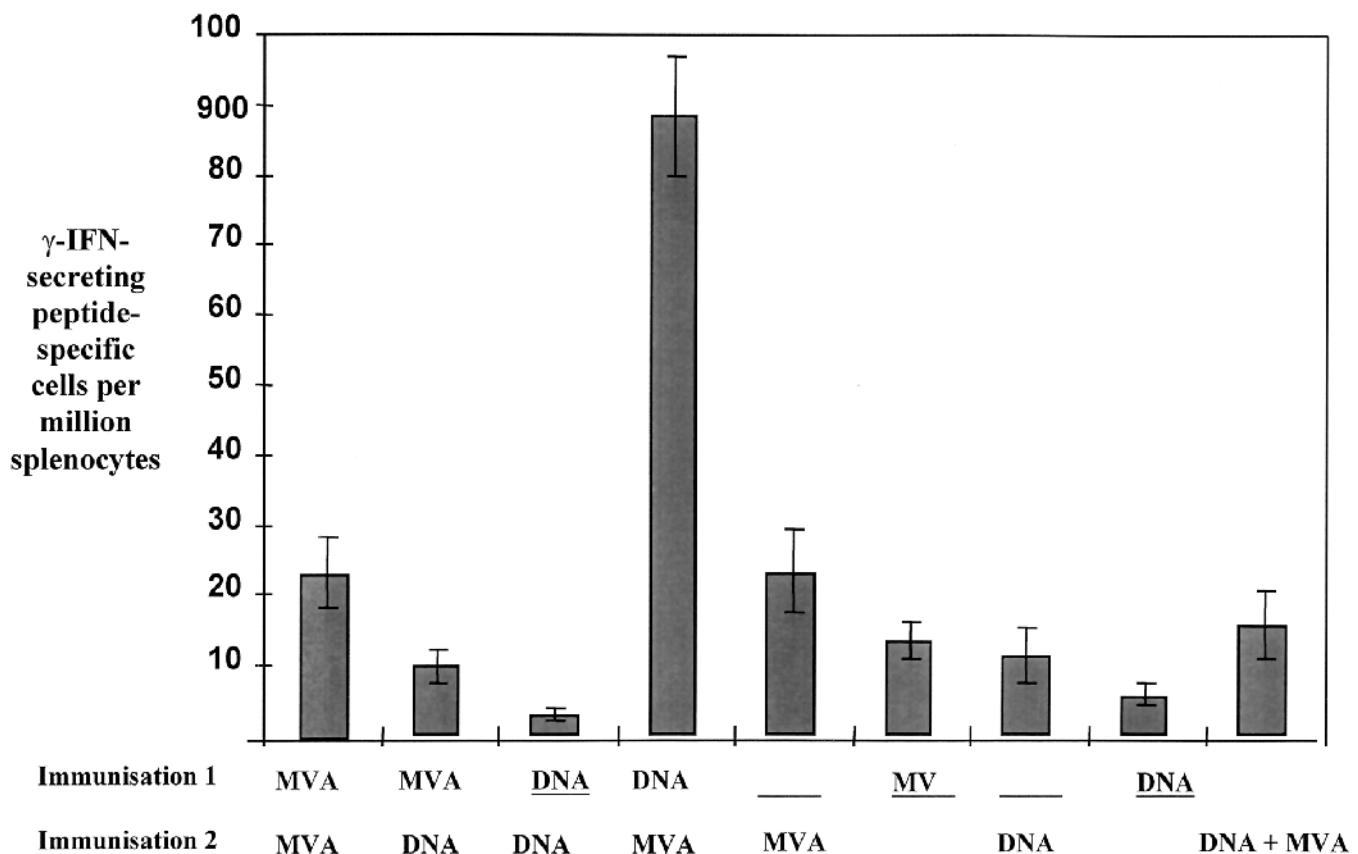

used briefly as a smallpox vaccine. NYVAC is a molecularly attenuated virus made from the Copenhagen strain of vaccinia virus.

Attempts to improve the efficacy of poxvirus or DNA vaccines by adding another type of subunit vaccine initially employed protein-adjuvant boosting. Several studies showed enhanced immunogenicity particularly for antibody responses, but this appears to represent an additive effect without synergy between the components [18,19]. In particular, effector T cell responses are not substantially enhanced by this approach. In retrospect, the first heterologous prime-boost immunization experiment that probably induced markedly enhanced CD8 T cell responses was reported by Li et al. [20] in a murine malaria model with the *Plasmodium yoelii* parasite. Greater protective efficacy was observed when a priming immunization with a recombinant influenza virus was followed by a boosting immunization with a recombinant replicating vaccinia virus encoding the same antigen than homologous immunization or the opposite order of immunization. T cell assays were not reported prechallenge, and the authors speculated that administering the vaccinia virus second might have enhanced homing of protective T cells to the liver, the target organ for protective T cell in pre-erythrocytic malaria models. Later analyses showed that this viral vector prime-boost approach did enhance T cell immunogenicity [21]. At about this time, DNA priming and fowlpox vector boosting was reported to enhance protection and antibody levels in an influenza model [22], but CD8 T cells were not measured after the fowlpox boost.

In 1995, what was apparently the first study of DNA followed by MVA immunization was initiated as part of studies of malaria vaccination in a chimpanzee model [23]. Boosting of animals primed with DNA by recombinant MVAs enhanced CD4 and CD8 T cell responses measured in ELISPOT assays, and murine studies employing both plasmid DNA and Ty-virus-like particles soon revealed markedly enhanced T cell immunogenicity and protective efficacy mediated by effector CD8 T cells [1,3,24,25]. Several of the principles of prime-boost immunization using nonreplicating viruses as boosting agents were elucidated in this series of studies that will be reviewed in more detail.

## III. MURINE STUDIES

Schneider et al. [1] described some key features of heterologous prime-boost immunization with DNA and MVA vectors using the *Plasmodium berghei* malaria model. Immunization with DNA followed at a 2-week interval by recombinant MVA induced a 5–10-fold greater level of CD8 T cells compared to immunization with either vector used in a homologous prime-boost regime (Figure 1). This enhanced immunogenicity was associated with a transformation in the level of observed efficacy against sporozoite challenge from 0–20% to 80–100% (Table 1). This was the first time that high-level protective efficacy had been achieved in this murine malaria model. The order of immunization was critical with MVA priming and DNA boosting neither more immunogenic nor protective than MVA used alone. Also, coadministration of DNA and MVA was

**Figure 1** Immunogenicity of various prime-boost immunization regimes. The CD8 T cell response to a nonamer Kd-restricted epitope in the CS protein of *P. berghei* was measured by gamma-interferon ELISPOT assay of Balb/c mouse splenocytes after various immunization regimes, shown on the *X*-axis legend. The interval between immunizations was 14 days [1].

ineffective and a minimum 9-day interval between priming and boosting was required for high-level immunogenicity [2]. In these studies, CD8 T cells were measured to an immuno-dominant H2-Kd-restricted class I T cell epitope, termed pb9, in the *P. berghei* circumsporozoite (CS) protein using  $\gamma$ -interferon ELISPOT assays and chromium release assays. However, the marked increment in T cell immunogenicity was more evident in the ELISPOT assay than the less quantitative chromium release assay. Subsequent studies with a pb9-specific tetramer reagent confirmed these findings and, interestingly, revealed substantially greater numbers of induced pb9-specific T cells than the ELISPOT assay (Sheu et al., unpublished data).

In studies of the route of MVA immunization, intradermal administration of MVA was more immunogenic and protective than intramuscular or subcutaneous MVA and almost as immunogenic as intravenous MVA [1]. DNA was an efficient priming agent when delivered either intramuscularly or intradermally using a gene gun [26]. A striking and then surprising finding was made in comparisons of the

boosting ability of replicating and nonreplicating strains of vaccinia virus. The nonreplicating MVA strain was more immunogenic than the replicating Western Reserve (WR) strain of vaccinia virus both as a priming and a boosting agent [1]. The mechanistic basis of this counterintuitive observation remains unclear, but this adds to the potential clinical utility of the MVA strain. In more limited studies, the nonreplicating NYVAC strain also appeared more immunogenic and protective than the WR strain.

The view that protective efficacy was mediated directly by CD8 T cells was supported by the use of constructs encoding only the nine amino acids of pb9 from the *P. berghei* genome, as these proved as immunogenic and protective as constructs encoding the entire CS antigen [1,25]. In the C57/BL6 mouse strain that is very sensitive to malaria infection, complete protective efficacy could also be induced using a mixture of constructs encoding the *P. berghei* CS and thrombospondin-related adhesion protein (TRAP) sporozoite antigens [1]. Data on prime-boost immunization in the *P. yoelii* malaria model with the NYVAC vector as a boosting agent showed comparable enhanced immunogenicity and protective efficacy [27]. Parallel studies of immunogenicity of an HIV epitope in mice indicated that this prime-boost principle was not limited to malaria antigens [3], and this has been extensively confirmed with examples of the capacity of poxvirus vectors to boost CD8 T cells now provided for epitopes from numerous viruses, bacteria, and parasites in a variety of species (Table 2). Epitopes have been encoded singly, as parts of whole antigens, as polyepitope strings, as parts of polyproteins, and in initial clinical trials as parts of polyepitope-protein constructs (see below).

In parallel with these DNA-MVA studies of malaria in mice, studies of Ty-virus-like particles followed by MVA boosting demonstrated enhanced immunogenicity and protective efficacy [24,25]. This suggested that the principle of prime-boost immunization owed little if anything to particular properties of DNA as a priming agent, and this has been extensively illustrated. A large variety of vaccine types have now been shown to prime CD8 T cells efficiently for a subsequent poxvirus boost. These include recombinant influenza virus [20], lipopeptides [28], protein with adjuvant, bacterial vectors, and several other viral vectors (e.g., adenovirus [29], see below).

The potential utility of heterologous prime-boost immunization for cancer immunotherapy has also been dem-

onstrated in small animal models. DNA and MVA vaccines encoding an epitope string that included the P1A tumor epitope were protective against mastocytoma tumor development in a prophylactic vaccination model in mice (Schneider et al., unpublished). Constructs designed for human use have also been immunogenic in mice [30]. Using beta-galactosidase as a model antigen, Irvine et al. [31] showed enhanced immunogenicity of heterologous prime-boost regimes using either fowlpox or replicating vaccinia as boosting vectors. Heterologous prime-boost regimes were more protective than homologous regimes against challenge with a murine colon carcinoma cell line transfected with the beta-galactosidase gene. In studies of vaccinia and fowlpox vectors expressing carcinoembryonic antigen as well as co-stimulatory molecules, enhanced immunogenicity was again observed with heterologous prime-boost immunization [32]. Anderson et al. (submitted for publication) studied an attenuated strain of fowlpox termed FP9 [33] and showed it to be particularly effective at induction of CD8 T cell responses compared to the widely used Webster's strain of fowlpox virus. In heterologous prime-boost studies with the *P. berghei* CS protein, FP9-MVA and MVA-FP9 immunization was considerably more immunogenic than DNA-MVA immunization with a concomitant increase in protective efficacy against sporozoite challenge. This study showed directly that T cell cross-reactivity postimmunization was minimal between the avipoxvirus and orthopoxvirus vectors.

There has recently been increasing interest in recombinant nonreplicating adenovirus vectors as alternatives to either DNA or MVA in prime-boost immunization regimes. In the *P. berghei* malaria model, recombinant adenovirus was shown to be capable of priming and boosting CD8 T cell responses, and adenovirus priming followed by MVA boosting was more protective using the intradermal route of immunization than intramuscular DNA followed by intradermal MVA [29]. In studies in the *P. yoelii* malaria model replication-defective adenovirus was a particularly immunogenic priming agent and could be boosted by replicating vaccinia [34,35].

An important feature of prime-boost immunization is that priming of T cell responses may occur by natural infection. Both *Plasmodium falciparum* and *P. berghei* malaria sporozoites were found to induce very weak T cell responses that could be substantially boosted by replicating vaccinia virus and MVA, respectively [28] (Schneider et al., unpublished). This observation may have important impli-

**Table 2** Heterologous Prime-Boost Immunization and Protection Against *Plasmodium Berghei* Sporozoite Challenge [1]

Immunization 1	Immunization 2	No. of infected	% Protection

cations for the use of these vectors as therapeutic vaccines, suggesting that in a therapeutic setting, the use of the boosting vector alone might induce strong T cell responses.

The duration of induced T cell responses has been assessed in some limited studies after DNA–MVA immunization in small animals. In the *P. berghei* model, protective efficacy had dropped from 100% at 14 days following the MVA immunization to 60% at day 150 (Schneider et al., unpublished). In the *P. yoelii* model in mice, protection of 70–100% persisted for 20 weeks and dropped to 30–40% by 28 weeks [36]. At this latter time point, effector CD8 T cells had declined from 12–20% of splenic CD8 T cells at 2 weeks to 6%. Complete protection at 3 1/2 months after priming was reported with an adenovirus–vaccinia immunization regime in the *P. yoelii* model. In this regime, better immunogenicity and protection were observed after increasing the interval between priming and boosting from 2 to 8 weeks [35]. More detailed comparative studies of the durability of induced T responses with different prime–boost regimes would be valuable.

Although DNA–MVA immunization was originally used to induce strong CD8 T cell responses, it has turned out to be a surprisingly effective means of inducing  $\gamma$ -interferon secreting CD4+ T cells. This was clearly illustrated in a tuberculosis model where Th1-type CD4 T cells are of particular protective importance [37]. Using antigens and a mouse strain where no CD8 T cell response was detectable, the strongest CD4 T cell responses were induced by three DNA immunizations followed by an MVA boost. However, in contrast to findings with CD8 T cell responses, CD4 T cell responses were as strong following single dose MVA–DNA prime–boost immunization as with DNA–MVA immunization. Using the gene for a major secreted antigen of *Mycobacterium tuberculosis*, Ag85A, as an insert, both CD4 and CD8 T cell responses were induced by DNA–MVA immunization with protective efficacy equivalent to the BCG vaccine [38] (Figure 2).

One of the potential concerns with viral vector boosting is that the vector might not be reusable for subsequent immunization against the same or another pathogen because of antivector immunity. However, Sheu et al. (submitted for publication) showed that DNA-recombinant MVA immunization retained good immunogenicity in MVA immune mice, although the immunogenicity of homologous recombinant MVA immunization was substantially compromised. Thus mice immunized with DNA and MVA encoding malaria antigens could generate strong T cell responses when subsequently immunized with DNA and MVA vectors encoding an influenza antigen.

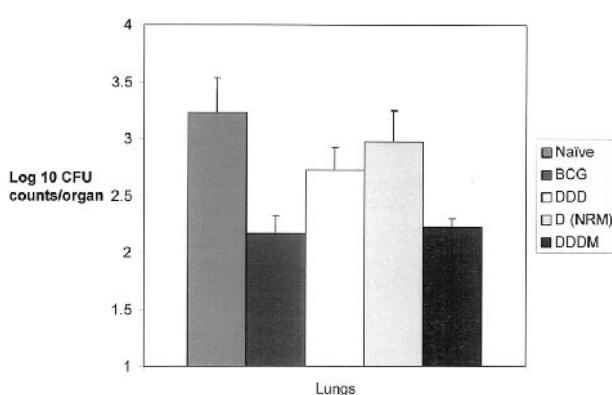

The capacity of nonreplicating poxviruses and adenoviruses to boost CD8 T cell responses naturally led to studies of triple vector immunization in which the capacity of a third vector heterologous to both the first and second is assessed. Disappointingly, in murine studies with the *P. berghei* CS antigen, no improvement in immunogenicity was observed over prime–boost immunization alone assessing various combinations of DNA, adenovirus, MVA, and fowlpox vectors in triple immunization regimes [29] (Anderson et al., unpublished).

Several vaccine delivery systems have now been assessed for their capacity to boost preexisting CD8 T cell responses. MVA and other nonreplicating poxviruses appear to boost most effectively and better than replicating orthopoxviruses. Avipoxviruses, which do not replicate in mammalian cells, can also boost efficiently perhaps less so than the orthopoxviruses. Nonreplicating adenoviruses also boost effectively in mice and are also very immunogenic priming agents. However, in general plasmid DNA, peptides, lipopeptides, and proteins either as particles or with adjuvants are relatively ineffective as boosting agents [1,25,28].

#### IV. NONHUMAN PRIMATE STUDIES

Studies in nonhuman primates have made an important contribution to the development of heterologous prime–boost immunization strategies. This has been facilitated by the application of new ELISPOT and tetramer assays to studies in nonhuman primates and by the availability of relevant challenge models in several species. In an early study of chimpanzees ELISPOT responses to a malaria pre-erythrocytic antigen, TRAP were not detected after DNA immunizations but were evident after boosting with recombinant MVA [23]. A chimpanzee infected with hepatitis B virus was immunized with DNA and remained viremic, but a booster immunization with a recombinant canarypox vector also expressing the hepatitis B surface antigen led to the clearance of HBV DNA [39]. However, the most substantial data on primate immunization come from HIV and SIV studies.

Prime–boost immunizations have been tested in macaques to generate CD8 T cell responses specific for simian immunodeficiency virus (SIV) or hybrid HIV–SIV viruses, SHIV. Pig-tailed macaques, immunized by DNA and then recombinant fowlpox expressing HIV proteins, were protected against HIV challenge [40]. Protection was associated with good CD8 T cell responses; however, HIV only weakly

**Figure 2** Protective efficacy against tuberculosis of DNA–MVA immunization with constructs expressing a major secreted antigen of *M. tuberculosis*, antigen 85A. Colony forming units were measured in lung tissue after various immunization regimes and compared with no vaccination and BCG vaccination. NRM = nonrecombinant MVA. (From Ref. 38.)

infects this macaque species, and this may not be a very robust model of HIV vaccine protection. In rhesus macaques, immunization with DNA encoding HIV and SIV protein epitopes, followed by MVA recombinant for the same DNA, could generate strong CD8 T cell responses, measured by tetramer staining, to the immunodominant epitope presented by the Mamu A01 class I MHC type [41]. Prior DNA priming was essential for the strong response after the MVA boost. Amara et al. [42,43] took this a stage further and showed that monkeys primed with DNA and boosted with MVA were able to survive challenge with the highly aggressive SHIV 89.6P virus. The immunity was not sterilizing, but virus loads were reduced by a thousand-fold and CD4 T cell counts remained stable. It was of interest that the challenge was 7 months after the last MVA immunization so protection was long-lived. Similar results have been obtained in macaques immunized by DNA that encodes the SIV gag protein, followed by recombinant adenovirus expressing the same protein [44]. Again, animals were not completely protected from SHIV 89.6 challenge but survived and did not lose CD4 T cells. However, a warning note for this type of study comes from a study where similar levels of protection against this virus were achieved in rhesus macaques using DNA and interleukin-2, but one animal became sick when the virus mutated a critical amino acid residue in the epitope and was no longer controlled by the T cell response [45]. Another note of caution comes from a study where DNA- and MVA-immunized macaques were challenged with the slightly less aggressive virus SIV 239 and showed only marginal transient reduction of virus level compared to controls [46]. It is not clear why this is so, but the route of DNA immunization, intramuscular in the former study compared to intradermal by gene gun in the latter study, could contribute if the intradermal route favors Th2 responses [47]. In both studies, the level of SIV-specific CD8 T cells was high and very similar. It is also possible that protection might actually be better at late time points after vaccine immunization.

There have been studies of challenge with each vaccine component alone. DNA immunization followed by recombinant adenovirus gave better protection in macaques than either alone or DNA followed by recombinant MVA [44]. However, two studies have shown that quite good protection against SHIV 89.6P challenge could be obtained by recombinant MVA alone [48,49]. These studies are focused on monkeys with the Mamu A\*01 MHC type, and the epitope usually monitored seems to be very immunodominant, whether delivered by SIV, DNA, recombinant adenovirus, or recombinant MVA. This may not be true of other epitopes in which case the DNA priming step may be needed so that the MVA generates a T cell response to the inserted gene product.

There has been one study that used the DNA prime, recombinant adenovirus boost approach to protect macaques from Ebola virus [50]. Both humoral and cellular immune responses were generated. The level of protection was impressive.

These results in macaques, which have been immunized by DNA followed by MVA, therefore confirm the results in rodents showing that DNA prime and MVA or adenovirus

boost gives better T cell responses and better protection than either component alone.

Macaques also provide a valuable model for preclinical testing of malaria vaccines. Rogers et al. [51] have evaluated DNA priming and both canarypox and NYVAC vectors as boosting agents in the *Plasmodium knowlesi* simian malaria model. Using a mixture of two pre-erythrocytic antigens and two blood stage antigens, detectable protection was induced with the DNA-canarypox regime and higher levels of protection with the DNA-NYVAC prime-boost regime [52].

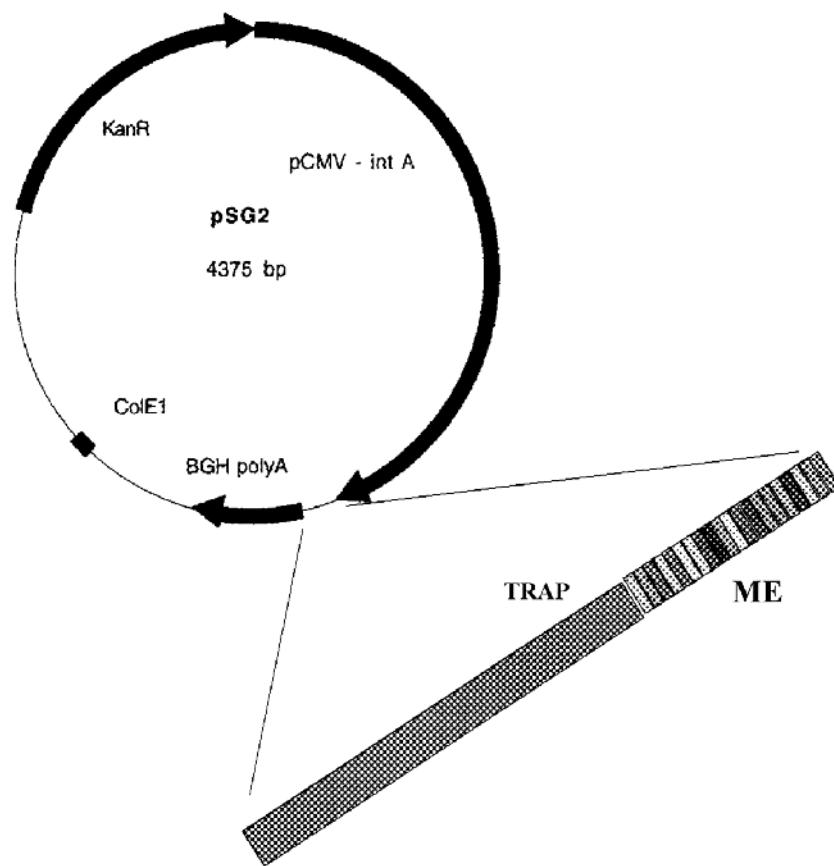

Macaques are not naturally infected by the major human malarias, but they are very susceptible to the human tuberculosis bacillus, *M. tuberculosis*. The long time scale of vaccine efficacy studies for tuberculosis has led to increasing interest in macaques as both an immunogenicity and efficacy model [53] for new tuberculosis vaccines. Goonetilleke et al. (unpublished) have evaluated prime-boost immunization strategies in macaques using a major secreted antigen of *M. tuberculosis*, Ag85A, as an insert in both MVA and FP9 vectors, with or without priming with the BCG vaccine. Strong CD8 T cell responses could be induced by a triple immunization regime employing a BCG prime and MVA and FP9 booster immunizations.

## V. CLINICAL TRIALS

### A. Malaria

In 1999, a series of heterologous prime-boost immunization trials were initiated in Oxford to ask whether heterologous prime-boost immunization with DNA and MVA vectors showed enhanced immunogenicity over the individual vaccines and to determine whether any efficacy could be achieved against sporozoite challenge [54]. Clinical trials are in progress of DNA-MVA immunization for malaria using as an insert a polyepitope string used to an entire pre-erythrocytic protein antigen, thrombospondin-related adhesion protein (TRAP) (Figure 3). The epitope string includes 14 CD8 T cell epitopes from six different pre-erythrocytic *P. falciparum* antigens and six other B cell or CD4 T cell epitopes. Doses of DNA from 0.5 to 2.0 mg have been delivered intramuscularly with a needle or a much lower dose of 4 µm delivered intradermally with the Powderject Vaccines ballistic device or "gene gun." MVA has been delivered intradermally with doses of  $3 \times 10^7$  to  $1.5 \times 10^8$  pfu. Overall, in over 150 vaccinees receiving either DNA or MVA or both, the safety profile of both of these vaccines has been good without any severe or serious adverse events [54a,54b].

T cell immunogenicity has been assessed in these studies principally with ex vivo ELISPOT assays to peptides spanning the entire insert sequence. Both CD4 and CD8 T cell responses have been observed, and these are focused more on the TRAP antigen than the string of largely CD8 T cell epitopes. A summary of the T cell immunogenicity observed in a series of small-scale studies is presented in Figure 4 [54b]. The time point shown is 7 days after the last immunization, at about the time of peak immunogenicity. The use of DNA and MVA at various doses induced detectable but modest immunogenicity with arithmetic mean responses measured

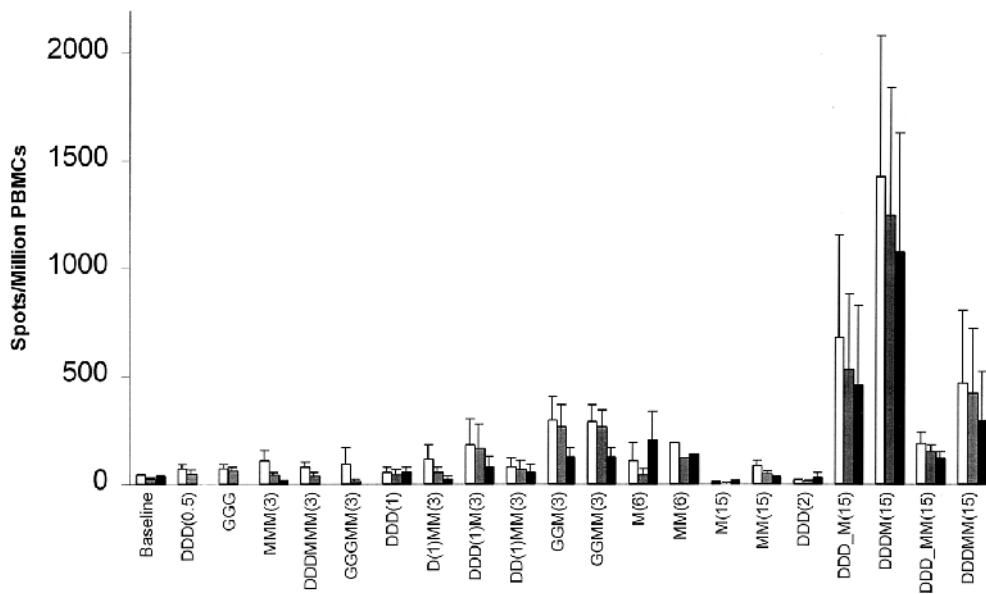

**Figure 3** Plasmid DNA construct used for DNA–MVA malaria clinical trials. The insert is an entire pre-erythrocytic antigen, thrombospondin-related adhesion protein fused in-frame to the C-terminus of a polyepitope string of 20 peptides, including 14 CD8 T cell epitopes from six different *P. falciparum* pre-erythrocytic antigens [24].

as under 100 per million peripheral blood mononuclear cells (PBMCs) by summing responses across the different peptide pools used in the assays. Importantly, substantially higher immunogenicity was observed with DNA–MVA heterologous prime–boost immunization, particularly using the higher dose regimes. In the regime with three priming DNA immunizations, a mean response of over 1000/million was observed 7 days after the first MVA boost (Figure 5). Responses were higher with a 3-week interval between the third DNA immunization and the MVA than with an 8-week interval. In this high responder group, the responses measured were predominantly CD4 rather than CD8 peptide-specific cells.

Polymorphism in major antigens is a significant difficulty in malaria vaccine development, and the TRAP antigen used in these vaccine constructs shows such variation. The strain used in the DNA and MVA vaccine constructs is from the T9/96 *P. falciparum* parasite that differs by about 6% in sequence from the 3D7 parasite strain generally used in human malaria sporozoite challenge studies [55]. Analysis in ELISPOT assays of T cell responses to both strains of TRAP showed substantial but incomplete T cell cross-reactivity. Sporozoite challenge studies in volunteers immu-

nized with various regimes showed a significant delay in time to patent parasitemia in volunteers immunized with DNA–MVA heterologous prime–boost immunization regimes but not with homologous immunization regimes (McConkey et al., submitted for publication). The efficacy observed with DNA–MVA in this sporozoite challenge study is encouraging in that this is the first time protection has been achieved with a subunit vaccine against heterologous strain challenge, and the estimated reduction in parasite numbers in the liver is of the order of 75%. Given that the dose of parasites used in the challenge model may be an order of magnitude larger than a natural field infection, greater efficacy may be observed in field studies.

Phase I trials of DNA–MVA immunization in Gambians naturally exposed to malaria have been undertaken with a view to larger-scale efficacy trials in this population [54a]. T cell responses evoked by natural infection against the ME-TRAP insert are low and of the order of 25 SFUs/million PBMCs, much lower than what can be achieved by DNA–MVA vaccination. In Gambians, safety data have been satisfactory and T cell immunogenicity is equal to or greater than that observed in nonimmune European volunteers [54a]. Furthermore, the cross-reactivity of the induced

**Figure 4**  $\gamma$ -Interferon ELISPOT responses to pools of peptides from the ME-TRAP malaria insert 7 days after various DNA and/or MVA vaccination regimes showing summed net responses to pools of peptides from all of the vaccine insert, from the T9/96 strain of TRAP encoded in the vaccine, and from TRAP from another *P. falciparum* strain, 3D7. The bracketed numerals included in the regimen names correspond to the dosage of vaccine, in milligram for DNA and pfu  $\times 10^7$  for MVA. The arithmetic mean of the responses for the subjects in that group are presented with an error bar to indicate the standard error of the mean. (From Ref 54b.)

T cell responses between strains was greater than in nonimmune vaccines. Phase IIb studies in larger numbers of adults of the efficacy of DNA–MVA against malaria infection are planned for the near future.

The greater immunogenicity of FP9–MVA than DNA–MVA prime–boost immunization observed in studies of murine malaria (Anderson et al., submitted for publication) led to the clinical assessment of an FP9 construct encoding the same insert as the DNA and MVA vaccines. Again, much higher T cell responses were observed with FP9–MVA

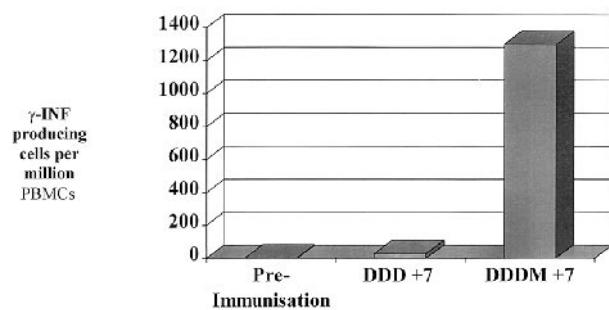

immunization than with homologous prime–boost immunization, and significant efficacy was observed against sporozoite challenge (Webster et al., unpublished). Although some volunteers immunized thus have been fully protected against sporozoite challenge, further analysis is required to determine whether DNA–MVA or FP9–MVA immunization regimes will be more immunogenic or protective.

In both the DNA–MVA and FP9–MVA studies, antibody responses induced to the malaria insert have been low or absent, indicating that in their current formulations, these approaches, like DNA vaccines used alone, induce low level or no antibody responses. Conversely, this finding implies that the protection observed in the malaria challenge studies is almost certainly cell-mediated rather than antibody-mediated.

In summary, these malaria studies have demonstrated that the DNA–MVA immunization in humans can be used safely and can generate effector T cell responses apparently higher than previously reported for any other subunit vaccination approach. Initial evidence of protection in malaria challenge studies is encouraging, and field studies are planned to assess the utility of this approach in a natural field setting.

## B. HIV

Attempts are in progress to make a vaccine that stimulates CD8 and CD4 T cells specific for HIV in humans. Early studies showed that relatively low doses of DNA immunization (<1 mg) elicit transient T cell responses in HIV-uninfected volunteers [56]. Similarly, recombinant canary

**Figure 5** Immunogenicity of DNA immunization compared to DNA–MVA immunization. T cell responses to the ME-TRAP insert (Figure 3) were measured in eight volunteers prevaccination, 7 days following three DNA immunizations with 2 mg per dose and 7 days following a booster immunization with MVA encoding the same insert. (From Ref 54b.)

pox vaccines have stimulated relatively weak T cell responses, particularly CD8 T cells [14,57,58].

A series of trials of DNA, MVA, and DNA plus MVA have recently been completed in Oxford and Nairobi, Kenya (Mwau et al., submitted for publication; Anzala et al., in preparation). The vaccine is a synthetic DNA construct which comprises HIV clade A consensus gag p24 and p17. DNA, encoding a string of 25 epitopes from other HIV proteins, was added to the 3' end [59]. The latter include the gag epitope presented by Mamu A\*01 and a gp120 V3 loop peptide presented by H2-Kd. Thus the vaccine could be tested in mice and macaques [60]. The MVA is recombinant for the same DNA construct. In humans, the DNA stimulated weak responses at early time points, but, surprisingly, strong CD4 and CD8 responses appeared 6 and 12 months after vaccination, possibly reflecting persistence of the DNA at the site of injection. MVA gave a more classical CD8 T cell response to a nonpersisting virus, but not all volunteers responded to the inserted sequence. Boosting of DNA-primed volunteers with MVA elicited good CD4 and CD8 responses. All volunteers who were given the DNA and MVA responded, and the quality of the response differed from that induced by MVA alone. Both vaccines appeared safe.

Further larger-scale trials are in progress, testing different doses of the vaccines, different routes, and schedules. If the vaccines prove to be safe and stimulate strong and broad T cell responses, it is planned to test them in efficacy trials in East Africa, countries where the A clade virus is predominant.

In a parallel series of clinical trials in humans, Emini et al. (<http://www.retroconference.org/2002>) have shown that DNA encoding HIV B clade gag, given by intramuscular injection, elicited definite T cell responses in some volunteers. The same construct presented by recombinant adenovirus gave stronger T cell responses, especially in recipients with lower levels of preexisting neutralizing antibody. Prime-boost studies are in progress.

These early studies in humans are reasonably encouraging. Some response is elicited by the main vaccine components, and optimization of the prime-boost approaches should result in enhanced T cell responses. Most of the current studies are focused on T cell responses, but it will be informative to monitor antibody responses as well.

Besides the prophylactic studies, there are some therapeutic studies that are aimed at stimulating T cell immunity in HIV-infected patients who are on antiretroviral drug treatment. If the T cell responses can be enhanced, it may be possible to withdraw drug treatment and maintain immunological control of the virus.

### C. Hepatitis B Virus Therapeutic Vaccination

One of the main objectives of strategies aimed at improving effector T cell responses is to allow therapeutic vaccination. Many such attempts have targeted the hepatitis B virus because most individuals manage to mount a sufficient immune response postinfection to effect viral clearance. However, others who fail to do so comprise 15% of adults in some developing countries and about 350 million individuals

worldwide. These carriers are at substantially increased risk of hepatocellular carcinoma. Current treatments for hepatitis B virus infection offer only transient suppression of virus load with antivirals or low responder rates using alpha interferon. The rationale for developing a therapeutic CD8+ T cell inducing vaccine derives from preclinical and clinical observations. In a murine HBV model, Guidotti and Chisari [61] demonstrated that INF- $\gamma$  secreting CD8+ T cells suppress transcription of viral genes. In murine studies, DNA-MVA immunization showed substantially enhanced CD8 T cell responses compared to vaccination with either DNA or MVA alone. A phase I trial of DNA and MVA vaccines encoding the hepatitis B surface antigen has been undertaken in the United Kingdom, and preliminary data show good safety and induced cellular immune responses. In The Gambia, a phase II trial with viral clearance as an outcome measure has commenced. In this trial, a potential synergistic effect of DNA-MVA prime-boost vaccination and the use of the antiviral drug lamivudine are being assessed.

### D. Melanoma and Other Cancers

The identification of tumor-associated antigens (TAA) recognized by CD8+ T cells offers targets for recombinant antigen delivery systems. There are now many CD8+ T cell epitopes available to target the cellular immune response to the tumor. Melanoma is the best-studied human malignancy in which numerous TAA have been identified. Currently, there are several products being tested using recombinant gene-based antigen delivery systems with the aim of inducing a tumor-specific CD8+ T cell response. The use of multiple antigens or CD8+ T cell epitope strings may induce a multispecific CD8+ T cell response minimizing the occurrence of antigen-loss variants and may increase the safety of these gene-based vaccines, particularly for newly identified TAAs whose biological roles are poorly understood. Epitope string-based DNA and MVA melanoma vaccines [30] have been tested in stages II and IV melanoma patients. A CD8+ T cell epitope string containing seven different epitopes presented by HLA-A2 and HLA-A1 derived from five different melanoma TAA was safe. An expansion of melanoma-specific CD8+ T cells was detected in the majority of the vaccinees, particularly following heterologous priming and boosting.

In a phase I trial of patients with tumors expressing the carcinoembryonic antigen, fowlpox and replicating vaccinia viral vectors were assessed in heterologous prime-boost immunization regimes. Stronger T cell responses were observed by boosting vaccine-primed patients with the fowlpox vaccine than the opposite order of immunization [62]. The use of heterologous boost-boost cycles (for example, recombinant MVA followed by recombinant adenovirus followed by recombinant fowlpox virus) is particularly attractive for chronic conditions such as cancer.

## VI. CONCLUSIONS AND PROSPECTS

Attempts to induce the high-level effector T cell responses with subunit vaccines are at an early stage of development.

Prime-boost strategies grew out of attempts to optimize protective CD8 T cell responses in mice and have entered clinical trials relatively rapidly. Safety data with both the DNA vaccines and the attenuated viral vectors tested to date in these trials look reassuring. As hoped for, some very high effector T cell levels have been achieved, at least as compared to previous subunit vaccination approaches. However, a major unknown is the level of response that will be required to provide protection in various diseases. Extrapolation from animal models is of limited value in making such estimates, and challenge studies, where feasible and ethical, may be of greater value in the short term. The characteristics of the induced responses with DNA-based vaccines appear different to protein-adjuvant strategies, with the former inducing higher effector T cell numbers but lower T cell proliferative responses as well as lower level antibody induction. Another key issue, particularly for prophylactic vaccination, remains the durability of induced T cell responses. In the malaria clinical trials discussed above, responses are maximal 1–2 weeks after the booster vaccination and decline to a plateau at about 28 days. How well sustained these responses are over subsequent years requires characterization.

It is likely that improvements to both the priming and boosting compositions of the DNA–MVA approach will be forthcoming. Improvements by adding cytokines or other types of adjuvant to DNA vaccines are discussed elsewhere in this volume. MVA may be improved, in principle, by addition of adjuvants or by modifications to the vector. The latter includes further deletion of genes that may dampen immune responses and also addition of extraneous genes such as cytokines and chemokines that may improve immunogenicity. Such modifications may either increase immunogenicity and efficacy at current doses or reduce the dose of the vector that is required for a defined response. This could be particularly important for DNA vaccines where current milligram doses may prove expensive for prophylactic vaccination in developing countries. It remains unclear whether optimization of the doses and regime of boosting will allow lower doses of DNA to be used in a prime in humans, but studies in mice suggest that this may be possible [63].

One of the attractions of DNA vaccines is the generic nature of the manufacturing process and the limited modification of this process required with a different plasmid. Furthermore, it is likely that DNA vaccines may be distributable without a cold chain, of great importance in some developing countries. Similar considerations apply to the use of recombinant poxvirus vaccines. Cost of manufacture is likely to be lower for these, the approach is generic, readily transferable to developing country manufacturers, and poxviruses may be freeze-dried. The WHO has previously used a poxvirus vaccine worldwide to eliminate smallpox.

Despite the efforts being made to assess DNA–MVA vaccines for malaria and HIV prophylaxis in Africa, the route to market for other diseases may be shorter. Demonstration of convincing efficacy against persistent viral infections or even malignancies might require smaller trials and less time. The capacity to induce readily measurable effector T cell responses to pathogen and tumor antigens with these vectors should allow rapid assessment of the potential of

induced T cells to reduce viral load or effect viral clearance in diseases such as persistent HBV and HCV infection as well as against HIV. The greater challenge of therapeutic vaccination against malignancies could be pursued with greater confidence if measurable T cell responses against tumor antigens prove to be inducible in the majority of patients by prime-boost vaccination strategies.

## Mucosal Immunization and Needle-Free Injection Devices

**Myron M. Levine and James D. Campbell**

*University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.*

### I. INTRODUCTION

Currently, most vaccines are administered parenterally by needle and syringe. However, in industrialized countries, a proportion of children and adults have an aversion to injections. Therefore, administering vaccines without needles would be expected to increase compliance. Indeed, concern among parents about the number of injections that must be given to infants and toddlers in order to deliver the recommended vaccines has been a strong impetus for the development of infant combination vaccines. Moreover, the administration of vaccines by needle and syringe poses occupational safety risks for health care providers. This could emerge as a more substantive issue in the future should it become necessary to immunize large populations expeditiously in response to a bioterror or emerging infection emergency.

The role of needles and syringes in immunization practice is even more problematic in developing countries, where there are efforts to increase immunization coverage and to introduce new vaccines. Except for the oral polio vaccine, all the other vaccines recommended by the Expanded Program on Immunization (EPI) are given parenterally, using needles and syringes. However, in developing countries, injection safety is a notorious problem [1,2], as improper practices involving nonsterile needles and syringes (often used from one subject to another) cause abscesses and transmit blood-borne pathogens (e.g., hepatitis B and C and HIV) [2]. Although parenteral vaccination accounts for only a fraction of the injections given by health workers, nevertheless, immunization must be held to a higher standard because it involves healthy individuals. The Global Alliance for Vaccines and Immunization (GAVI) and its associated Vaccine Fund are addressing the difficulties faced by immunization services in developing countries. As part of its concept, GAVI supports the vision that immunization in the future would be more efficient, economical, and effective if all vaccines could be administered without the need for injection by needles.

Three broad strategies are being advocated for needle-free administration of vaccines, each with its own advan-

tages [3]. The first strategy involves mucosal immunization; the second is based on injection using needle-free devices; the third involves transcutaneous immunization. Because transcutaneous immunization is covered in the chapter authored by Glenn, this chapter will limit itself to reviewing mucosal immunization and needle-free injection devices.

### II. VACCINES DELIVERED VIA MUCOSAL SURFACES

#### A. Potential and Practical Mucosal Sites for Administering Vaccines

Whereas the human oral, nasal, rectal, conjunctival, and vaginal mucosa are all amenable to the application of vaccines for immunization, not all options are equally practical. For example, the rectal route, which is highly efficient at eliciting immune responses [4–6], would be unpopular in a number of cultures globally. Although antigens can be immunogenic after instillation into the conjunctival sac [7,8], some antigens might elicit conjunctival inflammation which, on occasion, might secondarily lead to purulent conjunctivitis. The vaginal mucosa, despite having relatively sparse inductive sites, can serve as a route for immunization against certain infections in females [9]. Thus, in practical terms, oral and nasal administration are the most suitable options for all ages and both genders [10].

#### B. Inductive Sites for Immune Responses

Aggregates of mucosa-associated lymphoid tissue are found along the mucosa of the gastrointestinal, respiratory, and genitourinary tracts. These include the gut-associated lymphoid tissue (GALT), bronchus-associated lymphoid tissue (BALT), and the nasal associated lymphoid tissues (NALT). Specialized microfold (M) cells overlying the mucosa-associated lymphoid tissues in the intestine and the nose constitute competent portals by which antigens (including vaccines) can reach the underlying inductive sites for initiation of immune responses [11]. These inductive sites are rich

in antigen-presenting cells (macrophages, dendritic cells, etc.), in addition to the B and T lymphocytes that are present. Several reviews contain detailed descriptions of the anatomic architecture and cell types observed in the mucosa-associated lymphoid tissue [11–13].

The gastrointestinal and upper respiratory mucosa are constantly exposed to antigens from resident normal bacterial flora of the gut and nasopharynx, food, and inhaled materials. As a consequence, the mucosa of these anatomical sites can develop tolerance to an antigen, such that either a local immune response is not elicited or it is muted. This is more likely to occur if the antigen is delivered in a soluble form and given repetitively. Repetitive oral administration of a soluble antigen can also lead to systemic tolerance manifested by a diminished ability to mount an immune response upon parenteral administration of the same antigen [14]. Notably, as discussed later in this chapter, by administering the antigen of interest in a specialized delivery system or by coadministering strong adjuvants, potent immune mucosal and systemic responses can be elicited.

### C. Immune Effector Responses

Mucosally administered vaccines work well in preventing infections limited to the mucosal surfaces (e.g., cholera) [15,16], or those caused by pathogens that invade via the mucosa (e.g., poliomyelitis, *Salmonella Typhi*) [17–19]. Dimeric secretory immunoglobulin A (SIgA) is, by far, the predominant immunoglobulin found in gastrointestinal and respiratory tract mucosal secretions, saliva, and breast milk. Mucosal SIgA can mediate protection by neutralizing toxins, preventing virus entry into cells, or by inhibiting the fimbriae and other virulence adhesins that bacteria utilize to attach to epithelial cell receptors.

Because of the preponderance of SIgA in mucosal secretions, steps involved in the generation of this effector response have been the most extensively studied. Initial exposure of naive B lymphocytes to antigen in inductive sites in the mucosa-associated lymphoid sites (e.g., Peyer's patches, NALT) and draining regional lymph nodes, is followed by clonal expansion, isotype switching, affinity maturation, and migration [20,21]. At approximately 7–10 days following the administration of the mucosal vaccine, the migrating cells can be detected as antibody secreting cells (ASCs) found among peripheral blood mononuclear cells [22–29]. Mucosal immunization predominantly elicits IgA ASCs that carry on their surface the  $\alpha_4\beta_7$  homing receptor that directs them back to the lamina propria in mucosal sites [30,31]; they mainly return (but not exclusively) to the anatomic area from which they originated. The distribution of ASCs (mainly IgA) and memory B cells, upon their return to the mucosa, accounts for both the compartmentalization of the mucosal immune system (SIgA responses are usually strongest at the site of induction) and the phenomenon of the “common mucosal immune system” (whereby SIgA responses can often be detected in mucosal sites remote from the inductive site).

There is reason to believe that if the relevant immune responses can be generated, systemic infections (including those that do not involve initial invasion from a mucosal

surface, e.g., malaria) and toxicoses (e.g., tetanus) can also be prevented by administering the appropriate vaccines via mucosal surfaces [32]. Indeed, properly formulated, mucosally administered vaccines can stimulate virtually any relevant type of immune response: serum IgG neutralizing antibodies against toxins [32–34] and viruses [35–37], and the full array of cell-mediated immune responses including lymphocyte proliferation [38,39], cytokine production [38], and CD8<sup>+</sup> cytotoxic lymphocyte activity [38,40–42], in addition to stimulating mucosal secretory IgA antibodies [25,43–48].

### D. Duration of Protection Conferred by Mucosally Administered Vaccines

It was previously taught that vaccines administered via mucosal surfaces can only elicit relatively short-term protection. However, there are multiple examples of mucosal vaccines that have conferred long-term protection and have elicited long-lived immune responses that correlate with protection. For example, an enteric-coated capsule formulation of Ty21a live oral typhoid vaccine conferred 62% protection over 7 years of follow-up, and a more effective liquid formulation conferred 78% protection over 5 years of follow-up [49]. A prototype nonliving oral cholera vaccine consisting of B subunit and inactivated whole vibrios conferred 56% protection over 3 years of follow-up [50]. Titers of serum neutralizing antibody remain elevated for years following oral immunization with Sabin live oral polio vaccine [51].

### E. Oral Vaccines

Both live and nonliving antigens can be delivered orally with good results. The trivalent attenuated Sabin poliovirus vaccine, the keystone of the global poliomyelitis eradication program, constitutes a paradigm that has encouraged the development and use of other live attenuated vaccines administered orally that have been licensed or are near licensure. The Sabin oral polio vaccine sets the standard for ease of administration to subjects of any age. Other licensed oral vaccines include the following: Ty21a [49,52], live oral cholera vaccine strain CVD 103-HgR [53], and nonliving cholera vaccines [16,54]. Overall, the experience with oral vaccines has been highly satisfactory. Nevertheless, problems have emerged. Postlicensure surveillance in the United States detected a rare association between tetravalent reassortant rhesus rotavirus vaccine and intestinal intussusception [55] that ultimately led to withdrawal of the vaccine from the market. As a consequence of this experience, new generation rotavirus vaccines that are under development are addressing the risk of possible intussusception through large prelicensure clinical trials.

Another problem that is being investigated is why some, particularly live, oral vaccines appear to be less immunogenic among individuals in developing countries, compared to their counterparts in industrialized countries [56,57–61]. Factors that can play a role include the presence of small bowel bacterial overgrowth [62], competing enteric viruses, or intestinal helminths [63].

Various platform technologies are creating promising oral vaccine candidates. These include bacterial and viral live vectors expressing foreign antigens [32,64–67], DNA vaccines administered directly [68–70] or via bacterial vectors [71–74], transgenic plant “edible vaccines” [75,76], and various nonliving antigen delivery systems (liposomes, proteosomes, polylactide/polyglycolide microspheres, etc.), among others. Clinical trials with these technologies have generated mixed results [32,75,77], some of which have been promising [32,75].

### F. Nasal Vaccines

Nonliving and live antigens delivered nasally can also be highly immunogenic and protective. Indeed, in recent years considerable experience has been gained with an array of intranasal vaccines, recognizing that NALT is a particularly competent site for inducing immune responses. Based on its safety, immunogenicity and efficacy [78,79], live cold-adapted trivalent influenza vaccine, administered by a convenient single-use spray device that painlessly delivers vaccine to the nasal mucosa, has been licensed by the Food and Drug Administration (FDA) (albeit initially restricted to use in certain age groups).

Various soluble and particulate nonliving antigens have been administered intranasally with varying success. Research is seeking well-tolerated adjuvants and antigen delivery systems to enhance immunologic responses to nonliving vaccines administered via the nasal mucosal surface. Cholera toxin (CT) and heat-labile enterotoxin (LT) of enterotoxigenic *Escherichia coli* are powerful adjuvants that enhance local IgA and serum antibody responses to coadministered soluble or particulate antigens. While these toxin adjuvants are unacceptable as human oral adjuvants (because as little as 5.0 µg can cause severe diarrhea) [80], they have been investigated for nasal administration. Wild-type LT adjuvant was incorporated into a nasal nonliving influenza vaccine used in Europe [81]. The vaccine was well tolerated and immunogenic in prelicensure clinical trials. However, postlicensure surveillance identified a likely association with cases of Bell’s palsy, resulting in the withdrawal of that nasal influenza vaccine from the market. It is hypothesized that the promiscuous ganglioside binding mediated by the LT B subunits allowed toxin molecules to adsorb to facial nerve fibers and to translocate proximally, possibly resulting in neuronal damage [82].

Efforts have been made to develop adjuvants that retain the potency and versatility of LT and CT for enhancing immune responses to coadministered antigens, but with greatly improved safety profiles. One strategy has been to engineer mutant LT and CT molecules that exhibit reduced toxicity but retain adjuvanticity [83,84]. Theoretical safety concerns remain to be resolved with these proteins because, in some species, the unaltered ganglioside binding properties of the mutant LT and CT molecules allow uptake by nasal olfactory nerve fibers and retrograde transport to the olfactory lobes of the brain [82]. It is not known whether such neuronal transport of mutant LT and CT occurs in humans as well and, if so, what consequences might ensue. Accordingly, clinical trials using mutant toxins adminis-

tered intranasally are carefully surveying for possible adverse effects.

Safer intranasal adjuvants must be developed to realize more fully the potential of intranasal immunization with nonliving antigens. Several encouraging breakthroughs have been reported. One attractive adjuvant, referred to as CTA1-DD, links enzymatically active subunit A of CT to an Ig receptor binding peptide [85], thereby targeting the immune system’s B cells [85]. One may envision that adjuvants like CTA1-DD could be coadministered intranasally with existing diphtheria, tetanus, pertussis (DTP), hepatitis B virus (HBV), and Hib conjugate vaccines, as well as other relevant vaccines (e.g., pneumococcal and meningococcal conjugates, or common protein vaccines), resulting in the stimulation of potent mucosal and systemic immune responses.

Another promising approach involves the use of the mucoadhesive polycationic polysaccharide “chitosan” as an antigen delivery system. Chitosan increases the transport of antigen across the nasal epithelium by means altering intercellular tight junctions and decreases the mucociliary clearance of antigen [86,87]. In a Phase I human clinical trial, diphtheria toxin CRM<sub>197</sub>, given intranasally in a chitosan delivery system, elicited significantly higher serum neutralizing antitoxin titers and IgA antibodies than CRM<sub>197</sub> administered without chitosan [34].

These encouraging intranasal vaccine delivery strategies still have major hurdles to overcome. One of the most important challenges will be to assess their effectiveness in immunizing infants in developing countries, recognizing that in such infants, upper respiratory infections and nasal discharge are highly prevalent.

### G. Aerosol Measles Vaccine

Mass immunization campaigns in Latin America and pilot campaigns in Southern Africa with parenteral measles vaccine administered by needle and syringe have decreased measles incidence and mortality. Nevertheless, field experiences make it clear that such campaigns would be logistically simpler and safer if measles vaccine could be administered without needles. Measles vaccine administered by aerosol (creating small particles that reach the lung) is highly immunogenic and efficacious [35,88]. The early aerosol measles vaccine devices that generated the highly encouraging clinical results had limitations in rapidity, portability, or robustness. Much improved, more compact, simpler, and robust new devices are currently under evaluation in monkey studies and human clinical trials.

## III. NEEDLE-FREE INJECTION DEVICES

### A. Jet Injectors

Jet injectors are needle-free devices that propel liquid (nonliving or live) vaccine under high pressure through a minute orifice so that it pierces the integument to reach the dermis, subcutaneous tissue, or muscle, as desired. Needle-free jet injectors stimulate immune responses that are similar in magnitude and character to vaccine injected by needle and syringe. Vaccination with some jet injectors

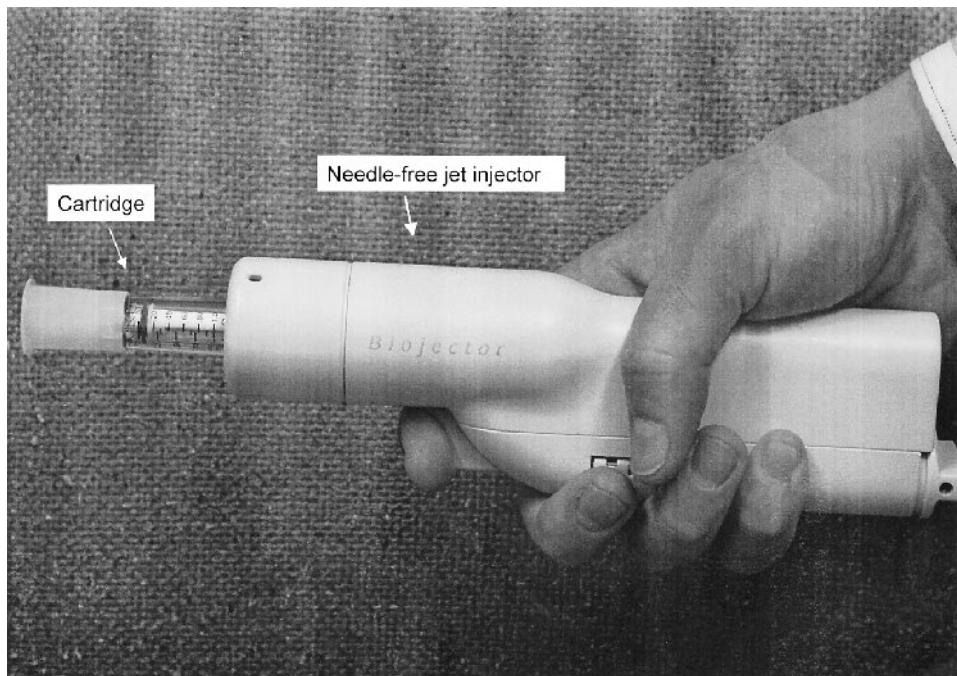

elicits higher rates of local reactions than needle and syringe. From the 1950s to the 1980s, high-workload, multiple-use-nozzle jet injectors were widely utilized in mass immunization campaigns in less-developed countries to deliver smallpox, measles, yellow fever, and other vaccines [89]. Multidose vials (containing up to 50 doses) permitted these devices to vaccinate 600–1000 subjects each hour using the same dose chamber, fluid path, and nozzle on consecutive subjects. The dosing chamber was automatically replenished from the multidose vial following each injection. In the mid-1980s, it came to be recognized that multiple-use-nozzle jet injectors could inadvertently transmit blood-borne infections (e.g., hepatitis B), albeit rarely [90]. Safety concerns stemming from the emerging global pandemic of HIV led health authorities to discontinue the utilization of the high-workload, multiple-use-nozzle jet injectors.

The anthrax emergency in the USA in late 2001 has prompted public health authorities to contemplate how they might conduct mass immunization campaigns if their jurisdiction is confronted by a bioterror event. Concern over how to administer, en masse and rapidly, vaccines against bioterror agents has reawakened interest in new high workload devices. One device of interest is a multiple-use-nozzle jet injector that incorporates a disposable cap to reduce the risk of splash back of blood or serum onto the nozzle after injection. Other injectors of interest employ disposable cartridges that disable after use. If large clinical trials convincingly document the safety of these devices, they could be utilized in mass campaigns in developing countries

(e.g., against measles and meningitis) as well as for use in campaigns in industrialized countries.

Single-dose jet injector devices also exist for administering vaccines under lower workload situations. These devices utilize disposable cartridges and nozzles for individual patients to avoid cross contamination [91]. Currently, in physician's offices and clinics in industrialized countries, some needle-free injection devices (e.g., Biojector 2000<sup>®</sup>) (Figure 1) are employed to administer vaccines to subjects who have extreme aversion to needles, and to avoid needle-stick injuries among health care workers [91,92]. These devices are not yet affordable for routine use in developing countries. A perceived drawback of the current devices in some venues is that vaccine must be transferred from its vial into the cartridge by means of a needle or special adaptor; this could pose safety problems in developing country settings [93]. On the other hand, this intermediate step is advantageous for reconstituting lyophilized vaccines. The need for the intermediate step could be entirely eliminated if manufacturers prefilled vaccines directly into universal standard single-dose cartridges that could fit a variety of injectors. One such experimental system, the Imule<sup>®</sup> cartridge [94], when inserted into a hand-wound spring-powered injector (Mini-Imojet<sup>®</sup>) [94], gave promising results in pediatric and adult clinical vaccine trials in both industrialized and developing countries [94].

A yet-to-be licensed needle-free jet injector that is highly promising, particularly from the purview of logistical practicality and ergonomics, is LectraJet HS<sup>®</sup> (Figure 2). This high-speed jet injection system has been designed as a "kit,"

**Figure 1** Biojector 2000<sup>®</sup>, a high-pressure, gas-driven, needle-free jet injector licensed by the FDA for the intramuscular or subcutaneous administration of vaccines. By attaching this device to a large tank of CO<sub>2</sub>, it can be adapted for use in high-workload situations.

**Figure 2** LectraJet HS®, a promising (but as yet unlicensed) high-workload, ergonomic jet injection system with disposable, single-use vaccine cartridges (shown in a multiple-cartridge magazine). (Published with permission of the manufacturer, DCI, Inc.)

containing everything needed for a large-scale, high-workload scenario. The system uses an individual auto-disable cartridge for each patient that is filled on-site. To maximize speed during high workload situations, the prefilled cartridge is extracted from a "magazine," the injection is administered, the used cartridge is discarded into a trash receptacle with the push of a button, and the injector is then ready to rearm with another cartridge from the magazine. The LectraJet HS® is electrically powered via rechargeable batteries or via an electrical outlet. For use in developing countries, where electrical power may not be reliable, manual power is also available. Notably, in addition to their usefulness in delivering a variety of protein and polysaccharides subunit vaccines, polysaccharide-protein conjugates, combination vaccines, and live attenuated viral vaccines, needle-free devices have also successfully delivered DNA vaccines in clinical trials [95].

#### IV. SUMMARY COMMENT

Advances in mucosal immunization, improved needle-free injection devices, and the rapidly developing field of transcutaneous immunization all engender optimism that vaccines will be increasingly administered without the need for needles. Because each of these strategies has its own particular advantages, it is likely that all three will be needed to realize the ultimate vision when all immunizations in all age groups will be administered without needles.

## Transcutaneous Immunization

**Gregory M. Glenn and Richard T. Kenney**

*IOMAI Corporation, Gaithersburg, Maryland, U.S.A.*

### I. INTRODUCTION

Transcutaneous immunization (TCI) and skin immune system targeting techniques are new vaccine delivery methods poised to have a major impact on approaches to immunization. Previously, the skin was seen as an impervious barrier for large molecules such as antigens and as an obstacle for vaccine delivery. Recently, our work and those of others have shown that the skin, most especially the epidermis, is an accessible and competent immune environment that is suitable for vaccine delivery. This led to a host of recent work that has focused on antigen delivery into the skin using a patch or similar means, and the establishment of a new vaccine delivery paradigm.

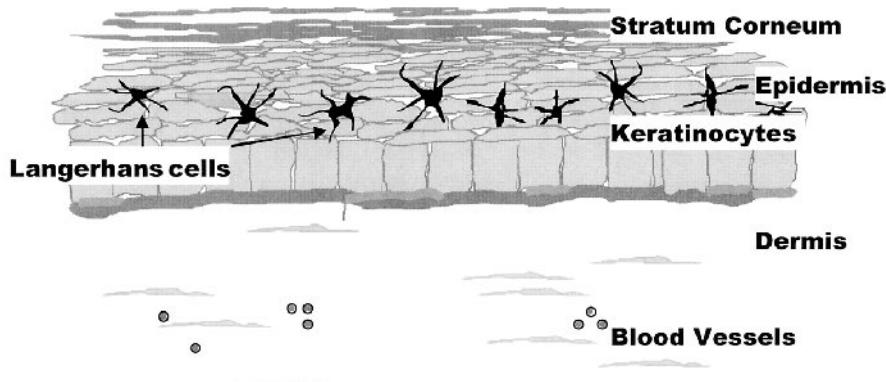

There are several compelling reasons to consider the skin as an important site for vaccine delivery. First, the skin contains a readily accessible and dense population of highly efficient antigen-presenting cells (APCs), which are an attractive target for vaccine delivery. Second, the newest and most promising vaccine developments encompass a variety of strategies for immunostimulation that enhance and focus the immune response to specific antigens. However, the advantages of immunostimulation are inevitably accompanied by acute safety risks associated with systemic adverse reactions to the immunostimulating compounds. Delivery of very potent immunostimulating compounds to the skin holds great promise for avoiding this complication. Thus, we suggest that the primary reason for considering the skin as a target for vaccine delivery is the potential for safe and potent immunostimulation. However, there are also practical aspects to patch-based skin delivery strategies that make this approach attractive. The Centers for Disease Control and Prevention, the World Health Organization, and the Global Alliance for Vaccines and Immunization have rated needle-free delivery as a priority for new development in vaccine delivery due to the risk of needle-born transmission of disease and hopes for increased compliance [1,2]. The simplicity of skin delivery strategies would improve access to and compliance with vaccination globally. In the developing world, needle-free administration of vaccines across the skin

would diminish the inadvertent transmission of infection (hepatitis B, hepatitis C, and human immunodeficiency virus) by reused, improperly sterilized needles and syringes.

In this chapter, we describe the scientific rationale for TCI as a strategy that counters some long-held notions regarding skin penetration and immune responses in the skin. We also briefly review the interactions between Langerhans cell (LC) biology and both adjuvants and microbes delivered into the skin. We then focus on the growing body of data showing that transcutaneous immunization results in relevant and robust immune responses. Finally, we discuss the near-term goals and development hurdles faced by skin immune system targeting strategies.

### II. BARRIERS AND TARGETS FOR TRANSCUTANEOUS IMMUNIZATION

Transcutaneous immunization is a vaccine delivery technique that focuses on delivery of vaccine components through the stratum corneum (SC) into the skin. The stratum corneum, the outer protective layer of the epidermis, is composed principally of quiescent, keratin-filled epidermal cells encased in a mortar of surrounding lipids that are secreted by maturing keratinocytes (Figure 1). The stratum corneum is widely accepted as the principal barrier to penetration [3]. The living epidermis that underlies the SC is composed primarily (95%) of epidermal keratinocytes, but also includes a significant population (3–5%) of immune surveillance cells [4] called Langerhans cells (Figure 1). In fact, 25% of the total skin surface area in humans is undergirded by Langerhans cells, which are evenly distributed among the viable keratinocytes [5]. Langerhans cells thus form an extensive, highly superficial network barrier of immune cells at the very surface of the skin. The considerable dedication of biological resources committed to immune surveillance in the superficial layers of the skin indicates that the SC is often penetrated by microbes, and suggests that it could be penetrated for purposes of immunization. The fact that TCI has been used in mice, rabbits, guinea pigs, cats,

**Figure 1** Langerhans cells are found in the epidermis among epidermal keratinocytes and represent highly superficial immune surveillance cells.

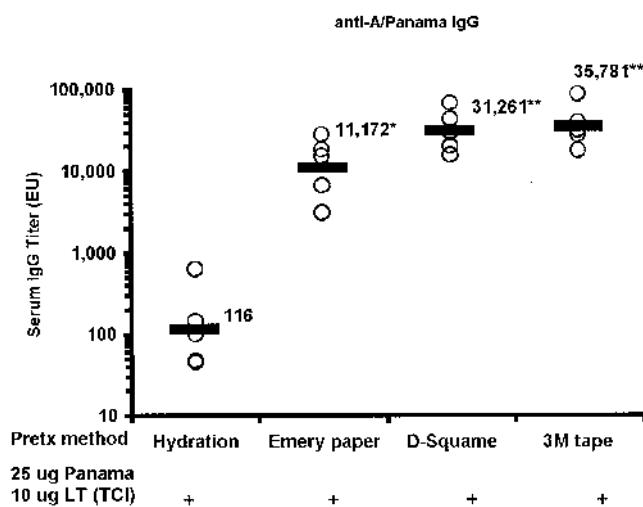

dogs, cattle, sheep, and humans has validated this premise [6–8].

Several strategies have emerged for the penetration of the SC. Occlusion, wetting of the skin, and other techniques lead to hydration of the SC. Hydration of the SC results in swelling of the keratinocytes, pooling of fluid in the intercellular spaces, and dramatic microscopic changes in the SC structure [9]; yet, remarkably, these changes have no lasting effect once the skin is allowed to dry. Hydrated SC clearly allows antigens to pass through the skin, although the transit pathways utilized by antigens to traverse the stratum corneum are unknown at this time. Transdermal drug delivery of polar drugs is thought to occur through aqueous intercellular channels formed between the keratinocytes, and it is reasonable to presume similar pathways for antigen delivery [9]. It has been important to conceptually differentiate TCI—the delivery of antigens (which are relatively large molecules) through the SC to the epidermal immune cells—from transdermal drug delivery. The latter generally delivers relatively small molecules through the epidermis and basement membrane, then into the dermis to blood vessels where the drug is adsorbed and carried to distant sites. The importance of this distinction in terminology is illustrated by the widely held maxim that only molecules < 500–1000 Da could penetrate the skin [3,10, 11]. Although this may be true for transdermal delivery of drugs, which have a tortuous and long pathway through the skin, we have definitively shown that very large antigens can be delivered into the skin using TCI [7,12,13]. Because the SC is the limiting barrier for penetration by both transcutaneous and transdermal techniques, the techniques and materials utilized (patches, formulations, and packaging) have provided a wealth of practical strategies for vaccine delivery to the skin.

The SC is breached by hair follicles and sweat ducts. These appendages are thought to play only a minor role in transdermal drug delivery [3]. Despite some evidence in mice that TCI using DNA may utilize hair follicles as a pathway for skin penetration [14], hair follicles and sweat glands are unlikely to be a significant pathway for vaccine and adjuvant delivery to skin dendritic cells [15–17]. This is supported by

the observation that outbred CD1 mice with normal hair follicle development and hairless SKH mice with sparse vestigial follicles respond equally well to topical immunization with tetanus toxoid (TTx) adjuvanted with heat-labile enterotoxin from *Escherichia coli* (LT). CD1 mice develop high-titer (ELISA units, EU = 652,000) serum IgG to tetanus that is not significantly different from the immune response elicited by hairless SKH mice (EU = 941,000) [17a].

A more likely pathway for vaccine delivery is by passive diffusion of vaccine and adjuvant from the skin surface into the most superficial cell layers in the epidermis. Simultaneous loading of antigen and GM1 receptor-mediated binding of LT by LCs is a more direct and efficient way to deliver vaccines and antigens into the skin. Although the most significant barrier to topical immunization is the SC, it is a fragile barrier that can be easily disrupted, allowing antigens to more readily diffuse to the target cell population. This concept is demonstrated when split virus influenza vaccine (A/Panama) adjuvanted with LT is applied to intact skin that has been pretreated to disrupt the SC. As illustrated in Figure 2, shaved intact mouse skin was hydrated with saline, or the skin was pretreated with emery paper (10 strokes) to disrupt the SC, or the SC was disrupted with D-Squame tape (10×) or 3M™ tape (10×). Immediately following the pretreatment, a solution containing 25 µg of A/Panama and 10 µg of LT was applied to the pretreated skin for 1 hr and rinsed to remove excess vaccine. After three immunizations every other week, serum was collected and evaluated for antibody titers to A/Panama. As illustrated in Figure 2, the serum antibody response to topical immunization was increased 10-fold to 300-fold by disrupting the SC immediately prior to topical application of the influenza vaccine with the LT adjuvant. The magnitude of the immune response is highly dependent upon codelivery of LT with the antigen, which provides the essential second signal necessary for the activation and mobilization of antigen-loaded LCs. Disruption of the SC as described is not normally accompanied by clinically apparent local reactions. The combination of hydration and SC disruption, using a swab or similar simple step, may improve the efficiency and therefore enhance the immune responses to

**Figure 2** Improved topical delivery of influenza split virus vaccine by disruption of the stratum corneum. C57BL/6 mice were shaved on the dorsal caudal surface 2 days prior to topical immunization. Exposed skin was hydrated by gently rubbing (20 strokes) with a saline-saturated gauze sponge. The SC was disrupted by mild abrasion with emery paper (10 soft strokes) or tape stripping with D-Squame (10 $\times$ ) or 3M tape (10 $\times$ ). A solution consisting of 25  $\mu$ g of A/Panama and 10  $\mu$ g of LT was applied to the pretreated skin for 1 hr and then washed off with warm water. Groups were immunized three times (days 0, 14, and 28) and serum was collected 2 weeks after the third immunization on day 42. Serum antibody titers to A/Panama were determined by enzyme-linked immunosorbent assay (ELISA), and titers were reported as ELISA units, the serum dilution equal to 1 OD unit at 405 nm. The geometrical mean titer for each group is indicated. Serum elicited by hydration pretreatment was compared to antibody titers elicited by skin pretreatment with emery paper or tape stripping. \* $P=0.012$ ; \*\* $P\leq 0.006$ .

antigens delivered by this method, while continuing to be well tolerated and practical.

### III. ADJUVANTS AND TRANSCUTANEOUS IMMUNIZATION

Adjuvants are used to augment the immune response to vaccine antigens as well as to direct the qualitative response, and are amply discussed elsewhere [18]. The induction of robust immune responses following TCI is dependent on the presence of an adjuvant in the formulation [6,12,19,20]. The use of adjuvants targeting potent APCs opens a host of possibilities for manipulation of the immune response and for enhancement of efficacy through augmentation of the immune response.

The greatest experience using adjuvants for TCI has been with the bacterial ADP-ribosylating exotoxins (bAREs), which include cholera toxin (CT), LT [21–25], and their mutants [18,20,26]. Bacterial ADP-ribosylating exotoxins have had extensive use as adjuvants via intranasal and oral routes and have generated data that can be applied

to their use on the skin. Transcutaneous immunization is similar to intranasal or oral immunization, as the simple admixture of CT or LT with a coadministered antigen such as TTx or influenza hemagglutinin results in markedly higher antibody levels compared to the administration of antigens alone, which can themselves elicit immune responses [6,12,20]. Similarly, bAREs administered either intranasally or by TCI can induce cellular immune responses to coadministered antigens mediated by CD4 $^{+}$  or CD8 $^{+}$  T-cells [16,27–29].

Among the bAREs, there are several adjuvant choices for TCI. Native CT and LT cause diarrhea when mixed in buffer solution and ingested by fasting subjects [23,30]. Accordingly, mutant toxins that have adjuvant activity similar to the native toxins but are much less prone to induce gastrointestinal side effects have been engineered should a skin patch containing the adjuvant be inadvertently ingested [26,29]. However, these side effects are of little relevance to TCI. Purified cholera toxin B-subunit (pCTB), which harbors trace amounts of holotoxin, is also a potent adjuvant on the skin in contrast to recombinant CTB (rCTB), which is far less potent but readily induces anti-CTB antibodies [20]. Other adjuvants, including bacterial DNA, cytokines, and LPS, have been shown to act as adjuvants, but their comparative potency on the skin needs to be evaluated [20]. However, the data suggest that a wide variety of adjuvants function in the context of the skin.

### IV. LANGERHANS CELLS AND TRANSCUTANEOUS IMMUNIZATION

Langerhans cells are thought to be the principal target in TCI. They are bone marrow-derived APCs that migrate to and reside in the epidermis, where they sample antigens and migrate out of the skin in low numbers to the draining lymph nodes. Langerhans cells are known to increase their rate of migration out of the skin in response to activating stimuli such as infectious agents, adjuvants, contact sensitizers, and cytokines, and to travel to the lymph node where antigen presentation to T cells occurs [4]. In immune pathologies, such as topically induced delayed-type hypersensitivity (DTH), sensitized T cells generated from previous antigen exposure migrate back to a site where antigen is present in the skin and produce local inflammation [31], but this afferent arm of DTH is not a necessary or typical component of TCI. This is best illustrated in human immunization studies using multiple applications of LT that can induce robust boostable immune responses in the absence of clinical or histological evidence of DTH [7], and have been confirmed in other laboratories [32,33].

The role of LCs in TCI is not fully characterized at this time, but there are accumulating data that clearly implicate the LC as the principal target. Intradermal administration of adjuvants, including bacterial DNA (CPGs as well as *E. coli* DNA), LPS, or TNF $\alpha$  as LC activators [4,34,35], induces classical markers of LC activation by FACS analysis of LCs in epidermal digests, including upregulation of MHC class II and the costimulatory molecule CD86, and downregulation of E-cadherin (mediates LC adhesion to

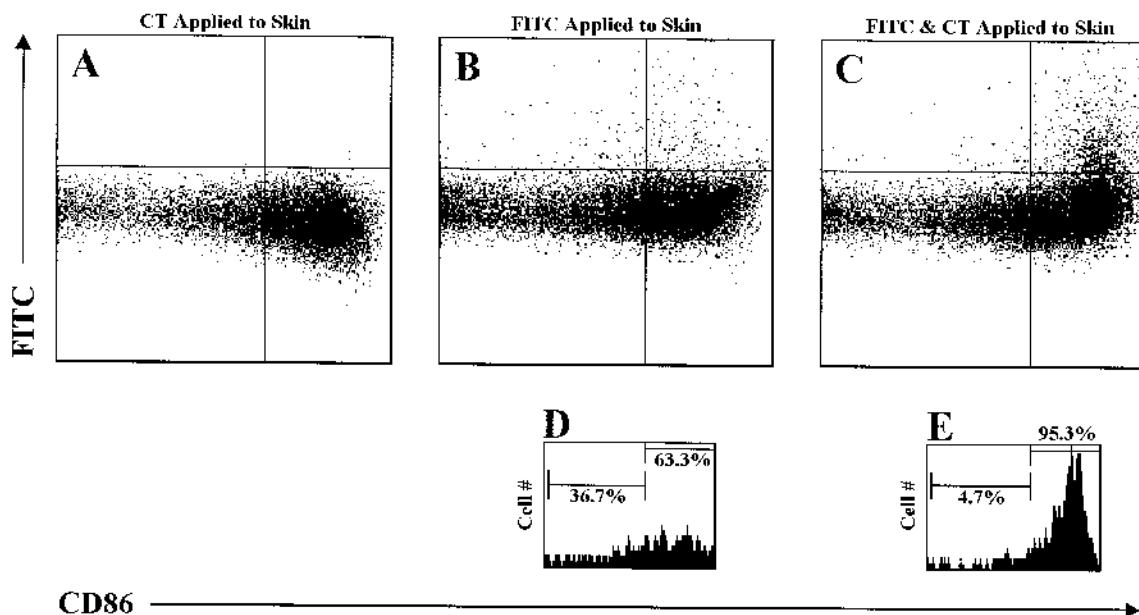

keratinocytes). Morphological changes and depletion of LCs from the epidermis in response to topical application of contact sensitizers, intradermally delivered LPS and cytokines [36], or viruses [37,38] are readily observed in stained epidermal sheets. After topical application of CT, LCs from epidermal sheet digests analyzed by flow cytometry similarly demonstrate upregulation of MHC class II and CD86, and downregulation of E-cadherin, in conjunction with morphological changes in LCs in epidermal sheets fluorescently stained for MHC class II [39]. When LT is placed on the skin, increased numbers of activated CD11c<sup>+</sup> cells are found in the draining lymph node, and both labeled adjuvant and antigen are seen in association with these cells after TCI, suggesting that these dendritic cells are loaded with adjuvant and antigen by TCI techniques [40]. Investigators using live inactivated herpes virus with CT delivered by TCI-stimulated potent T-cell response protected mice against challenge [32], and this was accompanied by increased numbers of LCs migrating out of the skin into the draining lymph nodes. In a cutaneous viral infection model using West Nile or Semliki Forest virus delivered intradermally by injection [41], increases in the number of activated murine LCs in the draining lymph node (MHC class II<sup>+</sup>/NLDC145<sup>+</sup>/E-cadherin<sup>+</sup>) and concomitant depletion of epidermal LCs in the skin were noted. When these viruses were inactivated by exposure to ultraviolet irradiation, the LC migration and depletion were abrogated, suggesting that the viral replication had LC-activating effects. Similarly,

increased numbers of fluorescein isothiocyanate (FITC)-loaded dendritic cells have been detected in the draining lymph node after topical application of adjuvant (Figure 3). These cells also show upregulation of CD86 in response to LT (Panel C), suggesting that their maturation has been prompted by the addition of adjuvants. In total, these data suggest that LCs are the primary target cells for TCI.

## V. IMMUNE RESPONSES TO TRANSCUTANEOUS IMMUNIZATION

Transcutaneous immunization represents a fundamental insight for vaccine delivery. Beginning with the observation that CT could be used as an adjuvant for topical immunization with toxoid antigens [6], we have shown that a wide variety of adjuvants and antigens can be used to induce robust systemic and mucosal immunity via this topical immunization technique [8,20,42]. Although the mechanisms by which adjuvants exert their effects are under investigation [21,43–45], their enhancing effects are well described [24], and the wealth of data in this field has been directly applicable to TCI. We have primarily focused on CT, LT, and their derivatives, given their potency and the breadth of available information on these adjuvants [21,44,46].

Because TCI represents a departure from other routes of immunization, it was important to test whether TCI could

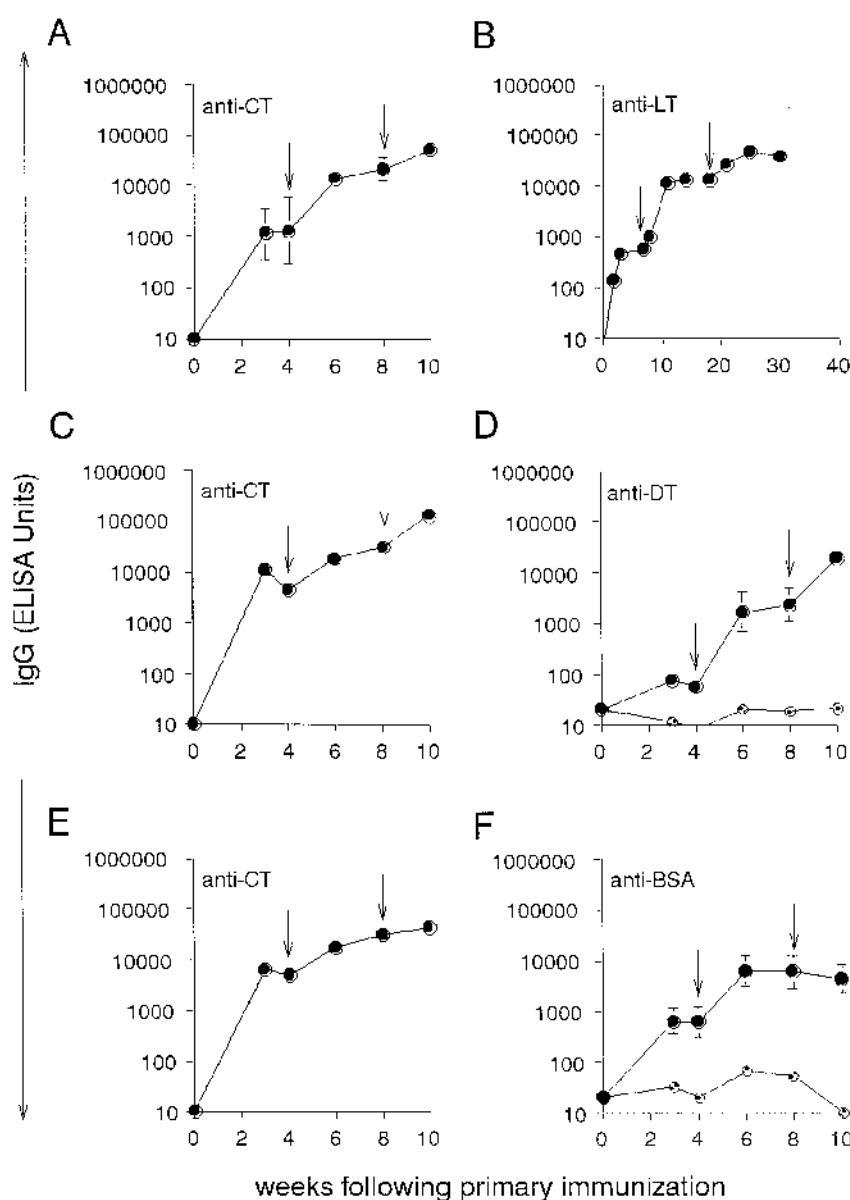

**Figure 3** Upregulation of CD86 on dendritic cells isolated from draining lymph nodes after topical application of cholera toxin and fluorescein isothiocyanate. C57BL/6 mice ( $n=5$ ) were transcutaneously immunized on the lower back with CT (A), FITC (B and D), or FITC coadministered with CT for 1 hr (C and E). Twenty hours after immunization, the draining (inguinal) lymph nodes were excised, and single cell suspensions of the lymph nodes were produced, stained for CD86 and I-A<sup>b</sup>, or CD86 and CD11c, and analyzed by flow cytometry. Dot plots in panels (A)–(C) were gated on large, MHC class II<sup>High</sup> cells. Similar results were obtained by gating on large CD11c<sup>+</sup> cells. Histograms in panels (D) and (E) were gated on FITC<sup>+</sup> cells in panels (B) and (C), respectively, and display the percentages of CD86<sup>High</sup> and CD86<sup>Low</sup> populations. Similar CD86 populations were observed by gating on large CD11c<sup>High</sup> FITC<sup>+</sup> cells. (From Crit Rev Ther Drug Carrier Syst 2001;18(5):503–525.)

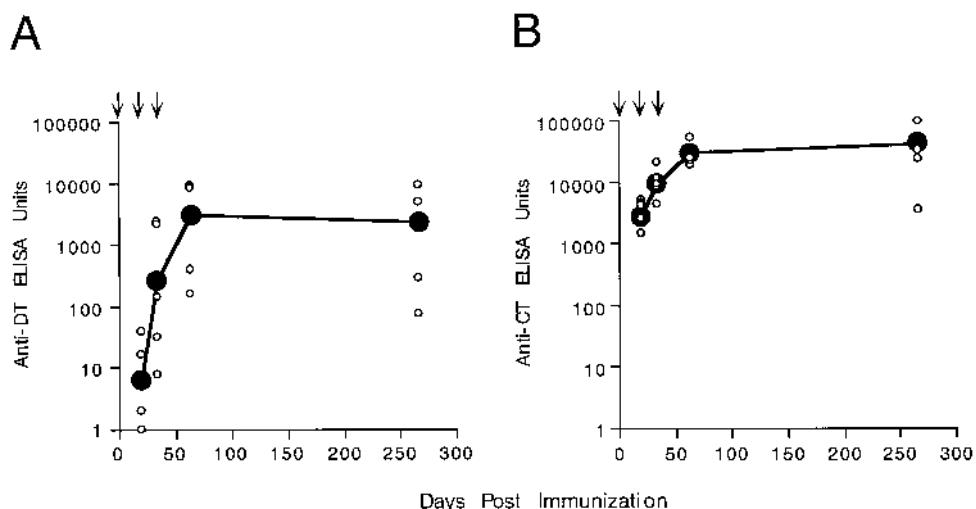

result in classical immune responses such as those induced by other routes of immunization. The use of adjuvant on the skin results in both primary and secondary serum antibody responses to coadministered antigens when boosting is conducted using CT or LT as adjuvants [42] (Figure 4). Mice immunized with CT or LT alone and subsequently boosted demonstrate a typical secondary antibody response to the toxins. Serial repeated immunization with the same adjuvant and different antigens may readily be achieved despite the presence of high-titer antibodies to the adjuvant (Figure 4)

[42]. Additionally, TCI appears to induce boostable, long-lasting immune responses. As shown in Figure 5, mice immunized with diphtheria toxoid (DT) and CT had little decline in their immune responses over 9 months.

The memory responses seen after boosting immunizations using TCI suggest that T-cell responses are induced [27]. This is evident using a variety of adjuvants. Mice were immunized with TTx and one of the following adjuvants: CT, rCTB, pCTB (which contains trace holotoxin activity), LT, and a mutant of LT known as LTR192G, which has

**Figure 4** Kinetics of the IgG (H + L) antibody response to CT (A, C, E), LT (B), DT (D), or BSA (F) in animals immunized and boosted (arrows) by the transcutaneous route. BALB/c mice ( $n=5$ ) were immunized with (A) CT alone (100 µg), (B) LT alone (100 µg), (C and D) CT + DT (100 µg of CT, 100 µg of DT), and (D) DT alone (100 µg of DT). Gray circles in (D) indicate antibody levels to DT in mice vaccinated without using CT as adjuvant. Antibodies were measured by ELISA at multiple time points. The results are reported as the mean $\pm$ SEM. Similar results were obtained in two independent experiments. (From Crit Rev Ther Drug Carrier Syst 2001;18(5):503–525.)

**Figure 5** Serum IgG antibody responses to DT and CT. C57BL/6 ( $n=5$ ) mice were immunized three times with DT and CT at 0, 3, and 6 weeks (arrows). equivalent adjuvant capabilities as native LT but has decreased potential for causing diarrhea on ingestion [47]. The antibody responses to TTx were similar for all adjuvants except rCTB, which lacks the ribosyl transferase activity associated with the A subunit [20]. T-cell proliferative responses in spleen and lymph node preparations from mice revealed the induction of tetanus-specific immunity, as well as mixed but predominantly Th2 cytokine profiles, as

assessed by matching the relatively higher serum anti-TTx IgG1 compared to IgG2a [27]. In a separate experiment, we also examined whether priming by the intramuscular route with TTx and alum, which was known to induce T-cell memory, could be followed by a booster immunization on the skin to induce secondary responses [27]. As shown in Table 1, intramuscularly primed animals respond vigorously to topical boosting, producing high levels of anti-TTx anti-

bodies. Taken together, these studies demonstrated that TCI and classical routes of immunization such as injection induce T-cell responses, which underlie the robust immune responses that follow boosting and are necessary for immunoprotection.

The role of the adjuvant appears to be critical to the induction of high levels of antibodies to a coadministered antigen. Transcutaneous immunization, with increasing doses of LT as adjuvant and different doses of TTx as antigen, produced robust levels of anti-TTx antibodies that are clearly dependent on the presence of adjuvant [20] (Figure 6). The same animals were fully protected against systemic tetanus challenge, and only animals receiving adjuvant with the antigen were fully protected [20]. Others have shown that anti-diphtheria toxin antibodies generated by TCI in the presence of adjuvant neutralize the highly potent diphtheria toxin [15]. Thus, the use of adjuvants greatly amplifies the immune response to antigen on the skin, and the use of adjuvant patches and clinically accepted skin preparation techniques has allowed the effective immu-

nization of mice with adjuvant/antigen doses at 0.5/5 µg, respectively. These and other studies have shown that the antibodies induced by TCI in the presence of adjuvant are robust [20], functional [13], and can lead to protection in disease settings [17,20,32].

## VI. MUCOSAL RESPONSES TO TRANSCUTANEOUS IMMUNIZATION

Topical immunization with LT and CT as adjuvants clearly induces both IgG and IgA antibodies in mucosal secretions of mice [48,49]. We have postulated that the skin immune system may be an extension of the mucosal immune system. The mucosa and skin share similar elements, including LCs and secretory organs, and the presence of IgA such as that found in the sweat glands [50,51]. Furthermore, microorganisms found on the skin demonstrate coating with immunoglobulins, including IgA and the secretory component of IgA [52,53]. Thus, the skin immune system has immunological

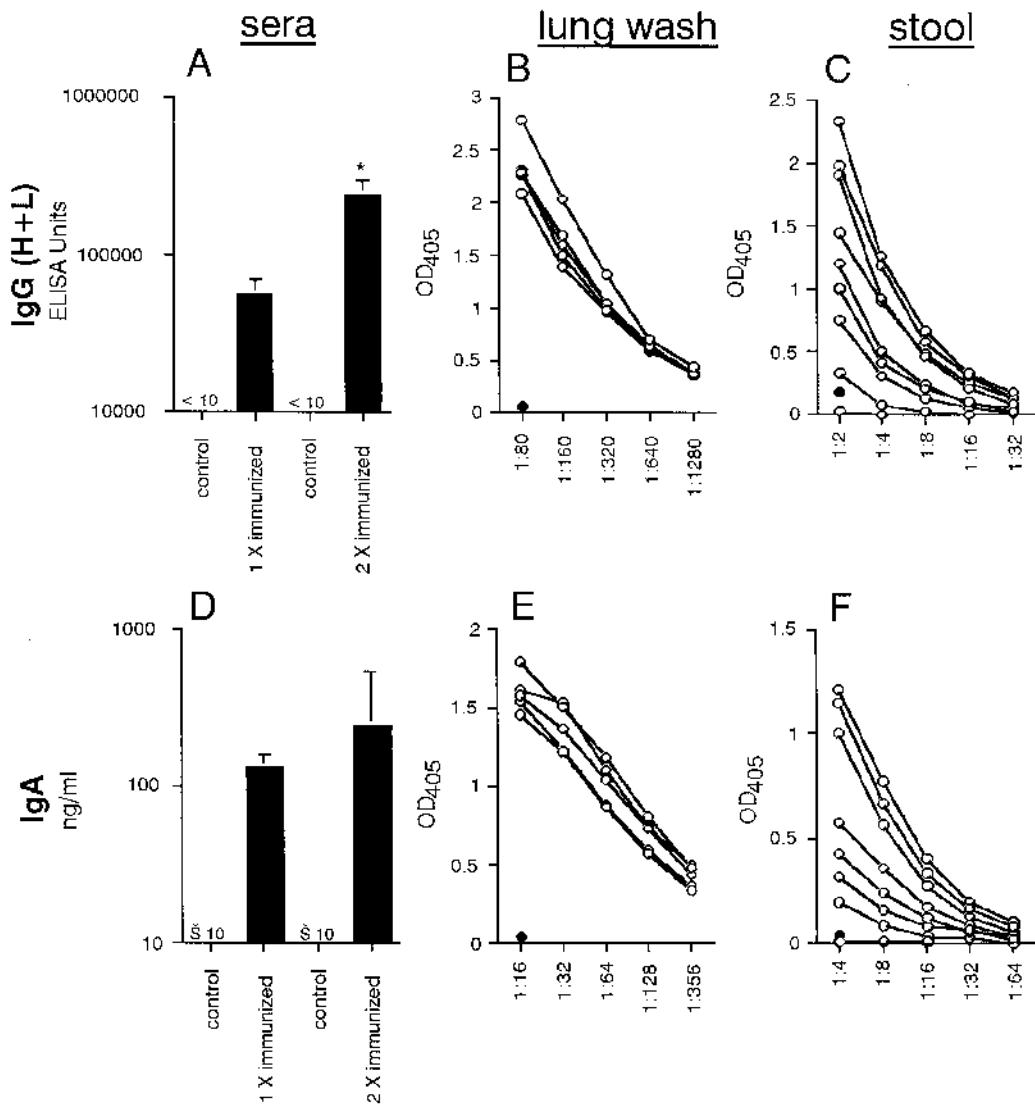

**Figure 6** Anti-TTx response in mice immunized with varying doses of antigen and adjuvant. C57BL/6 mice ( $n=5$ ) were immunized on the skin with LT (doses indicated above each panel) and TTx (doses indicated on the x-axis) at 0, 4 and 7 weeks. The intramuscular group was immunized with alum and TTx (5 µg) doses at 0, 4, and 8 weeks. Serum collected 2 weeks after final immunization was assayed for TTx-specific IgG by ELISA. The geometrical mean (bar) and individual values (open circles) are shown for each group. (From Infect Immun 2000; 68(9):5306–5313.)

responses to microbes that are mucosal-like, suggesting that the skin and the mucosal immune system may be related.

The topical application of bAREs, such as LT, CT, and coadministered antigens, induces antibodies that can be detected at the mucosa [20,32,48], as well as mucosal cellular responses [33]. Mice immunized transcutaneously with CT produce anti-CT IgG and IgA antibodies in the stool and pulmonary secretions (Figure 7) that are toxin-neutralizing [48]. IgG antibodies to the coadministered antigen have been

detected in the mucosa in several settings [20,32,42], and IgA antibodies to tetanus and herpes antigens have been detected in mice immunized topically with CT and TTx or inactivated herpes virus [32,33]. The detection of antibodies in the stool and lung wash of immunized mice suggests that antibody-secreting cells have homed to the mucosa; it has been shown that anti-TTx antibody secreting cell (ASCs) can be detected in the vaginal mucosa of mice immunized topically using CT and TTx [33], but migration of LCs to the gut may also

**Figure 7** Sera (A and D), mucosal lung (B and E), and stool (C and F) antibody responses to CT after TCI. In panels (A) and (D), C57BL/6 mice were immunized transcutaneously at 0, or at 0 and 3 weeks with 100 µg of CT. Data shown are the geometrical mean  $\pm$  SEM for ELISA measurements from five individual animals. \*A statistically significant ( $p < 0.05$ ) difference between the titers measured in the 1× and 2× immunization groups. In panels (B) and (E), C57BL/6 mice were immunized transcutaneously at 0 week; lung washes were collected at 3 weeks. IgG and IgA levels were assessed by ELISA; the titers (OD = 405 nm) from individual animals are shown. In panels (C) and (F), C57BL/6 mice were immunized transcutaneously at 0 week, and single stool pellets were collected immediately after defecation at 6 weeks. IgG and IgA levels were assessed in fecal homogenates by ELISA; the dilution curves from eight (F) or nine (C) individual animals are shown. (●) Indicates the maximal level of anti-CT IgG or anti-CT IgA Ab detected in control lung washes from mice immunized with an irrelevant protein (B and E) or in 1/2 dilutions of stool from unimmunized mice (C and F). (From Crit Rev Ther Drug Carrier Syst 2001;18(5):503–525.)

explain these findings [49]. Alternatively, antibodies may represent transudates into the mucosal secretions, although recent data have shown that anti-LT antibodies detected in the stool and lung wash contain the secretory component of IgA, indicating that local antibody production occurs [13]. Plasmid DNA immunization delivered by TCI similarly induced both serum IgG and fecal IgA against the M protein encoded in the plasmid, and elicited a protective immune response on influenza virus challenges [17]. Anti-LT IgG and IgA antibodies were found in humans immunized topically with LT, which is consistent with the repeated observations in mice [7]. The presence of antibodies in the secretions of animals immunized by TCI raises many mechanistic questions, but the data suggest that induction of mucosal and systemic responses by TCI may be used to enhance vaccine efficacy.

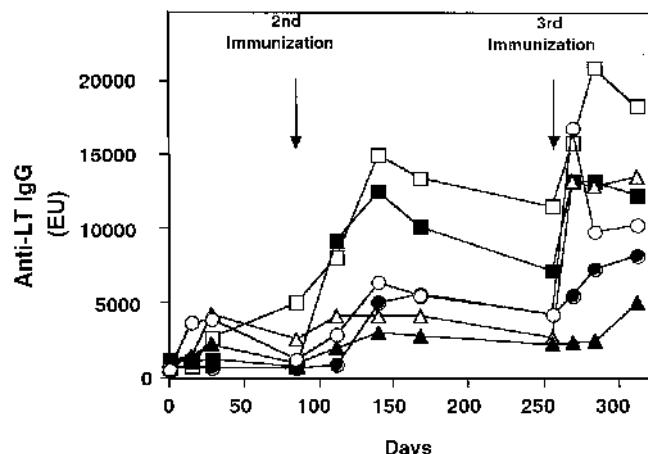

## VII. HUMAN STUDIES

There are a number of potential targets for the creation of new vaccines delivered via the skin. The goals at this early stage of human studies have been to demonstrate the safety and clinical utility of TCI with various antigens, to begin to optimize their delivery by studying skin preparations and patch types, and to assess the immune responses induced.

The initial clinical study used LT alone, capitalizing on its ability to act both as an antigen and an adjuvant, in a dose-escalation format to assess the safety and immune response to simple liquid application of LT to unprepared skin [7]. Eighteen healthy volunteers received 25, 50, 250, or 500 µg of an LT solution that was added to a simple gauze pad under an adhesive patch and applied to the upper arm, without skin pretreatment, for 6 hr, with a boost at 12 weeks. Six in the 500-µg LT group returned for a third immunization 35 weeks after the first immunization. No serious vaccine-related adverse reactions were observed, either systemically or locally (at the site of immunization). Histological sections of biopsies taken at the dosing sites were normal, consistent with the absence of DTH clinically. Langerhans cells visualized in the same biopsy using anti-CD1a staining consistently demonstrated enlarged or rounded LC cell bodies at the site of immunization at 24 and 48 hr compared to the control biopsies from the opposite arm, similar to the chronically activated LCs seen in sections of the tonsilar crypts in the mouth [54] and in sections from mice topically exposed to CT [39].

Both systemic and mucosal immune responses to LT were achieved using TCI. All subjects in the high-dose group produced a greater than fourfold rise in serum antibodies against LT, with clear boosting responses (Figure 8), along with IgG or IgA antibodies against LT in either the urine or stool. This group had a 14.6- and 7.2-mean fold rise in serum anti-LT IgG and IgA, respectively, at 44 weeks. Antibodies against LT were durable and persisted long after the second immunization, with a clear booster response after the second and third doses. There were minimal responses in other dosing groups.

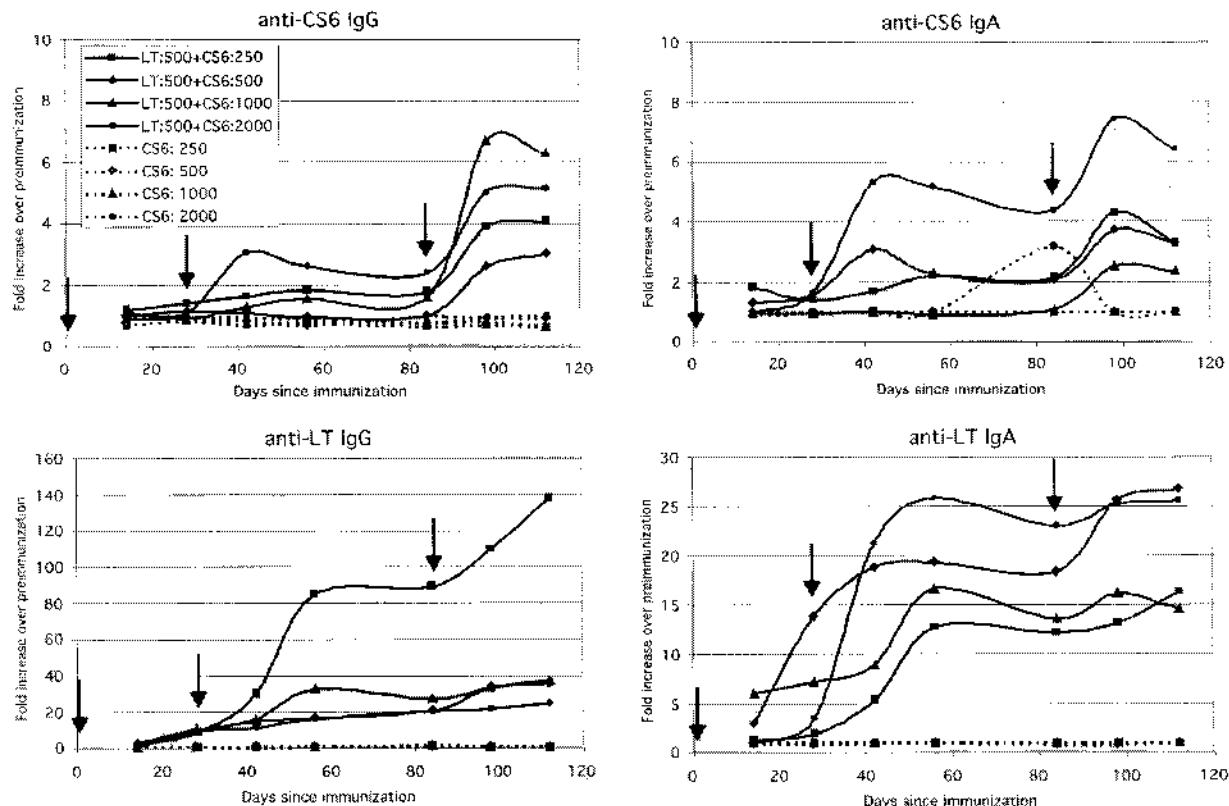

The importance of the role of the adjuvant in the induction of immune responses to a coadministered antigen

**Figure 8** Individual human serum IgG antibody responses to LT. Six volunteers were immunized using a patch containing 500 µg of LT placed on the upper arm for 6 hr at 0, 12, and 35 weeks. Individual anti-LT IgG antibodies are shown over the time course of the trial and reported as ELISA units, the inverse dilution at which the sera yield an optical density of 1.0. (From Crit Rev Ther Drug Carrier Syst 2001;18(5):503–525.)

was initially tested in the context of *E. coli*-related traveler's diarrhea using the colonization factor CS6, a multisubunit intestinal epithelial cell-binding protein [55]. Normal adult volunteers were enrolled in a dose-escalating study of 250, 500, 1000, or 2000 µg of CS6 alone or with 500 µg of LT dosed at 0, 1, and 3 months [12]. Fourteen of 19 volunteers (74%) in the combined groups had mild DTH skin reactions with the second or third dose. No other adverse events correlated with vaccine administration. As shown in Figure 8, volunteers receiving LT as adjuvant produced serum anti-CS6 IgG and IgA. The response to LT was very robust in comparison to the previous trial (above), and may be explained by the use of simple skin preparation steps before application of the patch. Overall, when CS6 was given with LT, 68% and 53% had anti-CS6 IgG and IgA, respectively, and 100% and 90% had anti-LT IgG and IgA, respectively. This anti-CS6 response compares favorably to that observed when volunteers were experimentally challenged with CS6-expressing ETEC strain B7A, whereupon 35% and 31% of the subjects developed anti-CS6 IgG and IgA, respectively [56,57]. The anti-LT response that occurs when LT serves as the adjuvant in TCI would likely contribute further to protection against LT toxin-induced diarrheal disease [58]. Antibody-secreting cells were also measured in the peripheral blood. In the combined-dose TCI groups, 37% and 42% developed anti-CS6 IgG and IgA ASCs, respectively, compared to 50% that developed anti-CS6 IgA ASCs following challenge, historically [57]. There were no immune responses seen in the CS6 alone groups.

The vaccination provided prolonged immunity, and a booster effect to both LT and CS6 was seen once again (Figure 9). The two highest-dose groups had the strongest anti-CS6 IgG response. There was a marked IgG response to

**Figure 9** Human serum IgG and IgA responses to coadministered CS6 and LT. Normal adult volunteers were enrolled in a dose-escalating study of 250, 500, 1000, or 2000  $\mu\text{g}$  of CS6 alone or with 500  $\mu\text{g}$  of LT dosed at 0, 1, and 3 months (arrows). The mean serological response for each group is shown over the time course of the trial and reported as fold increase of ELISA units over baseline.

LT, particularly in the lowest-dose CS6 group. This may indicate some degree of competition for antigen presentation, such that more APCs were available for the LT to act as an antigen when the ratio of CS6/ to LT was lower. The lack of response to CS6 without LT and clear responses in the presence of LT confirmed the universal finding in animal studies that the adjuvant plays a critical role in TCI. Favorable induction of an immune response in comparison with the one seen after a live challenge suggests that the vaccination may provide a similar degree of protection.

Finally, optimization of TCI requires evaluation of new strategies in the human setting. Preclinical studies suggested that the dose of LT could be dramatically reduced with retention of immunogenicity by altering the SC. The effect of mild disruption of the SC on the delivery of LT was explored with commercially available medical products, including abrasive pads used to enhance EKG signal conductivity, or adhesive tapes used to evaluate skin hydration [17a]. We compared the immunogenicity of LT on human skin pretreated with hydration alone in a high-dose (400  $\mu\text{g}$  of LT) group, compared with hydration, mild abrasion, or tape stripping in lower-dose (50  $\mu\text{g}$  of LT) groups of normal volunteers.

SC disruption achieved about a four-times-greater immune response compared to hydration alone. Three weeks after the second dose, there was a significant increase in the

GMT fold rise of LT-specific IgG and IgA in the pretreatment group compared with hydration alone, as well as in the tape-stripping group with IgA. SC disruption and tape stripping consistently achieved a greater than twofold rise in geometrical mean titer for each patient in those groups (100% response rate). The titers were persistent, with no significant decrease in any group at 6 months. These results suggest that this is a safe method of delivering LT, although a self-limited, mild, irritant dermatitis was occasionally observed. Overall, this study demonstrated that with effective skin pretreatment to disrupt the SC, the dose of LT can be decreased by at least a log with no decrease in immunogenicity. Further refinements of the pretreatment methodology should allow a simple approach for use in final commercialization in conjunction with a patch.

## VIII. CONCLUSION

Over the past few decades, clinicians have witnessed the tremendous positive impact of new vaccine products such as the Hib and, more recently, meningococcal C vaccines [59,60], which sprang from a basic observation [61]. Development of the original observation into a deliverable product required a great deal of formulation studies, preclinical testing, and clinical testing. Without underestimating the

effort required to create a vaccine formulation delivered by a patch, certain strategies may compress the development time frame for a TCI-based product. Transdermal patch materials and manufacturing strategies, established vaccine antigens such as tetanus and influenza that are currently licensed, and adjuvants that are commercially manufactured are being utilized to accelerate development. In cooperation with the Food and Drug administration (FDA), we have conducted several Phase I trials, which have demonstrated the safety and immunogenicity of this approach, and product development trials are underway. Additionally, preclinical development has clearly shown that low doses of adjuvant may be optimal, and doses of antigen in the range of doses given parenterally can be effective. Translation of these findings into the clinic will be an important goal. More widespread use of TCI in other laboratories, publication and dissemination of related data and techniques, and adoption of this approach by industry suggest that transcutaneous immunization will move from an investigational observation to a product in the future.

### I. INTRODUCTION

A combination vaccine consists of two or more immunogens which are physically combined and administered at the same time in the same anatomic site. In this chapter, a sign (+) will be used to indicate the vaccines administered simultaneously but at separate anatomic sites, and a virgule (/) will indicate combined vaccines. The administration of multiple antigens in the same syringe eliminates the need for separate injections, which is painful for the child, time-consuming for medical personnel, and economically costly. Although many combination vaccines have been routinely used for decades, more are needed. Pediatric combination vaccines presently licensed or under development are listed in Table 1 [1]. This chapter will consider the negative consequences of multiple injections, potential problems from combining vaccines, regulatory perspectives, existing combination vaccines, and combinations under evaluation.

The following five new parenteral vaccines have been introduced into many routine infant vaccination schedules in the last 15 years: conjugate *Haemophilus influenzae* type b (Hib), conjugate multivalent pneumococcal vaccine, trivalent inactivated poliovirus (IPV), varicella (V), and hepatitis B (HB). Hepatitis A (HA) vaccine is also administered to young children in some areas with high hepatitis A endemicity. A consequence of this successful development and deployment of new pediatric vaccines is that the number of injections a child in the United States, for example, receives in the first 18 months of life has increased from 4 to 20. Consequently, 25% of U.S. parents surveyed felt that their children's immune systems were weakened by too many vaccines [2]. This has led some parents to choose to forego some vaccines or to request extra visits to complete the

immunization series. These developments threaten to diminish the high immunization levels many have worked so hard to achieve.

Combining vaccines into one syringe may result in a combination product with enhanced reactogenicity, or diminished immunogenicity, or efficacy, compared to the separately administered vaccines. There are several mechanisms proposed to explain how one vaccine might interfere with the immunogenicity of another when mixed together. Physical or chemical interaction between components of the vaccines might alter the conformation of the necessary epitope. As an example, studies of the combined inactivated polio vaccine (IPV) and diphtheria toxoid–tetanus toxoid–whole cell pertussis (DTwP) vaccine demonstrated that the preservative thimerosal can destroy the potency of IPV [3]. The pertussis component also lost potency over time, possibly as a result of the destruction of antigen or formulation without merthiolate stabilizer [4,5]. Mixing an adjuvanted vaccine with one that does not contain an adjuvant may result in the displacement of the one vaccine from its adjuvant, resulting in diminished immune response to that component. Interference between components of live viral vaccines has also occurred. One such instance was the reduced seroconversion to the mumps component of the bivalent Urabe Am9/Schwartz mumps–measles vaccine [6]. Viral strain interference is thought to be a consequence of competition for mucosal receptors or lymphocyte binding sites. It is also possible that the immune responses, such as interferon production, stimulated by one vaccine viral strain may interfere with the replication of another virus strain. Therefore, new combinations of vaccine products must be evaluated with the same methods and rigor as if it were a new vaccine.

**Table 1** Pediatric Combination Vaccines Presently Licensed or Under Development<sup>a</sup>

Combination vaccine <sup>b</sup>	Producers or vendors of licensed vaccines		
	Licensed in the United States	Licensed outside the United States	Under development <sup>c</sup>
Td-IPV		AvP-Fr, AvP-Ca, AP MSD	
DT-IPV		AvP-Ca, AP MSD	
DT-HB		AP MSD	
DTP-IPV		AvP-Ca, AvP-Fr, AP MSD	
DTP-Hib	AvP-US, WL	AvP-Ca, AvP-Fr, AP MSD, GSK, WL	
DTP-Hib-IPV		AvP-Ca, AvP-Fr, AP MSD	
DTP-HB		GSK	
DTP-Hib-HB		GSK	
DTaP-IPV		AvP-Ca, AP MSD, NAVA, GSK	
DTaP-Hib	AvP-US <sup>d</sup>	AvP-Fr, GSK	
DTaP-IPV-Hib		AvP-Ca, AP MSD, GSK	
DTaP-HB		GSK	
DTaP-IPV-HB	GSK	GSK	
DTaP-Hib-HB		AP MSD, GSK	Yes
DTaP-Hib-IPV-HB			Yes
DTaP-Hib-IPV-HB-HA			
HB-Hib	Merck	AP MSD	
HB-HA	GSK	GSK	
MMR-V			Yes
PnC-MnC			Yes
PnC-MnC-Hib			Yes

*Abbreviations:* aP, acellular pertussis vaccine; AvP, Aventis Pasteur (formerly Pasteur Mérieux Connaught; Ca, Fr, US, and AP MSD designate, respectively, vaccines sourced from the Canadian, French, and US subsidiaries or the AvP-Merck European joint venture); D, diphtheria toxoid vaccine; HA, hepatitis A vaccine; HB, hepatitis B vaccine; Hib, conjugate *H. influenzae* type b vaccine; IPV, enhanced inactivated trivalent poliovirus vaccine; MMR-V, measles, mumps, rubella, and varicella vaccine; MnC, meningococcal conjugate vaccine; NAVA, North American Vaccine; P, whole-cell pertussis vaccine; PnC, pneumococcal conjugate vaccine; GSK, GlaxoSmithKline; T, tetanus toxoid vaccine; WL, Wyeth Lederle Vaccines and Pediatrics.

<sup>a</sup> Products combining only multiple serotypes of a single pathogen are excluded, as are DT, DTP, DTaP, OPV, IPV, and MMR themselves. Only those manufacturers who distribute their products globally are listed; other manufacturers may produce some products (e.g., DTP-IPV) for local or regional use. Some products represent components derived from, or joint efforts of, more than one manufacturer, in such cases, their principal distributor is shown.

<sup>b</sup> No discrimination is made between products distributed in combined form and those distributed in separate containers, for combination at the time of use.

<sup>c</sup> Indicated vaccines may be under development by more than one company.

<sup>d</sup> Licensed for the fourth (booster) dose only.

*Source:* Ref. 1.

## II. REGULATORY ASPECTS

Each country or region has separate regulatory agencies responsible for licensure or registration of new combination vaccines. The Food and Drug Administration (FDA) of the United States must follow the Code of Federal Regulation (CFR). Two codes directly apply to the approval of combination products. One of these, 21 CFR 300.50, states that a fixed combination prescription drug must demonstrate that each component makes a contribution to the claimed treatment effects, and that the dosage is such that it is safe and effective. It is further stipulated in 21 CFR 601.25(d)(4) that safe and effective active components may be combined if each component makes a contribution to the claimed effects, combining does not decrease purity, potency, safety, or effectiveness of the individual component, and when used correctly, provides preventive therapy or treatment. The

FDA issued in 1997 a “Guidance for industry for the evaluation of combination vaccines for preventable diseases: Product, testing and clinical studies” to assist the industry in the manufacture and testing of combination vaccines.

## III. DESIGN OF COMBINATION VACCINE TRIALS

The safety, immunogenicity ( $\pm$ efficacy) of combination vaccines must be compared to that of the individual components in prospective, randomized, blinded trials. Two general approaches may be used. The fully combined final product (A/B/C/D) may be compared to each of its components (A + B + C + D). A disadvantage of this method is that it requires multiple arms ( $2^n$ ), and the sample sizes are large. It also carries the danger that if there is enhanced reactoge-

nicity or diminished immunogenicity with the combination, it cannot be determined which component(s) was (were) responsible. Therefore the evaluation method most commonly used is to proceed in a stepwise manner. If the ultimate goal is to combine four vaccines (A/B/C/D), the initial study compares bivalent A/B to A+B. If no interference is observed with the bivalent vaccine, the next evaluation will be of A/B/C vs. A/B+C. If that is successful, then a final study comparing A/B/C+D vs. A/B/C/D would be performed.

The optimal study compares the protective efficacy of the components of a combination vaccine to its separately administered components. This may not be possible if the routine use of the single component has dramatically reduced or eliminated the disease under study. A trial that demonstrates efficacy in one country may be used to support licensure in a different country if a bridging study is performed, showing that the immunogenicity of the vaccine component in the second population is similar to that in the original efficacy study. The use of serologic markers of protection is another approach. For example, the presence of neutralizing antibody to polioviruses may be considered proof of immunity to infection. Therefore, if a poliovirus vaccine is combined with another product, one simply must demonstrate that the combination product stimulates neutralizing antibodies to the three poliovirus strains contained in the vaccine. This method is only feasible with diseases for which serologic correlates of protection have been established, such as diphtheria, tetanus, hepatitis B, and, arguably, *H. influenzae* type b (Hib). Unfortunately, immunologic correlates of protection are not recognized (or are not widely accepted) for many pathogens, including *Bordetella pertussis* and *Streptococcus pneumoniae*.

The statistical approach to the evaluation of combination vaccines is to demonstrate the noninferiority (one-sided equivalence) of the components in the combination compared to the components administered separately [7]. Immune response end-points in noninferiority trials are the geometric mean concentration (GMC) and/or the proportion of children achieving a defined level of antibodies. The trial is designed to reject the null hypothesis that the combination is inferior by a predetermined amount. In comparisons of GMCs, the null hypotheses ( $H_0$ ) for each component is  $H_0: \theta = \mu_{\text{combined}}/\mu_{\text{separate}} \leq \theta_0$ . The choice of  $H_0$  is based on what is thought to be a clinically meaningful difference and, by necessity, may sometimes be arbitrary. For evaluation of differences in the proportion of responding vaccinees, the null hypotheses for each component is  $H_0: \delta = P_{\text{combination}} - P_{\text{separate}} \leq -\delta_0$ . Here, again, the value of  $\delta$  is determined by what is judged to be clinically meaningful.

Successfully combined vaccines in widespread use for many years include DTwP, IPV, measles-mumps-rubella (MMR) vaccine, DTwP/*H. influenzae* type b (Hib), Hib/hepatitis B (HB), 23-valent polysaccharide pneumococcal vaccine, quadrivalent polysaccharide meningococcal vaccine, and the trivalent inactivated influenza vaccines. These combination products will not be discussed further in this chapter. Attention will be focused on vaccines that have not been universally accepted by regulatory bodies.

#### A. Diphtheria Toxoid–Tetanus Toxoid–Acellular Pertussis (DTaP) Combined with Inactivated Poliovirus Vaccine, with or Without Hepatitis B

Combining IPV with either DTwP or a DTaP containing two pertussis antigens (aP<sub>2</sub>) has been reported to result in decreased geometric mean titers (GMTs) of antibody to pertussis antigens [8,9]. Precise serological correlates of protection have not been determined for protection against pertussis, thus the biological significance of diminished pertussis antibody levels is unknown. Also, 100% of children administered three doses of the DTaP<sub>2</sub>/IPV vaccine had fourfold increase of antibody to pertussis toxin (PT) and filamentous hemagglutinin (FHA), and the GMC of neutralizing antibody to all three poliovirus serotypes were actually higher among children administered the DTaP<sub>2</sub>/IPV combination compared to those receiving the vaccines simultaneously at separate anatomic locations [8].

The combination of DTaP<sub>3</sub>/HepB/IPV (Infanrix<sub>DTaPa</sub>-HepB-IPV) has been extensively evaluated in German and U.S. children, who received vaccine at a 3-, 4-, 5-month or a 2-, 4-, 6-month schedule. Immune responses following combination vaccine that were noninferior compared to separately administered vaccines included: (1) the rates of seroprotection against diphtheria, tetanus, all three types of poliovirus, and hepatitis B; and (2) the GMCs of antibodies to pertussis toxin, and pertactin. The GMCs of antibody to FHA were lower in those children given the combination vaccine [10]. However, efficacy studies of pertussis vaccines suggest that the role of FHA in protection against disease is minimal [11]. Children given the combination vaccine experienced higher rates of low-grade fever but no differences in the rates of high fever were observed [10]. Children who received a birth dose of hepatitis B vaccine and were subsequently given the combined DTaP<sub>3</sub>/HepB/IPV experienced no more reactions than those who had not been given a birth dose. (Presented at the Vaccines and Related Biologics Products Advisory Committee, FDA, Bethesda, MD, 3/7/01. [www.fda.gov/ohrms/dockets/ac/cber01.htm](http://www.fda.gov/ohrms/dockets/ac/cber01.htm).)

#### B. DTaP/Hib ( $\pm$ IPV and/or -HB) Combinations

The successful combination of DTwP and Hib vaccines was, in retrospect, deceptively simple. The reconstitution of conjugate Hib vaccines with DTwP vaccines was accomplished with generally no significant increase in reactogenicity or decrease in immunogenicity of the antibody response to the polyribosyl-ribitol-phosphate (PRP) component [12–14]. Unfortunately, this same experience was not generally repeated when lyophilized conjugate Hib vaccines were reconstituted with liquid DTaP vaccines. Statistically significant diminution in the immune response to the Hib component (PRP) has occurred with three of four DTaP/Hib products evaluated after the primary series of vaccinations in infancy, Table 2 [9,15–24]. The mechanism(s) responsible for this diminution is unclear. Hypotheses include: (1) loss of the adjuvant effect of whole cell pertussis vaccine, (2) carrier-induced epitopic suppression [18,25,26], (3) effects on anti-

**Table 2** Comparison of Anti-PRP Seroresponses to Combined and Separately Administered Hib Containing Vaccine After the Primary Infants Series

Vaccine	Reference (Location)	Schedule	% >0.15 µg/mL	% >1.0 µg/mL	GMC
DTaP <sub>2</sub> <sup>a</sup> /IPV/PRP-T	[9] (Chile)	2, 4, 6 mo.	99.3	97.1	7.5
DTaP <sub>2</sub> /IPV + PRP-T			99.3	96.3	14.0

DTaP <sub>2</sub> + PRP-T			100	100	7.0
DTaP <sub>2</sub> /PRP-T	[22] (United States)	2, 4, 6 mo.	94	79	3.2
DTaP <sub>2</sub> + PRP-T			98	80	4.4
DTaP <sub>3</sub> /HB/PRP-T	[16] (U.S.A.)	2, 4, 6 mo.	81.3	58.2	1.2
DTaP <sub>3</sub> + HB + PRP-T			93.8	87.5	5.5
DTaP <sub>3</sub> /IPV/PRP-T	[20] (Canada)	2, 4, 6 mo.	96.4	66.3	1.6
DTaP <sub>3</sub> /IPV + PRP-T			95.1	76.5	3.2
DTaP <sub>3</sub> /HB/IPV/PRP-T	[24] (Germany)	2, 3, 4 mo.	99.3	77.2	2.6
DTaP <sub>3</sub> + HB + IPV + PRP-T			100	88.2	4.5
DTaP <sub>3</sub> /HB/PRP-T	[23] (United States)	2, 4, 6 mo.	87.8	71.3	1.6
DTaP <sub>3</sub> + HB + PRP-T			98.3	90.4	6.15
DTaP <sub>5</sub> /IPV/PRP-T	[19] (Canada)	2, 4, 6 mo.	98.5	84.7	3.8
DTaP <sub>5</sub> /IPV + PRP-T					5.0
DTaP <sub>5</sub> /PRP-T	[21] (Taiwan)	2, 4, 6 mo.	100	98.5	13.0
DTaP <sub>5</sub> + PRP-T			100	95.3	11.8

<sup>a</sup> Subscript indicates number of pertussis antigens.

gen capture, processing or presentation [18], or (4) interference with lymphocyte recognition and responses. An alternative explanation offered is that Hib conjugate vaccine may be incompatible with the aluminum adjuvant in DTaP vaccines [25]. Interestingly, suppression of the immune response to PRP has not been observed following the infant primary series of the combination vaccine consisting of the five-component DTaP<sub>5</sub>, manufactured by Aventis Pasteur, with IPV and PRP-T (Table 2). It is unclear why this product has been an exception. Hepatitis B has also been added to the DTaP<sub>5</sub>/IPV/PRP-T mixture. Following this hexavalent combination, the postdose GMC of antibody against PRP and hepatitis B surface antigen (HBsAg) was lower in the DTaP<sub>5</sub>/IPV/PRP-T/HB group than the DTaP<sub>5</sub>/IPV/PRP-T + HB group. However, the seroprotection rates, defined as anti-PRP antibody level  $\geq 0.15 \mu\text{g/mL}$  and anti-HBsAg  $\geq 10 \text{ IU/mL}$ , were noninferior in the fully combined vaccine group [27].

The GMC of antibody to tetanus toxoid has also been observed to be lower, following vaccination with DTaP/PRP-T combinations [8,14,21]. However, all children achieved the putative protective level of 0.1 IU/mL of antitoxin. Reduction in antibody responses to the tetanus toxoid contained in DTaP/Hib combinations has not been a problem.

The biological significance of diminished anti-PRP responses following primary immunization with DTaP/Hib combinations is actively debated. The obvious concern is that lower levels of antibody may translate into an increase in carriage of *H. influenzae* type b organisms in the population, leading to loss of herd immunity and to increase in disease rates, as what has occurred in Alaska [28]. However, the postprimary series GMT, achieved after immunization in many of the studies with DTaP/Hib combinations, have

often been higher than seen historically following the licensed Hib vaccines. It also has been shown that children with low or even undetectable antibodies to PRP after intake of a DTaP/PRP-T combination are primed for an anamnestic response. Evidence for this includes demonstration of rapid development of high levels of anti-PRP after a fourth dose of either conjugated or unconjugated PRP given to toddlers [16,20,29–31] and the observation that the antibodies produced by these children to the fourth dose are primarily IgG1 [29] and are of high affinity [32,33]—primarily indicating a T-cell-dependent response. There is disagreement about whether the anamnestic response will occur with sufficient rapidity to consistently protect children against invasive disease. Some older children presenting with *H. influenzae* type b meningitis have high levels of anti-PRP antibodies shortly after hospitalization for disease, which suggests that they may have been primed but not protected from invasive infection [34]. Both priming and existing serum antibody are probably important in protection against invasive disease [35].

There are reassuring surveillance data indicating the reliable effectiveness of DTaP/Hib combination vaccines against *H. influenzae* type b invasive disease in German children. Two surveillance systems, one-hospital based and one laboratory-based, were utilized for detection of invasive Hib disease in 1998 and 1999. Although only 70% of children had received three doses of the DTaP/Hib-containing vaccines in the first year of life, the overall vaccine effectiveness among children given at least one dose was 97.5% (95% CI, 96.3–98.4). Vaccine effectiveness was 98.8% (98.2–99.3) following three doses of combination vaccine [36]. The demonstration of population-based field effectiveness is compelling evidence that these DTaP/Hib combinations have been successfully utilized in German children. It is unclear

whether these results can be safely extrapolated to other populations of children living in different circumstances.

### C. Hepatitis A/Hepatitis B Combination

The inactivated hepatitis A vaccine and recombinant hepatitis B vaccines manufactured by GlaxoSmithKline Biologicals have been combined, and, in the United States, are approved as a three-dose series (0, 1, and 6 months) in individuals 18 years and older. Safety of the vaccine has been evaluated in 2165 adults. Systemic and local reactions experienced were similar to those seen following monovalent hepatitis B immunization [37]. After two doses of vaccine, 98.8% of recipients achieved a putative protective titer of antibody to hepatitis A, but only 78.2% had an anti-HBsAg titer of  $\geq 10$  mIU/mL, subsequently necessitating a third dose [38]. This combination vaccine is indicated for individuals at risk of exposure to both hepatitis A and hepatitis B.

## IV. INVESTIGATIONAL COMBINATION VACCINES

### A. Measles–Mumps–Rubella–Varicella Vaccine (MMRV)

Soon after the completion of development of the Oka strain vaccine against varicella, efforts began to combine it with the combined measles–mumps–rubella vaccine. With the initial vaccine compositions, the measles component interfered with the immune response to the varicella component [39–41], necessitating the adjustment of the quantity of varicella in the vaccine. A new formulation of MMRV has been reported to elicit equivalent or better GMT and seroconversion rates to all component of the vaccine compared to separately administered MMR+V [42]. Licensure of this product will save children one injection at 12–15 months of age. It is not yet known whether the quadrivalent MMRV or the MMR will be recommended for the second preschool dose. Cost of the vaccine will be an important determining factor.

### B. Conjugate Combination Vaccines

The currently available seven-valent pneumococcal vaccine conjugated to CRM<sub>197</sub> (7vPnC) contains serotypes—4, 6B, 9V, 14, 18C, 19F, and 23F. These seven serotypes are responsible for approximately 85% of cases of invasive disease in the industrialized world [43]. Serotypes 1 and 5 also are important causes of pneumococcal infection in certain pediatric groups in the United States, such as southwest Native American, older children, and children in the developing world. The addition of serotypes 1 and 5 to the current heptavalent vaccine would extend protection to these groups of children.

It has been estimated that *Neisseria meningitidis* serogroup C causes more sepsis and meningitis in children less than 2 years of age than any of the individual pneumococcal serotypes in the heptavalent pneumococcal vaccine [43,44].

Conjugate meningococcal serogroup C (MnC) vaccine has been licensed and widely used in Great Britain and parts of Canada. Introduction of a separate, injectable MnC vaccine may not be readily accepted in the United States. Therefore safety and immunogenicity studies of a nine-valent pneumococcal vaccine conjugated to CRM<sub>197</sub>/meningococcal group C conjugated to CRM<sub>197</sub> (9vPnC–MnCC) $\pm$ *H. influenzae* type b conjugate to CRM<sub>197</sub> (HbOC) are underway. The preliminary results of a study of a three-dose schedule at 2, 4, and 6 months of age indicate that the combination vaccines are no more reactogenic than separately injected 7vPnC and HbOC vaccines. The humoral immune responses to the seven pneumococcal vaccine serotypes by both the 9vPnC/MnCC and 9vPnC/MnCC/HbOC were noninferior to those stimulated by 7vPnC. Anti-PRP responses in the 9vPnC/MnCC/HbOC were diminished compared to those of recipients of separately administered HbOC and 7vPnC, but the anti-PRP responses in the 9v-MnCC+HbOC group satisfied the criteria for noninferiority. Primary IgG responses to MnC and pneumococcal types 1 and 5 were observed. These preliminary results suggest that 9vPnC/MnCC is acceptably reactogenic and immunogenic, and should be further developed [45].

Introduction of new parenteral vaccines into the routine childhood immunization schedule will require the licensure and availability of further combinations of vaccines. If surveillance data from additional countries employing DTaP/Hib combination vaccines indicate the control of Hib disease, perhaps the criteria for establishment of immunologic noninferiority may be reexamined. Ongoing communication and cooperation among investigators, industry, and regulatory bodies will be necessary to advance this important field.

## Meningococcal Conjugate and Protein-Based Vaccines

**Rino Rappuoli**

*Chiron S.r.l., Siena, Italy*

**Andrew J. Pollard and E. Richard Moxon**

*University of Oxford, John Radcliffe Hospital, Oxford, England*

*Neisseria meningitidis* remains as one of the leading infectious causes of death in childhood in many industrialized countries and a cause of devastating epidemics in nonindustrialized nations. About 500,000 cases of endemic meningococcal infection are thought to occur annually worldwide [1], with the greatest burden of disease in Africa and Asia. Of great public health importance, meningococci are the cause of cyclic epidemic meningitis in Africa [2] and Asia [3], and occasional outbreaks have been associated with population movements and overcrowding in other regions over the past half century [4].

Currently, five serogroups of meningococci, A, B, C, Y, and W135, defined by the biochemistry of their polysaccharide capsule, are responsible for almost all meningococcal disease, although the overall proportions of cases caused by each serogroup vary widely around the globe. In industrialized nations, serogroup B meningococci cause 30–70% of cases of sporadic meningococcal disease [5–7], and have been responsible for pockets of persistently increased rates of disease [8–10]. Serogroup C meningococci are particularly associated with small outbreaks of disease among teenagers and young adults and sporadic disease in individuals of other ages [6]. Serogroup Y disease is uncommon in the United Kingdom but accounts for up to 30% of cases in the United States [6], and rates of Y-disease may also be on the rise in some parts of Canada [7]. Occasional sporadic disease caused by W135 meningococci had been largely ignored until a recent large outbreak among pilgrims to the Hajj in 2000 [11]. Although the epidemiological characteristics of disease caused by each serogroup are intriguingly different, the clinical features of invasive disease are mostly indistinguishable. The shifting epidemiological patterns of meningococcal carriage and disease are poorly understood, and the lack of predictability concerning the future spatial and temporal distribution of this pathogen must be taken into account as vaccines are developed. Nonetheless, several new

vaccine initiatives provide the possibility of a major reduction in the global burden of this disease during the coming decade. The contribution of vaccines in the control of meningococcal disease is particularly important because of the rapidity of its onset, and the short window of time that may exist between health, acquisition of meningococci, fulminant disease, and death. Antibiotics and specialist intensive care have significantly reduced the mortality rate from meningococcal septicaemia [12] in specialized centers in industrialized countries. However, the timely and universal availability of such treatment cannot be provided for most of the world, particularly in countries where access to antibiotics and primary health care, let alone sophisticated intensive management, is virtually unavailable on a day-to-day basis. Widespread control of meningococcal disease is an important public health goal, and immunization is the only realistic means to achieve this aim.

The bedrock of progress rests on the crucial role of capsular polysaccharides (PS) of meningococci in virulence and the protective role of serum antibodies to these surface-exposed carbohydrate antigens.

The protective role of antibodies able to promote complement-mediated killing of bacteria [bactericidal activity (BCA)] was demonstrated in the 1960s [13]. This information was used to develop and license vaccines composed of purified capsular polysaccharides, which are currently available as bivalent vaccines against serogroups A and C, or as tetravalent vaccines against serogroups A, C, Y, and W135. Although there is proven efficacy for MenA and C plain polysaccharides (PS), polysaccharide vaccines are still used only in people at increased risk (for instance, military recruits), or in response to outbreaks. They have never been considered for universal vaccination because of several shortcomings that compromise their utility. Specifically, immunization with MenA PS does not confer long-term protection (it is effective for about 6 years), and MenC PS

is unsatisfactory as a vaccine in children aged less than 2 years. Most importantly, polysaccharide vaccines do not induce immunological memory. Improved immunogenicity and immunological memory-mediated longer-term protection, especially in infants and young children, can be realized through conjugation of the capsular PS to carrier proteins. Described for the first time in 1992 [14], conjugate/protein-polysaccharide vaccines (CV) were introduced into the U.K. primary infant schedule in November 1999 against MenC, after many years of careful assessment of their safety and immunogenicity. They had a major impact on disease caused by Serogroup C meningococci in childhood in the United Kingdom [15, see Chapter 45]. MenC CVs have also been licensed in other countries around Europe [16] and in Canada [7]. Furthermore, combination A/C conjugate vaccines have already been proven immunogenic in clinical trials performed in infants and children [17], while combinations of A, C, Y, and W135 protein-polysaccharide CVs are underway, and there is a reasonable expectation that these combination meningococcal vaccines will be available within a few years, and will provide effective protection from infancy onward. This optimism has been boosted by the announcement of significant funding from *The Bill and Melinda Gates Foundation* in July 2001. This initiative and, in addition, further development of a serogroup A/C conjugate vaccine under the direction of the Global Alliance for Vaccines and Immunization (GAVI) could halt the cycle of epidemic disease in Africa [18].

Progress toward the global control of disease caused by A, C, Y, and W135 must be tempered in view of the current failure to find a solution to the problem of MenB disease. The highest attack rate of meningococcal disease is in children under 5 years of age and, at this age, 50% of disease is caused by MenB in the USA (1992–1996) [6], 39% in Canada (1985–2000) [7], and more than 65% in the UK (1999–2000) [5].

The major stumbling block concerning a MenB vaccine is that the polysaccharide capsule is a homopolymer of sialic acid, chemically identical to polysaccharides found in human tissues, especially fetal brain during development [19]. Hence the Group B capsule is seen by the immune system as a self-antigen; this may partly account for its poor immunogenicity, even after its conjugation to a protein carrier [20]. Although the lack of immunogenicity of the sialic acid capsule is a major problem in the development of a MenB vaccine, research efforts in this area continue because of the attractiveness of a vaccine antigen that is, by definition, shared across this group of meningococci. There are obvious attractions to employing an approach using principles that have successfully worked for other capsular polysaccharides. Jennings and workers have pioneered an innovation in which chemical modification of the polysaccharide (*N*-propionylation) retains immunogenic epitopes. This approach has resulted in the development of a protein-polysaccharide conjugate vaccine that elicits functional (bactericidal) antibody in both mice and nonhuman primates [21,22]. Some of the antibodies elicited have activity against polysialic acid and therefore have the potential to be auto-reactive in humans, although no deleterious effects have been noted in early human trials (P. Fusco and Baxter, personal commun-

ication, 2001). Nonetheless, there is a strong sense that the strategy of polysaccharide–protein conjugation is not attractive to vaccine developers who anticipate ethical and regulatory difficulties that may be difficult, if not impossible, to resolve in taking forward these vaccines as commercially viable propositions. However, other antibodies that arise after immunization with a conjugate *N*-propionylated serogroup B polysaccharide vaccine do not cross-react with human tissues. A derivative approach that might avoid the cross-reactivity issue is to use molecular mimetics of non-autoreactive epitopes as potentially safe serogroup B vaccine antigens [23].

The problems encountered in the development of MenB polysaccharide-based vaccines has resulted in the consideration of a variety of alternative candidates, some of which have already shown encouraging efficacy in clinical trials; others are being rigorously evaluated in early-phase clinical trials and preclinical development programs.

Evaluation of the potential utility of these alternative MenB vaccine candidates is difficult because of the lack of an accepted laboratory surrogate of protection. Other than to capsular polysaccharides, no defined level of circulating antibody to serogroup B meningococci relates to protection against invasive disease. However, indirect evidence suggests that a certain titer of bactericidal antibody (dilutions of serum that can kill meningococci in the laboratory in the presence of complement) might be correlated with protection at the population level [13].

Because of these difficulties in realizing an effective MenB polysaccharide vaccine, investigators have turned their attention to other bacterial surface structures as vaccines. Potentially, surface-exposed components of the cell envelope of meningococci include a large number of outer membrane proteins (OMPs), lipoproteins, and lipopolysaccharide (LPS).

The OMPs of MenB have been extensively studied as potential vaccine constituents since the 1970s. A drawback to their candidacy as vaccines is that these proteins tend to be highly variable not only among different MenB isolates, but also within clonal populations of the same strain. As a consequence, any outer membrane protein from a single strain is unlikely to provide cross-protection to all other MenB strains. Furthermore, the antigenic regions of many of these protein structures evolve rapidly within bacterial populations because of the natural selection on carriage strains, especially through the acquired host immune clearance mechanisms mediated by local and systemic B cells. Despite these problems, outer membrane-based vaccine candidates have reached trials and one is currently in routine use in Central and South America [24]. However, to date, there is little convincing evidence that these vaccines are effective in young children in whom the attack rates for invasive MenB disease are highest.

The earliest OMP vaccines comprised of insoluble aggregates of outer membrane proteins that were poorly immunogenic in humans [25]. Purified OMPs noncovalently complexed to meningococcal C-polysaccharide were tested in a trial in Chile and resulted in substantial protection in older children and young adults (70%), but were poorly protective in children less than 5 years of age [26]. To im-

**Table 1** Summary of the Efficacy Trials Against Meningococcus B Performed with Outer Membrane Vesicle Vaccines

Trial (year)	Vaccine (strain)	Doses	Efficacy, adults (age)	Efficacy, children (age)	Efficacy, infants (age)	Efficacy, total	Ref.
Norway 1988–1991	NIPH 15:P1.7,16	2 doses	87% (10 mo) 57% (29 mo) (13–16 yr)	/	/		[26]
Cuba 1987–1989	Finlay 4:P1.19,15	2 doses	83% (10–14 yr)	/	/		[23]
Brazil 1990–1991	Finlay 4:P1.19,15	2 doses	74% (>48 mo)	47% (24–47 mo)	–37% (<24 mo)	54%	[27]
Chile (Iquique) 1987–1989	Cuban type 15:P1.7b,3	2 doses	70% (30 mo) (5–21 yr)	/	–23% (30 mo) (1–4 yr)	51%	[25]

prove immunogenicity, OMP vaccines were produced in spheres of bacterial outer membrane, known as outer membrane vesicles (OMVs) [26]. These OMV vaccines have now been evaluated in large-scale trials (Table 1) and, using two doses, have resulted in substantial protection in older children [24,26,27], but not in children under 4 years of age [24,26,28,29]. Furthermore, bactericidal antibody tends to be directed to the serogroup B meningococcal “type strain” included in the vaccine (Table 2, [30,31]).

The major target of protective immunity in these OMV vaccines is PorA, a porin that is the basis of the subserotyping system of meningococci, and therefore known to be antigenically variable. The role of PorA as a target for protective antibodies, the problem of its variability, and the lack of cross-strain protection have stimulated research culminating in second-generation OMV vaccines. This approach used genetic techniques so that six different PorA proteins, expressed in two engineered strains, were included. Phase II trials in various age groups have demonstrated variable and, overall, disappointing immunogenicity to each PorA type [32]. Furthermore, mutations in the genes encoding this protein are common and result in evasion of complement-mediated killing of the organism, further complicating the success of this approach [33].

Nonetheless, the observation that some protection and induction of bactericidal antibody directed against the vaccine strain is induced with monovalent OMV vaccines suggests that these vaccines may be of use in outbreaks of serogroup B disease caused by a single “type strain” of

bacteria. For example, over the past decade, the rates of MenB disease in New Zealand are 4–20 times higher than other industrialized countries [8]. In July 2001, the Ministry of Health in New Zealand announced plans for further development of a monovalent OMV vaccine with Chiron Corporation in conjunction with the National Institute for Public Health (NIPH), Norway, in the hope of halting serogroup B disease [34]. Considering the antigenic variability of PorA and the disappointing efficacy of OMV vaccines in children, preclinical research into other surface-exposed membrane proteins as vaccine candidates has been undertaken. Antigenic variability or inconsistent accessibility to antibodies across genetically different strains has proved to be problematical and none has been taken forward into clinical trials except for the transferrin binding protein (TbpB), for which the immunogenicity was disappointing [35].

In addition to surface expressed proteins, another major component of the cell envelope of all gram-negative bacteria, including meningococci, is lipopolysaccharide (LPS). The potential use of LPS as a vaccine has been impeded by concerns about toxicity, especially through lipid A (endotoxin) and the molecular mimicry of *N. meningitidis* glycoforms, especially lacto-*N*-tetraose, expressed on human cells. However, there is now compelling evidence to support the potential of meningococcal LPS as a vaccine, or as a component of one. Evidence of protection by antibodies to the LPS has been documented in animals [36,37] and humans [38,39], although antibodies induced by outer membrane vesicle vaccines retaining LPS lacked bactericidal activity

**Table 2** Strain Specificity of the Immuno-Response in Infants and Children After Immunization with OMV Vaccines

Test strain	Bactericidal activity, Norwegian vaccine			Bactericidal activity, Cuban vaccine		
	Infants	Children	Adults	Infants	Children	Adults
Chile	12	35	60	10	31	37
Cuban	2	24	46	<b>90</b>	<b>78</b>	<b>67</b>
Norwegian	<b>98</b>	<b>98</b>	<b>96</b>	31	41	56

Comparison of bactericidal responses against homologous and heterologous strains induced in infants, children, and adults in a clinical trial in Iquique (Chile) using the Cuban and Norwegian OMV vaccines. As shown, three doses of OMV vaccines induce good bactericidal titers against the homologous strain at all ages. No or low titers found against heterologous strain in infants and children, respectively.

**Table 3** Bactericidal Activity Against a Panel of Different Strains Induced by Three Prototype Antigens Against Meningococcus B

	B	B	B	B	B	B	A	C	C
Strain	2996	BZ232	1000	MC58	NGH38	394/98	F612	C11	BZ133
OMP	16,000	2048	—	—	—	—	—	—	—
OMV	65,000	8000	—	2048	—	—	32,000	—	—
Non-OMP	65,000	512	4000	8000	32,000	4000	8000	1024	16,000

OMP is a purified outer membrane protein with a predicted typical beta-barrel structure spanning the outer membrane. OMV is a typical OMV vaccine produced from strains 2996. Non-OMP is a new surface-exposed protein discovered with the genomic approach.

[40,41]. A Phase 1 study of detoxified LPS (immunotypes L3, 7, and 9) was immunogenic, but most of the functional antibody was directed against OMPs [42]. Nontoxic LPS vaccines have been also produced by conjugating the core saccharide to protein carriers, but this strategy failed to induce antibodies with bactericidal activity [43–45]. A different approach, one also addressing the unproven but theoretical concern of an autoimmune response induced by lacto-*N*-tetraose, has resulted in vaccines based on the inner core region of LPS. This component is relatively conserved across the species, and there is strong evidence to indicate the accessibility of inner core epitopes to antibodies based on studies of in vitro grown and ex vivo organisms [46,47]. Monoclonal antibodies (Mabs) specific for inner core epitopes indicate that that these structures can be targets for bactericidal activity and protective immune responses in animals (infant rats) challenged with some, but not all, strains of meningococci [48].

## I. GENOME-BASED DISCOVERY OF NEW ANTIGENS

The recent availability of two meningococcal genomes [49, 50] allowed to pursue vaccine development in a new way that was named “reverse vaccinology” [51]. Novel potential vaccine candidates were identified in silico using computer programs and subsequently expressed as recombinant fusion-proteins in *Escherichia coli*. The recombinant antigens were then purified and used to immunize mice. Finally, the sera obtained were tested in vitro for their ability to kill bacteria in the presence of exogenous complement. The work was performed while the sequence was in progress and by the time the sequence was published, the first screening for new antigens was also completed. Computer analysis identified approximately 600 potential antigens predicted to be surface-exposed. A total of 370 of these were successfully expressed in *E. coli*, purified, and then used to immunize mice. Of the 370 sera tested, 29 showed bactericidal activity. As soon as the 29 novel antigens had been identified, a lot of work was put into their characterization in order to select those that induced the best bactericidal activity against all strains. In a first approach, the genes of the novel antigens were sequenced in a panel of strains representative of the genetic variability of the worldwide population of meningococcus B. Surprisingly, many of the novel genes were found to be quite conserved among genetically diverse strains, suggesting that some of the novel proteins could be used to

develop a vaccine against all serogroup B meningocci. Finally, the bactericidal activity induced by all of them was tested against a panel of genetically diverse strains. Some of the novel antigens were indeed found to induce a bactericidal activity against most of the strains tested; however, many induced bactericidal activity only against a subgroup of them. Table 3 compares the immune response against a recombinant OMP, an OMV-based vaccine, and a recombinant protein found by the genomic approach. As shown, while the recombinant OMP and the OMV vaccine induce bactericidal antibodies against a subset of strains, the genome-derived antigen is able to induce immunity against all strains tested. The proteins inducing the most cross-reacting bactericidal response are now being studied alone or in combination in order to find a vaccine formulation that, hopefully, is going to be effective against all strains. The combination of several antigens in the vaccine formulation should be able to avoid the generation of escape mutants, which are to be expected for single antigens. One of the antigens identified by genome screening (GNA 33), although conserved in sequence, was found to induce immunity against only a subgroup of strains having P1.2 porin. It was found that this antigen contains a QTP (Q = glutamine; T = threonine; P = proline) peptide, which induces strong antibodies against the loop 4 of porin A, where the QTP sequence is also present. This example shows that the genome-based approach not only finds genuine antigens, but can also pick up mimetic antigens which induce protective immunity against other targets present in the bacterium [52].

Protein antigens have been found not only by using the genomic approach, but also by using more conventional techniques. The best known of these is NspA, a protein of the outer membrane which is well conserved among strains and induces bactericidal antibodies against many but not all of them [53,54].

## II. CONCLUSIONS

Polysaccharide vaccines against serogroups A, C, Y, and W135 of meningococcus have been available for decades and have been useful for immunization of at-risk groups and control of outbreaks. They have never been used for general immunization because they provide a short-term immunity with no memory and, in most of the cases, they do not work in infants and children. A conjugate vaccine against meningococcus C, licensed in the United Kingdom in 1999, has been extremely effective in eliminating the disease in all ages,

showing that conjugate vaccines are an excellent solution for the prevention of meningococcus. In fact, they induce immunological memory and are efficacious at all ages. Conjugates against serogroups A, Y, and W135 are also in development, and are expected to be licensed within 3–6 years. The conjugation approach cannot be applied as such to serogroup B because the capsular polysaccharide is a polysialic acid identical to a self-antigen. To avoid this problem, a number of alternative approaches have been tested. These include the chemical modification of the polysaccharide, the use of OMVs, the use of the core structure of the LPS, and the search for conserved proteins inducing a bactericidal response. The use of the whole genomic sequence to identify novel protein targets has provided many novel antigens. It is reasonable to hope that within the next decade, we may have vaccines for the universal prevention of all meningococcal diseases.

### I. BACKGROUND

Polysaccharide–protein conjugate vaccines are new tools for the prevention of serious disease caused by encapsulated bacteria. Conjugate vaccines to prevent disease caused by *Haemophilus influenzae* type b (Hib) and serogroup C meningococcus (SCM) have already been introduced into routine national immunization programs. In this chapter, we review development and implementation of these vaccines, and present data from countries demonstrating their striking impact.

#### A. The Bacteria

*H. influenzae* and *Neisseria meningitidis* are unrelated bacteria which share a number of characteristics, the most obvious being their tendency to cause bacterial meningitis and septicemia in humans.

*H. influenzae* is a gram-negative cocco-bacillus which colonizes the human oropharynx. A minority of these organisms have polysaccharide capsules. The encapsulated strains are characterized based on the antigenic properties of the capsule. Of the six serologically identified types (designated a–f), organisms with the type b capsule (Hib) are the most virulent.

As humans are the only biologically relevant reservoir of *H. influenzae*, transmission of the organism occurs by person-to-person spread, usually through direct or indirect exchange of oropharyngeal secretions. After introduction into the oropharynx, *H. influenzae* may establish relatively long-term colonization (often lasting several months or

more), or primarily in the case of Hib, may invade through the mucosa and enter the bloodstream. Once in the blood, the organism multiplies and may seed other sites, such as the meninges, joint spaces, or soft tissue. If Hib remains unchecked, clinical sepsis may follow, with or without manifestations of localized disease. *H. influenzae* may also cause lower respiratory tract infection, presumably by aspiration or direct extension from the oropharynx, but only a minority of these respiratory tract infections result in bacteremia.

*N. meningitidis* is a gram-negative coccus with a polysaccharide capsule. The capsular polysaccharides of meningococcus define the serogroup. Five serogroups are associated with human disease, of which A, B, and C are the most important in terms of morbidity and mortality worldwide, accounting for 90% or more of disease. All three serogroups may cause endemic disease. Serogroup A strains have caused most of the major outbreaks, especially in the African meningitis belt. Recently, outbreaks in Africa caused by serogroup W135 have been reported. Serogroups B and C have been associated with outbreaks in the developed world, usually with substantially lower incidence rates than those in the meningitis belt. Humans are the only recognized host for *N. meningitidis* and there is no known animal or environmental reservoir.

*N. meningitidis*, similar to Hib, also colonizes the human oropharynx. Meningococcus is highly adapted to this commensal existence in humans, with a range of strategies for evasion of the immune response. The carrier state may last for a few days to months; it provides a reservoir for infection and enhances the immunity of the host. Similar to Hib, invasive disease—primarily meningitis and/or sepsis—may

follow carriage, but meningococcus is a less common cause of pneumonia than Hib.

### B. Epidemiology of Disease: Hib

Although Hib disease incidence, age distribution, and presentation vary with socioeconomic and geographic factors, the bulk of disease occurs in children less than 5 years of age. Table 1 shows the incidence of invasive Hib disease and meningitis in children less than 5 years of age in selected areas [1–8]. In the United States, overall rates of invasive disease from various studies in the prevaccine era ranged from 50 to 100 cases per 100,000 children below 5 years of age, with rates of meningitis between 30 and 60 per 100,000. Rates of disease in Europe tended to be somewhat lower, with rates of all invasive disease usually between 30 and 60 cases per 100,000 children below 5 years of age. Rates of disease in Latin America and the Middle East tend to be similar to those in Europe, while those in Africa are somewhat higher. Although additional studies are ongoing in Asia, current data suggests that the incidence of Hib disease in many Asian countries (e.g., China, Japan, South Korea, Singapore) is substantially lower than in Europe or the United States. Some population groups have much higher rates of meningitis and invasive disease, for example, 200–300 cases per 100,000 children below 5 years of age among Aboriginal Australians and Native Americans.

Table 1 also demonstrates that, in addition to variation in disease incidence, substantial variation exists in the age distribution of disease. In the United States, prior to immunization, somewhat over one-half of *H. influenzae* meningitis in children less than 5 years of age occurred in children under 1 year of age, with peak incidence in children 6–8 months of age. In contrast, in many developing countries, a substantially larger proportion of cases occur in children less than 1 year old. In western Europe, the age distribution is shifted in the other direction, so that less than 50% of all cases occur in children less than 1 year of age and nearly half occur in those between ages 1 and 3 years.

Hib may cause meningitis, epiglottitis, bacteremia without focus, facial cellulitis, pneumonia, arthritis, and other infections. Disease manifestation and outcome also vary by

socioeconomic status and geography. In much of the developed world, meningitis is the most common form of invasive disease. Meningitis represented 60–70% of all invasive *H. influenzae* disease in children in the United States before widespread immunization. The case fatality rate for meningitis in the United States has ranged from between 3% and 6% since 1985. Morbidity from meningitis includes sensorineural deafness in up to 15% of survivors and other neurological deficits less commonly. In comparison with Western countries, meningitis occurs at a younger age and has a higher mortality in many developing countries. For example, the case fatality rate in rural Africa is often between 30% and 45%. Although epiglottitis was the next most common manifestation of Hib disease in developed countries in North America and Europe, in many developing countries epiglottitis is a rare entity. The primary manifestation of *H. influenzae* disease in developing countries may be lower respiratory tract infection. Hib accounted for about 20% of chest x-ray documented clinical bacterial pneumonia in field trials of Hib conjugate vaccines in the Gambia and Chile [9,10].

### C. Epidemiology of Disease: Serogroup C Meningococcus

In contrast to Hib, which causes a relatively stable burden of childhood meningitis in a given country, meningococci not only contribute a continuing burden of endemic disease, but also cause epidemics with widely varying rates, occurring at unpredictable intervals. Worldwide, there are around 1.2 million cases of endemic and epidemic meningococcal disease each year, with an estimated 135,000 deaths [11]. The disease can occur anywhere, but the largest and most frequent epidemics arise in the African meningitis belt, where epidemic waves of meningococcal disease occur every 5–12 years, usually attributable to serogroup A organisms with serogroup C and W135 strains playing a smaller role. Emergency mass immunization using meningococcal serogroup A and C polysaccharide vaccine is initiated within this area, when the incidence rate reaches a predefined epidemic threshold level [12]. Rates of disease are highest during hot and dry weather and subside with the onset of the

**Table 1** Epidemiology of Hib Disease in Selected Areas

Country	Incidence, children < 5 yrs (cases/10 <sup>5</sup> )		% of Meningitis	
	All	Meningitis	In < 1-yr-olds	In < 2-yr-olds

China (Hong Kong) (8)	3	2	35	70

rains. During epidemics in Africa meningococcal disease is generally more prevalent in older age groups, although this is not always the case [13].

Certain factors are thought to increase susceptibility to meningococcal infection including climate, crowded living conditions, upper respiratory tract infection, and waning population immunity. Disease onset is often sudden and even with correct treatment, individuals may be left with severe disabling sequelae, in particular, brain damage and loss of limbs. The case fatality rate is high—10–20% of all cases of meningococcal disease die—but varies with serogroup, clinical presentation (meningitis, sepsis), and the availability of prompt antibiotic treatment.

In developed countries (as well as developing countries outside the meningitis belt), serogroups B and C predominate as a cause of invasive disease. Through the period 1993–1996, the overall incidence of meningococcal disease within countries in Europe was 1.1 per 100,000 [14]. The incidence rate of meningococcal disease increased within Europe to 1.5 per 100,000 in 1997/1998 and to 1.7 per 100,000 in 1998/1999. Within Europe, there is variation in both the overall incidence of meningococcal infection, probably reflecting real differences in epidemiology but also in national ascertainment, and the proportion of cases that occur as a result of serogroup C infection (Table 2). During the 1990s, increased incidence of group C disease was observed in England and Wales (Figure 1), Finland, Greece [15], Spain [16], and the Republic of Ireland [17] among others. Between 1993 and 1996, serogroup C cases rose from 26% to 32% of cases in Europe, with the number of cases increasing by 35% [14].

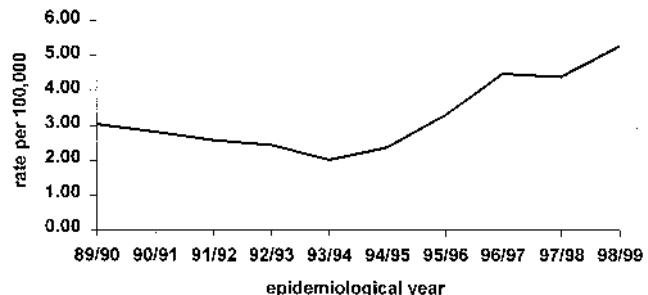

During the 1980s, the annual incidence of invasive meningococcal disease in Canada increased slowly from a low of 0.8 per 100,000, and serogroup C began to account for

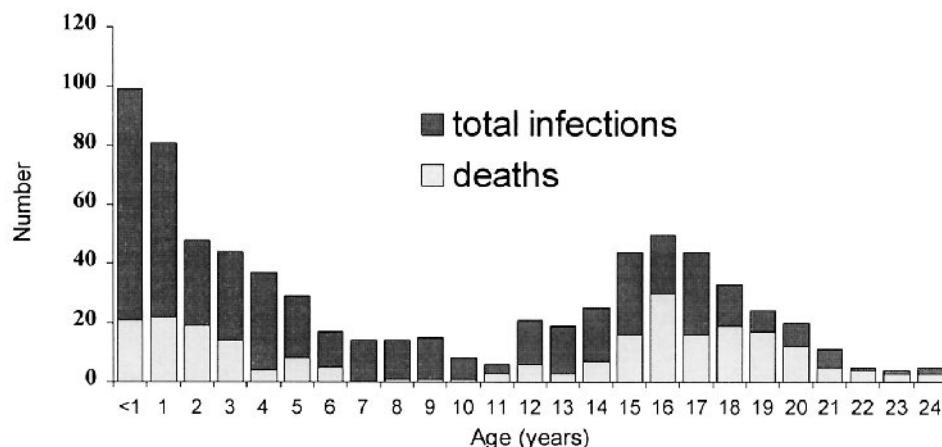

**Figure 1** Incidence of confirmed cases of all meningococcal disease by epidemiological year (1 July–30 June), England and Wales, 1989/1990 to 1998/1999. (Health Protection Agency, Meningococcal Reference Unit, England.)

a larger proportion of cases [18]. The proportion of serogroup C cases increased significantly from 24% in 1985 to 65% in 1992, against a background of increasing incidence of all meningococcal infection. The 14.5% case fatality rate for serogroup C disease was higher than that for other serogroups. Much of the increase was accounted for by the emergence of a particular strain of serotype C:2a that was associated with a high case fatality and sequelae rate. There was considerable geographical variation across the regions, and Quebec introduced a mass immunization campaign in which polysaccharide vaccine was offered free to all those aged 6 months to 20 years from December 1992 to March 1993 [19]. At the time that the campaign started in 1993, the incidence of serogroup C disease was 1.4 per 100,000 and this decreased to 0.3 per 100,000 by 1998. There was no evidence of protection in those under 2 years of age and protection began to decrease within 2 years of immunization in other age groups.

The United States has a relatively low incidence of meningococcal disease, with an annual incidence ranging from approximately 0.8–1.3 per 100,000 population [20]. In 1998/1999, cases with a confirmed serogroup in the United States were equally distributed among serogroups B (30.5%), C (29.4%), and Y (31.5%). Outbreaks of serogroup C meningococcal disease began to occur more frequently in the United States from the early 1990s [21]. These outbreaks were dispersed geographically throughout the United States and disproportionately affected adults and school aged children, in comparison to sporadic cases.

Throughout the developed world, the peak incidence of meningococcal C disease is in children aged under 2 years of age with a secondary peak in individuals aged between 15 and 18 years. Unlike disease due to meningococcal B or Hib infection, the death rates are highest in those aged between 15 and 18 years, as illustrated in Figure 2 for England and Wales. In 1998/1999, about 25.6% of cases in reporting European countries occurred in those aged 1–4 years old and 20.4% in those aged 15–19 years old [22]. About a third (37%) of serogroup C cases were aged less than 5 years in that epidemiological year, compared to about half (48%) of group B. The age distribution changes during epidemics, with an increase in the proportion of cases observed in

**Figure 2** Meningococcal serogroup C disease and deaths by age. Isolates referred to the Public Health Laboratory Service in 1998/1999. (Health Protection Agency, Meningococcal Reference Unit, England.)

teenagers and young adults. There is clear seasonal variation with the highest incidence of disease, endemic and outbreaks, in the winter months. Case fatality rates tend to be relatively high, but there is significant variation in the rates reported, for example, the rates in Australia, Canada, and European countries are approximately 10–15% [14,18,23]; whereas in the United States, the case fatality rate appears to be very low at 3.4% [20].

## II. HIB VACCINE DEVELOPMENT AND IMPACT

### A. Immunology and Development

In spite of differences in age-specific rates and disease manifestations and regardless of socioeconomic status or geographic area, the major burden of Hib disease was in children less than 2 years of age, and it was in that group that effective immunization was crucial. A major advance in understanding immunity to this disease resulted when Fothergill and Wright [24] demonstrated an inverse correlation between disease rates and whole-blood killing activity by comparing age-specific incidence data with laboratory data in persons of different ages. Hib disease incidence was lowest in newborns (who had maternally derived immunity) and older children (who apparently acquired immunity through carriage of Hib or cross-reactive bacteria) and highest at the nadir of whole-blood bactericidal activity between ages 5 and 11 months. Subsequent studies demonstrated that antibody to the type b capsular polysaccharide, polyribosyl-ribitol-phosphate (PRP), was the primary component of immunity.

Initial attempts to make Hib vaccines were focused on development of vaccines with PRP alone. Immunogenicity studies of the polysaccharide vaccine showed measurable antibody levels in children 2 years of age and older, but absent or poor immunogenicity in younger children. A large-scale double-blind study of PRP vaccine in Finland in children 3 months to 5 years of age [25] showed >90% efficacy for children who received vaccine at age 18 months or in

older, but no protection in younger children. The vaccine was licensed in the United States in 1985, but a series of postmarketing efficacy studies in different U.S. populations showed, at best, moderate efficacy (point estimates of efficacy between 47% and 80% in children 2 years and older), and one study showed no statistically significant protective effect [26].

Although the PRP vaccines were ultimately disappointing as a public health measure, evaluation of these vaccines contributed to development of the newer conjugates. Robbins and coworkers [27] had suggested that the protective level of anti-PRP antibody was between 0.06 and 0.1 µg/mL, based on studies of healthy adults (who are not at risk for Hib disease) and persons with immunoglobulin deficiency who were routinely receiving intravenous immune globulin. Kayhty et al. [28] reviewed data from the Finnish PRP efficacy trial and estimated, based on rates of disease, vaccine efficacy, and postvaccination antibody, that 0.15 µg/mL of anti-PRP antibody was adequate for protection at the time of “challenge,” and that a postimmunization peak level of 1.0 µg/mL indicated long-term protection of up to 1 year. Although the actual “protective level” of antibody required is still debated, the levels of 0.15 and 1.0 µg/mL are generally used by researchers reporting immunogenicity data for Hib vaccines.

The poor immunogenicity and efficacy of PRP vaccines in those at greatest risk for disease was due to the T-cell-independent nature of PRP as an immunogen. Failure to stimulate T-cell interaction led to little or no primary immunological response in infant immune systems, and a failure to prime cells for subsequent booster responses to additional doses. In contrast, T-cell-dependent antigens, such as diphtheria and tetanus toxoid, did accomplish these tasks, although several doses were required. Earlier work by Avery and Gobel [29] showed that coupling strong antigens (such as proteins) to otherwise poor immunogens could result in a credible response to the formerly inactive component. Several investigators developed protein poly- or oligosaccharide conjugates. Each of these vaccines differed not

only in the conjugated protein but also in the size of the saccharide chain used and the presence or absence of a “spacer” between the protein and the saccharide unit, among other things (Table 3).

Not surprisingly, most studies showed that immunogenicity of these vaccines differs. Table 4 shows results of one comparative study [30]. PRP-D, HbOC, and PRP-T behaved similarly, each requiring two or three doses to reach substantial antibody levels. However, in most studies, PRP-D shows the poorest immunogenicity, often with less than 60% of vaccines achieving 1.0 µg/mL after three doses [31,32]. In contrast, most HbOC and PRP-T recipients routinely achieve higher levels after three doses. Recipients of PRP-OMP demonstrate a markedly different pattern. After one dose of this vaccine, a majority of recipients achieve antibody levels of 1.0 µg/mL. In part, because of these immunogenicity differences, PRP-D, HbOC and PRP-T have generally been evaluated in three-dose primary regimens, while PRP-OMP has been evaluated as a two-dose primary series. Regardless of which vaccine was used for the primary series, antibody levels decline after the third dose, so that one year after the third dose, the circulating level of anti-PRP antibody is relatively low. In the United States, a booster dose has been recommended after a primary series of each of these vaccines at 12–15 months of age. In booster studies, each of these vaccines demonstrated the ability to prime T cells for response to subsequent booster doses. These studies also highlight the issue of whether circulating antibody levels are as essential for protection induced by the conjugate vaccines as they were for protection by polysaccharide vaccines [33]. Because the conjugates induce immunological memory, which may rapidly respond to challenge by Hib, they may obviate the need for preexisting circulating antibody at time of challenge.

Widespread use of Hib conjugate vaccines did not occur until large, prospective efficacy studies were completed. The first conjugate vaccine to be formally evaluated in a prospective efficacy study was PRP-D [34]. In 1986, a total of 114,000 infants (98% of all eligible Finnish infants) were involved in a prospective randomized field trial with PRP-D. Overall protective efficacy was 94% (95% CI, 83–98%) with 90% after three doses and 100% efficacy after the fourth (booster) dose. However, Ward et al. subsequently evaluated this vaccine in a randomized, controlled trial among Native Alaskans and did not find evidence of significant efficacy in that population (point estimate 35%; 95% CI, 57–73%) [35]. Extensive review of the Alaska study did not reveal any methodological problems that may have led to an inaccurate

**Table 4** Immunogenicity of *Haemophilus influenzae* Type b Vaccine Among Infants [30]

Vaccine	Baseline	Postdose 1	Postdose 2	Postdose 3
PRP-D	0.07 <sup>a</sup>	—	0.08	0.28
PRP-OMP	0.11	0.83	0.84	1.14
HbOC	0.07	0.09	0.13	3.08
PRP-T	0.10	0.05	0.30	3.64

<sup>a</sup> µg/mL of serum.

estimate of efficacy. The immunogenicity of the vaccine at both sites was similar and relatively poor. One explanation for the disparate results has centered on the difference in the epidemiology of disease in the two sites—with relatively low disease incidence and high socioeconomic status in Finland and very high incidence of disease and markedly different lifestyles in Alaska. Nevertheless, the failure of the vaccine in Alaska, even in the face of the somewhat vague notion of higher disease “pressure,” found a serious problem with the vaccine.

HbOC was evaluated in a large Northern California health maintenance organization by Black et al. [36]. The study demonstrated significant efficacy for children who completed a series of three doses at 2, 4, and 6 months of age (100%; 95% CI, 68–100%). No efficacy was demonstrated for fewer doses, but the study was too small to estimate efficacy in those not receiving the recommended schedule. A subsequent case-control efficacy study by Vadheim et al. [37] did demonstrate the efficacy of one (71%; 95% CI, 38–87%) and two doses (89%; 95% CI, 60–97%) and confirmed the efficacy of three doses (94%; 95% CI, 68–99%). Santosham et al. [38] demonstrated the efficacy of 97% in persons who received a single dose of PRP-OMP. Prospective evaluations of PRP-T were halted in the United States after licensure of HbOC and PRP-OMP for infants, but prior to the implementation of nationwide Hib vaccination in the United Kingdom, a prospective controlled community intervention study was conducted in the Oxford health region (population about 2,500,000) to assess the efficacy of PRP-T vaccine [39]. Doses of PRP-T were given at 2, 3, and 4 months of age. A booster dose was not offered in the second year of life. The uptake of PRP-T was in excess of 90%, with nearly 28,000 infants being vaccinated. By January 1, 1993, the estimated efficacy of vaccination with PRP-T was 95% with only one vaccine failure.

**Table 3** Hib Conjugate Vaccines: Selected Characteristics

Vaccine	Polysaccharide	Linkage	Protein carrier
PRP-D	medium	6-carbon	diphtheria toxoid
HbOC	small	none	CRM <sub>197</sub> mutant
PRP-OMP	medium	thioether	C diphtheria toxin
PRP-T	large	6-carbon	<i>N. meningitidis</i> group B outer membrane protein tetanus toxoid

Hib conjugate vaccines demonstrated another unexpected but important benefit over PRP vaccines—reduction of nasopharyngeal carriage of Hib among immunized children. In a carriage study in Finland, 725 healthy children attending clinic for a routine examination were enrolled between April 1987 and October 1990. Up to October 1988, Hib carriage was found to be 3.5% in 3-year-old children (who had not received PRP-D vaccine) [40]. None of the 327 vaccinated children sampled thereafter were carriers. Subsequent studies in the United States in populations receiving primarily PRP-D, HbOC, and PRP-OMP confirmed the following results: (1) decreased carriage among immunized children compared to unimmunized children [41] and (2) drastically reduced carriage rates (<1%) in children 2–5 years old compared to historical levels [42]. A carriage study in Oxford, England, has also demonstrated the impact of PRP-T on Hib carriage rates. In the 6 months after completion of the accelerated vaccination schedule, only 1.5% of PRP-T recipients carried the Hib organism, compared with a 6.3% carriage rate in control infants (relative risk, 4.3) [43].

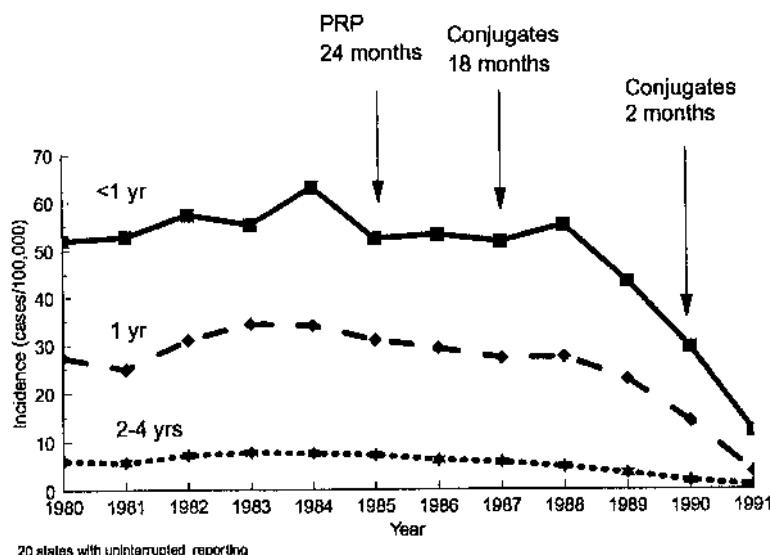

## B. Impact of Hib Immunization Regimens

### 1. The United States

Hib immunization was introduced in the U.S. population in three distinct stages, based on the availability of efficacy and immunogenicity data. The PRP vaccines were licensed for children 24–60 months of age (and those 18–24 months if in day care) in April 1985. Uptake of these vaccines was slow, however, and estimates of vaccine coverage of the eligible age group were rarely more than 35–40%. The PRP vaccines were the only Hib vaccines in use in the United States from

mid-1985 through December 1987, when PRP-D was licensed for use in children between 18 and 60 months of age, based on the Finnish PRP-D efficacy trial. Although HbOC and PRP-OMP were subsequently licensed for use in this older age group, between December 1987 and late 1990, PRP-D was used for the vast majority of children who received Hib conjugate vaccines. In October 1990, following the Northern California efficacy study, HbOC was licensed for use in infants beginning at 2 months of age in a three-dose primary series. Between 1990 and 1993, at least 90% of all vaccine distributed in the United States for infant immunization was HbOC. Thus for all practical purposes, children were immunized with PRP vaccines at 18–24 months between 1985 and 1987, with PRP-D at 18 months between 1987 and 1990, and with HbOC beginning at 2 months between 1990 and 1993.

A variety of surveillance systems were used to evaluate the impact of these programs. The Centers for Disease Control and Prevention (CDC) coordinated a passive national system for reporting bacterial meningitis beginning in 1977. Although many states did not participate, between 1980 and 1991, a total of 20 states reported consistently. Adams et al. published data from this system comparing reported rates of meningitis caused by *H. influenzae*, *N. meningitidis*, and *S. pneumoniae* in children less than 5 years of age [44]. Although rates of disease caused by the meningococcus and pneumococcus changed very little, between 1988 and 1991, the rate of *H. influenzae* meningitis dropped by over 80%. The incidence of *H. influenzae* meningitis declined only marginally during the PRP years, consistent with the moderate efficacy of the vaccine and low coverage. The major decline in incidence occurred during the time when PRP-D was being used in older children (1988–1990) and continued after introducing HbOC and PRP-OMP for infants (Figure 3).

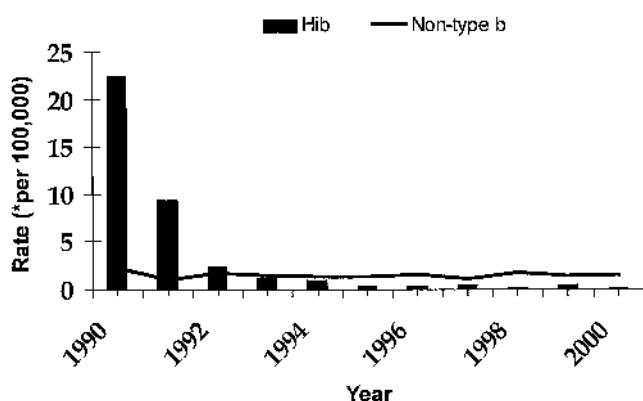

**Figure 3** Age-specific incidence of *H. influenzae* meningitis in the United States between 1980 and 1991 (National Bacterial Meningitis Reporting System, Ref. 1). Rates in children less than 1 year old shown with solid line, rates in children 12–23 months old shown by hatched line, and rates for children 2–4 years old shown by dotted line. Licensure dates for polysaccharide vaccine (PRP) and conjugate vaccines are shown by arrows.

The rapidity of the decline between 1988 and 1990 came as a surprise, given the fact that most disease occurred in age groups younger than those for which the vaccine was licensed. Evaluation of age-specific decline in disease incidence (Figure 3) confirmed a significant decline in disease even in children less than 1 year of age. Adams et al. [44] and Murphy et al. [45] found similar results from prospective, population-based laboratory surveillance studies.

Data from other sources confirmed the decline in *H. influenzae* disease. Several groups used multistate or national hospital discharge data to identify decreased hospital admissions for *H. influenzae* disease. Schoendorf and colleagues used national mortality data to confirm that although deaths attributed to *H. influenzae* meningitis had been declining slowly since 1980, a significant change in the rate of decline occurred in both children less than 1 year of age and those between 1 and 4 years of age beginning in 1989, shortly after introduction of Hib conjugate vaccines in older children [46].

The remarkable success of Hib conjugate vaccines, with the unexpected benefit of herd immunity attributed to reduction in oropharyngeal carriage, led to hope for rapid elimination of Hib disease among children less than 5 years old in the United States. The early reduction in disease incidence was accomplished in spite of less than optimal vaccination coverage. Although accurate national coverage data for Hib vaccines are not available for most of the time between 1985 and 1991, estimates from case-control and focused immunization coverage studies suggest overall immunization rates in the late 1980s through 1990 probably were not above 60% and were probably much lower.

Recent data from the CDC showed that by the year 2000, 93% of children in the United States received at least three doses of the Hib conjugate vaccines. The overall rates of invasive Hib disease fell from about 100 out of 100,000 children less than 5 years of age in the prevaccine era to 0.23 out of 100,000 by the year 2000 [47]. This suggests less than 100 cases of Hib disease are identified each year in the United States. Notably, nontype b disease remained at low levels throughout the 10-year period (Figure 4).

**Figure 4** Race-adjusted incidence rate of *H. influenzae* type b and nontype b invasive disease detected among children aged < 5 years—United States, 1990–2000. (From Ref. 47.)

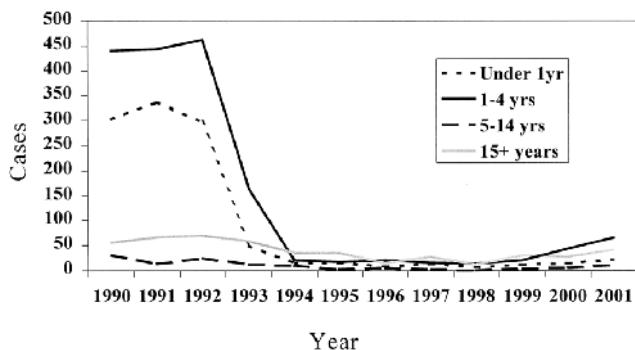

As Hib disease has declined in incidence, some investigators raised the possibility of other organisms filling the disease “niche” left by Hib. Several early studies found no evidence for such “replacement disease” caused by other *H. influenzae* types or other organisms. Neither the National Bacterial Meningitis Surveillance System nor national mortality data showed increased disease due to meningococcus or pneumococcus through 1991, when major declines in Hib disease occurred. Similarly, laboratory-based studies of disease caused by nontype b *H. influenzae* did not show increased rates, Figure 4 [47–49]. Continued surveillance for increased rates of disease by any of these agents in appropriate. However, the role of Hib in human disease was largely a function of the characteristics of the organism, including virulence of the Hib capsule, transmission modalities, and other organism-specific factors; it is unlikely that having another organism filling the ecological niche in the human oropharynx that Hib once filled is sufficient to cause substantial amounts of human disease.

## 2. The United Kingdom

The United Kingdom began routine vaccination against Hib in October 1992. A catch-up program of vaccination against Hib was mounted in the first year after vaccine introduction. It aimed to cover infants and young children up to 4 years of age by offering those below 1 year of age three doses of PRP-T at monthly intervals, while children aged 13 months to 4 years of age were given HbOC as a single dose. Just over a year after the launch, the average national uptake figure for PRP-T in the accelerated schedule was 92% (varying within a tight range of 89–96% for the United Kingdom’s 15 health regions) [50], and the uptake for children aged 1–4 years was around 75% [51].

Coincident with the introduction of Hib conjugate vaccines into the routine immunization schedule in the United Kingdom in 1992, a national prospective surveillance study to detect cases of invasive *H. influenzae* disease in vaccine recipients was undertaken [52]. It sought to determine the incidence of vaccine failure in a large population and to estimate the effectiveness of PRP-T in the field, particularly in the longer term in the absence of a booster dose.

The Hib vaccination program was highly effective, resulting in over 97% reduction in disease incidence in children under 5 years of age in the postvaccination compared with the prevaccine era, from 31 per 100,000 to 0.67 per 100,000 in 1998 in England and Wales (Figure 5). The percentage reduction in disease in infants who would have completed routine primary immunization with three doses of vaccine remained remarkably steady over a period of 3 years, such that in children aged 5–11 months, percentage reduction was 99.4% (95% CI, 98.9–99.6%), in those 12–23 months of age 98.0% (95% CI, 97.0–98.6%), and in those 60–71 months of age, 97.3% (95% CI, 79.2–99.7%) [52]. This high level of population protection was maintained in spite of a gradual and progressive loss in antibody in children, such that by age 72 months, 32% of children had less than 0.15 µg/mL of anti-PRP antibody, a level previously associated with protection. However, from 1999 a small increase in Hib disease in all age groups, in particular

**Figure 5** Invasive Hib infections by age group, 1990–2001, England and Wales. (HRU/CDSC, London, UK.)

those under 5 years who had received 3 doses of Hib vaccine in infancy, was observed (Fig. 5) [52a].

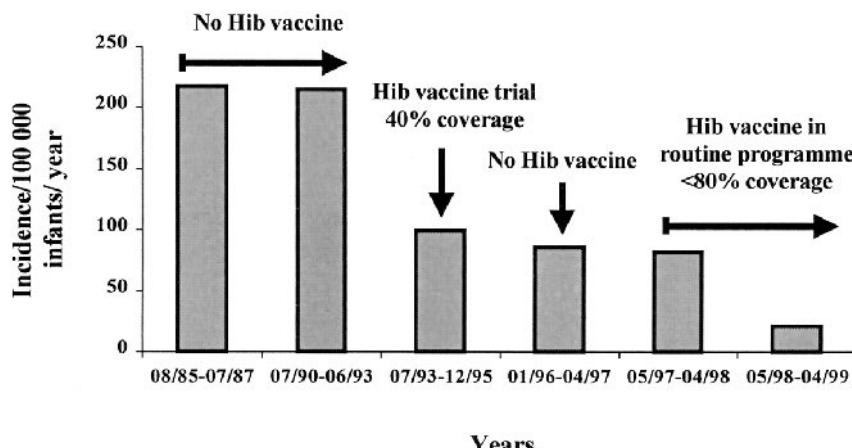

Although overall program effectiveness remains high, the direct protection afforded by the vaccine in the United Kingdom, as measured by the screening method [53,54] was estimated at only 56.7% (95% CI, 42.5–67.4%) between October 1993 and December 2001, incorporating the period of observed increase in disease [52b]. Taking underestimate of vaccine coverage into account, true efficacy may lie nearer 71.8%. Both of these figures are lower than previously published but those earlier figures were based on comparison of attack rates before and the reduction in rates after the introduction of Hib vaccine in vaccinated children [52]. The difference between vaccine efficacy and percentage reduction in disease incidence in vaccinated children confirms the generation of a herd immunity effect. Efficacy was significantly lower in children vaccinated in infancy rather than as part of the UK catch-up cohort; it declined with time since immunization and was significantly lower in a period when DTaP-Hib vaccine was used where previously wholecell DTP-Hib was used exclusively. These findings following the observed increase in cases in all age groups in recent years aided the decision by the Department of Health to

implement a second Hib catch-up campaign in the United Kingdom in 2003 for children between 6 months and 4 years of age [52c]. The need for a routine booster dose in the U.K. program is being kept under review.

### 3. The Gambia

The Gambia was the first country in Africa in which the efficacy of Hib conjugate vaccine was evaluated, and which introduced the vaccine into its routine infant immunization program. Critical impact data were provided from each experience. During a randomized, controlled efficacy trial performed from 1993 through 1995, the vaccine was 94% effective against Hib meningitis [9]. More importantly, vaccinated children had 21% fewer episodes of chest x-ray documented bacterial pneumonia than unvaccinated children. In this study population, for every case of invasive Hib disease prevented, at least three cases of chest x-ray documented pneumonia were prevented.

Soon after the vaccine trial ended, the vaccine was introduced into the routine program. Figure 6 shows the impact of the various Hib vaccine interventions on rate of Hib meningitis in children less than 1 year of age in The Gambia [56]. Two baseline studies confirmed rates of over 200 per 100,000 before immunization began. As a result of the trial, during which an estimated 40% of the at-risk population was immunized, the overall rate of disease dropped by over 50%. After the trial, there was a gap in immunization, when no vaccine was given for approximately 16 months. The rate of Hib disease remained stable. Subsequently, Hib vaccine was introduced as a routine infant immunization (without a catch-up program) and although rates of disease did not change in the first year, the second full year after introduction saw a drop to 21 per 100,000 (95% CI, 7–48%). Several points can be made from these Gambian data. First, the initial impact of the Hib trial was greater than would be expected from vaccination of 40% of the at-risk population, again suggesting the influence of herd immunity. Second, during the interim period when no vaccine was available, Hib disease rates remained low. This phenomenon has been observed in other countries where Hib vaccine was started,

**Figure 6** Incidence rate of *H. influenzae* disease in The Gambia. (From Ref. 56.)

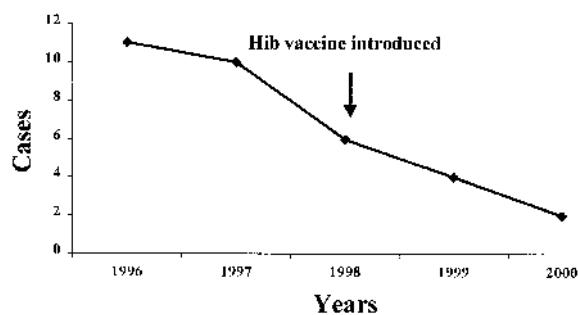

then discontinued, and then restarted. This may be due in part to immunization of the (now) older cohort in the previous year, thus leaving siblings of the incoming birth cohort less likely to carry, and subsequently transmit, the organism. Finally, reinstitution of vaccination, even with less than 80% coverage, resulted in a reduction of over 90%, again, most likely because of the impact on carriage and herd immunity.

#### 4. Uruguay

The government of Uruguay introduced Hib vaccine in 1994. Introduction included immunization of the incoming birth cohort, and catch-up immunization of children up to 5 years of age. Figure 7 shows the number of cases notified to the national government before, during, and after introduction [57]. The Uruguayan experience is a striking example of the rapidity with which Hib vaccine introduction can reduce disease burden, especially when introduced with a catch-up campaign. By vaccinating older children, from whom carriage is most likely transmitted to higher-risk infants, maximal impact on organism transmission can be realized. It must be recognized, of course, that conduct of catch-up campaigns require substantially greater resources and vaccine supply than introduction into the routine infant immunization program alone.

#### 5. Saudi Arabia

Saudi Arabia introduced Hib vaccine nationally in 2002. However, before the national program was put in place, specific populations were offered vaccine, including the families and dependants of employees of the National Guard. Data from the Fahad National Guard Hospital was recently published showing effect of introduction of Hib vaccine into this population [58]. A constant decline in cases was seen over a 3-year period, such that by the last year, there was an 80% reduction in Hib meningitis in this population (Figure 8). The somewhat gradual decline in Hib disease is consistent with other countries, such as Chile and the United States, which did not conduct simultaneous introduction into the infant program and mass catch-up campaigns of all children up to 5 years of age. Another factor which may have contributed to the slower decline in incidence is that the entire country was not being immunized, so

**Figure 8** Number of cases of Hib meningitis in children less than 5 years of age at King Fahad Hospital, Saudi Arabia. (From Ref. 58.)

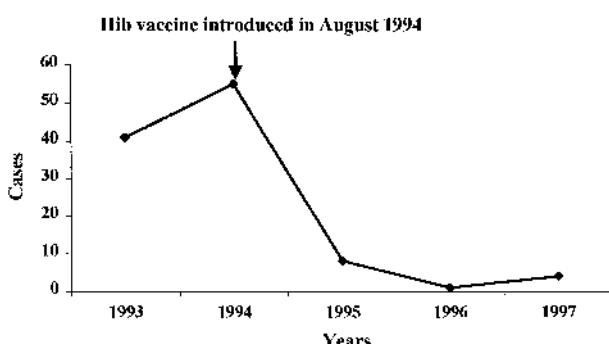

a full "herd" immunity effect could not occur because of the constant reintroduction of the bacteria from children outside the vaccinated group. The clear impact of Hib vaccination in spite of this epidemiological setting is very encouraging.

### III. MENINGOCOCCAL C VACCINE DEVELOPMENT AND IMPACT

#### A. Immunology and Development

The pathophysiology and epidemiology of serogroup C meningococcal disease are similar in some respects to that of Hib, and present some of the same difficulties for vaccine development. The highest attack rate for serogroup C meningococcal disease in the developed world occurs in infancy with a secondary peak in teenagers and young adults. As for Hib, meningococcal capsular polysaccharides are poorly immunogenic in young children. The more immunogenic surface-protein antigens are highly variable and vaccines directed at these antigens would require multiple components. Thus the mechanisms that enable sustained colonization of human hosts have also made vaccine development problematic.

Capsular antigens have been crucial in the development of licensed vaccines against meningococcal C disease [59]. Promising results from early trials of a multivalent pneumococcal polysaccharide vaccine demonstrated that capsular polysaccharides could elicit protective immune responses. Initial trials of candidate meningococcal A and C polysaccharide preparations were disappointing but a new purification technique, developed in the 1960s, enabled the production of highly purified, high molecular weight meningococcal polysaccharides. These were shown to be safe and highly immunogenic in adults and older children and are the basis of the presently licensed bivalent A and C and tetravalent A, C, W135, and Y meningococcal polysaccharide vaccines. However, meningococcal polysaccharide capsules usually act as T-cell-independent antigens. This means that T-lymphocytes are usually not involved in the induction of immune responses against these antigens [60]. T-independent responses are age-dependent, not generally occurring before 18 months of age, and do not induce immunological memory. Consequently, currently licensed polysaccharide vaccines are

**Figure 7** Number of cases of Hib meningitis in Uruguay. (From Ref. 57.)

ineffective in protecting young children against group C disease and do not provide long-term protection.

The relatively recent development of Hib conjugate vaccine was closely followed by the development of meningococcal conjugate vaccines. The vaccines are made from oligosaccharides derived from purified capsular polysaccharides that are chemically conjugated, using different methods, to tetanus toxoid or diphtheria CRM 197 carrier proteins to convert them into T-dependent antigens [61]. Clinical trials of meningococcal C conjugate (MCC) vaccines found them to be immunogenic in all age groups and their reactogenicity profiles were in line with other routinely recommended vaccines with no serious adverse events identified [62–66]. The vaccines also induced immunological memory, which lasted at least 5 years, and are expected to provide long-term immunity against meningococcal C disease [67]. More than 25,000 children received the vaccine in trials worldwide before the first MCC vaccine was licensed in the United Kingdom in September 1999. It was recognized that the low overall incidence of serogroup C disease made Phase III controlled efficacy trials impractical, and licensure was based on recognition that a correlate for protection already existed for serogroup C polysaccharide vaccines in the serum bactericidal assay [68].

## B. Impact of Meningococcal C Conjugate Vaccines

As with many other developed countries, the incidence of laboratory-confirmed meningococcal infection of all types increased through the 1990s in England and Wales. The incidence rose from 2.8 per 100,000 in the 1990/1991 epidemiological year (running from July to June) to 5.3 per 100,000 in 1998/1999. The rise was partly a result of better ascertainment following the wide availability of more sensitive polymerase chain reaction (PCR) methods for the identification and serogrouping of meningococci [69,70].

Historically, approximately 60–70% of all confirmed meningococcal disease in England and Wales was caused by meningococcal B infection. Almost all of the remaining meningococcal infection (25–30%) was due to serotype C. The disease profile changed in the mid-1990s, when the incidence of meningococcal disease increased. Cases of serogroup C disease increased proportionately more than other serogroups, signifying a true rise in the level of endemic serogroup C infection rather than solely better ascertainment. Based on enhanced surveillance, it was estimated that annually there were 1500 cases of meningococcal C infection and that these caused 150 deaths in England and Wales [71]. Cases and deaths caused each year by serogroup C meningococci in those less than 18 years of age were separately estimated at 1137 and 72, respectively [72].

In November 1999, the United Kingdom became the first country in the world to introduce MCC immunization into the routine infant schedule. A national catch-up campaign began on November 1, 1999 and was planned to run over approximately 1 year. All children under 18 years of age (12 million in England and Wales) were offered MCC vaccine during the campaign. At the time that the campaign started, there was only one licensed MCC vaccine available and there were not enough MCC vaccine supplies for all children under

18 years [73]. Further supplies were phased in over the next 12 months as two other MCC vaccines were licensed. Therefore each age group was assigned a time to be immunized within the campaign schedule prioritized according to the profile of meningococcal C disease in the 0–18 years age range.

Vaccine was offered first to all children aged 15–17 years, the age group with the highest disease incidence (other than in those under 2 years of age), the highest risk of outbreaks, and the highest mortality rate. Very shortly after this, the vaccine was introduced into the routine infant schedule at 2, 3, and 4 months of age. The vaccine was offered to different age groups of children as supplies became available through the duration of the campaign, according to the priority assigned to each age group. Recorded MCC vaccine coverage for school children aged 5–17 years inclusive was 85%. Coverage for the catch-up groups of children aged 5 months to 4 years of age was recorded at 78%. Routine infant immunization by first birthday reached 89% coverage by the beginning of 2002 [74].

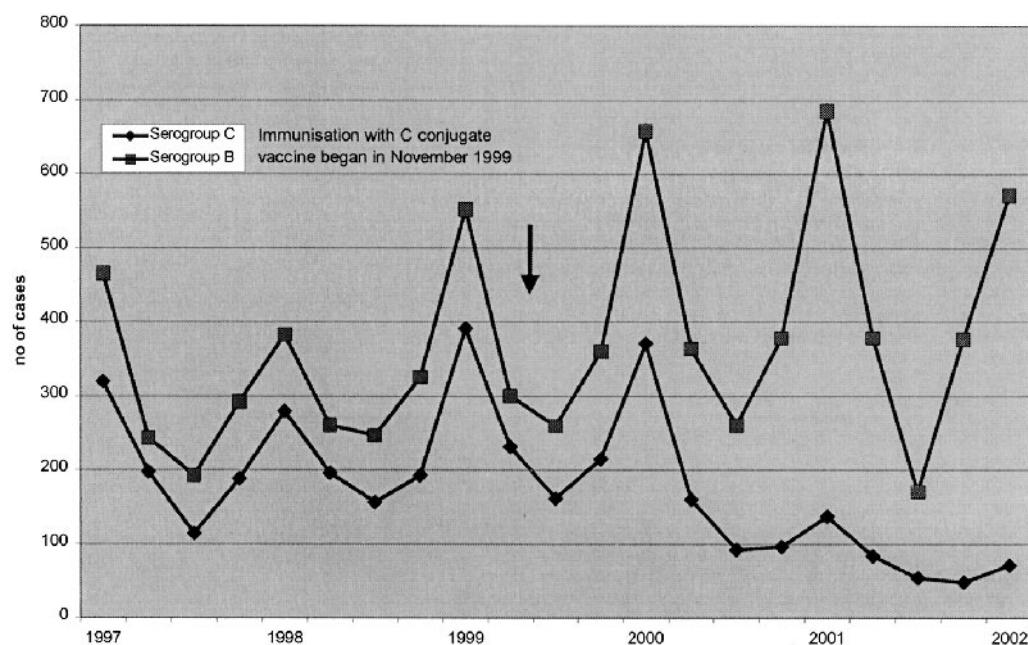

### 1. Impact on Disease

Cases of meningococcal B and C infection in all age groups are shown in Figure 9, for England and Wales, from January 1997 to March 2002 by quarter. This graph clearly demonstrates that, in the 2000/2001 epidemiological year (which runs from July 1 to June 30), Group B cases occurred at the levels previously recorded, while the level of Group C disease was markedly reduced. Group C cases decreased by 56% overall in 2000/2001, compared to 1998/1999.

With the exception of some university/college students offered meningococcal C polysaccharide vaccine only those aged 20 years and over were left completely unimmunized against meningococcal C disease up to the end of the 2000/2001 epidemiological year. The impact of the campaign in each age group targeted for immunization was rapid and marked and occurred in close temporal association to the introduction of the vaccine [75]. In the 2000/2001 epidemiological year, the numbers of confirmed cases of serogroup C disease were consistently 63–94% lower than 1998/1999 in every age group that was targeted for immunization with MCC vaccine in England. Table 5 summarizes the comparative number of group B and C cases in England in each age group for the 1998/1999 and 2000/2001 epidemiological years.

As summarized in Figure 10, in the 2000/2001 epidemiological year, the number of cases of meningococcal C disease in those aged 20 years and over in England was similar to the previous year (with a 6% decrease). The number of cases of group C disease in those under 20 years of age fell from 574 to 130, an overall decrease of 77%. In comparison, the number of cases of group B disease in those aged 20 years and over and under 20 years remained relatively stable with increases of 7% and 9%, respectively.

These data suggest that the changes in the epidemiology of meningococcal disease have been specific to serogroup C and to the age groups that were offered MCC vaccine. These general observations support the suggestion that any changes observed in serogroup C disease in immunized age groups were attributable to the MCC vaccine.

**Figure 9** Laboratory confirmed cases of serogroup B and C meningococci in England and Wales. (Health Protection Agency, Meningococcal Reference Unit, England.)

The number of deaths following meningococcal C infection in England in individuals under 20 years of age fell in the epidemiological year 2000/2001 with 10 deaths compared to 73 deaths in 1998/1999 (source: Office of National Statistics). The number of deaths in those aged 20 years and over increased from 37 to 55 in the same time period: this was in line with the increase in the number of cases of meningococcal C infection seen in that age group over that period of time.

## 2. MCC Vaccine Efficacy

Up to the end of the 2000/2001 epidemiological year, immunization status had been determined in 98% of confirmed serogroup C cases in individuals eligible for immunization with MCC vaccine in England and Wales. The short-term efficacy of this MCC vaccine was 97% (95% CI, 77–99.9%) for teenagers and 92% (95% CI, 65–98%) for toddlers during the first 9 months following the introduction of the

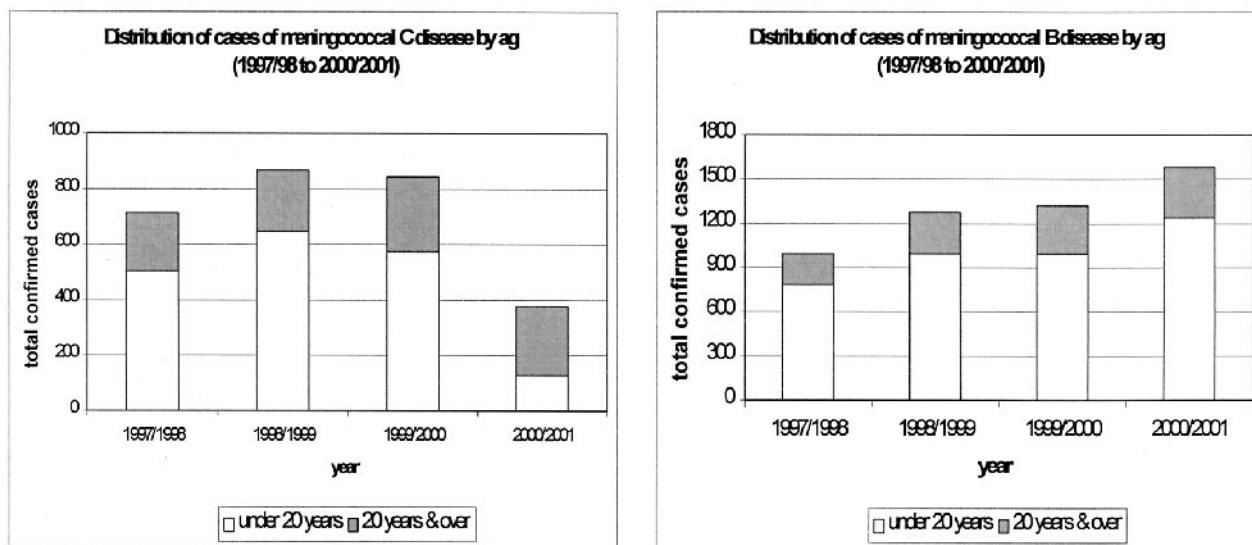

vaccine [76]. After 18 months of follow-up in England, the estimated efficacy in 15- to 17-year-olds was 93% overall (95% CI, 79–96%) and 89% (95% CI, 72–96%) for toddlers [73]. The preliminary data on vaccination status of cases in each of the other vaccinated age group is consistent with a high vaccine efficacy in the short term. Surveillance is continuing in order to monitor long-term efficacy that will depend on the ability to mount a rapid booster response on exposure to the organism. This is particularly important in the light of recent changes in the epidemiology of Hib disease in the United Kingdom with associated changes in the effectiveness of the Hib vaccine program and as no meningococcal vaccine booster is currently given in the U.K. program.

## 3. Meningococcal Isolates

Concerns have been raised about the possibility of capsule switching arising from selection pressure by MCC vaccine on

**Table 5** Impact of Serogroup C Meningococcal Conjugate Vaccine—Number of Cases of Confirmed Meningococcal B and C Disease in England in 1998/1999 and 2000/2001 Epidemiologic Years (July 1–June 30)

Age group	Cases of serogroup C disease			Cases of serogroup B disease		
	1998/1999	2000/2001	% Change	1998/1999	2000/2001	% Change
Under 1	98	18	-82%	311	337	8%
1–4 yr	194	42	-78%	376	509	35%
5–8 yr	71	26	-63%	93	119	28%
9–10 yr	18	1	-94%	29	26	-10%
11–14 yr	74	9	-88%	47	88	89%
15–19 yr <sup>a</sup>	190	34	-82%	139	182	31%
20+ yr	222	257	16%	283	347	23%

**Figure 10** Distribution of cases of meningococcal C and B disease in England in age groups targeted and not targeted by meningococcal C conjugate vaccine (1997/1998 to 2000/2001). (Health Protection Agency, Meningococcal Reference Unit, England.)

serogroup C strains [77]. If capsule switching occurred more serogroup B strains would be expected to display P1.5/NT/NT or P1.5/P1.2/NT sero-subtype patterns (the common sero-subtypes of serogroup C). The analysis of sero-subtype for groups B and C for the years 2000 and 2001 showed no evidence of increases in group B organisms with sero-subtypes corresponding to the more common C strains (P1.5, P1.2) (personal correspondence Manchester Reference Unit). Therefore there is no evidence of capsule switching occurring to date.

#### 4. Use of Meningococcal C Conjugate Vaccine in Other Countries

The meningococcal C conjugate vaccine was launched in the Republic of Ireland at the beginning of October 2000 against a background of high and increasing meningococcal C infection [17]. Ultimately, everyone under the age of 23 years will be offered the vaccine. Groups B and C are the predominant forms of invasive meningococcal disease seen in Ireland, accounting for approximately 60–65% and 30–35% of cases, respectively. The incidence of group C disease fell dramatically in 2000/2001 from 4.6 per 100,000 (167 cases, excluding 1 imported case) in 1999/2000 to 1.8 per 100,000 population (66 cases, excluding 1 imported case) in 2000/2001, a 61% reduction [78]. The incidence of group C had declined in all age groups other than the over 24 years age group during this period. The incidence of group B invasive meningococcal disease (IMD) also fell, but to a lesser extent, by 14% to 6.5 per 100,000 population in 2000/2001 from 7.6 per 100,000 population in 1999/2000.

There are currently recommendations for routine MCC vaccine use in the United Kingdom, Republic of Ireland, Luxembourg, and all regions in Spain (<http://www.aepap.org/calvaces.htm>). The vaccine has also been introduced into

Belgium and Greece, for administration on a voluntary basis by clinicians; use is said to be high in both countries [23]. The Netherlands and Madeira, an autonomous region of Portugal, propose to use the vaccine in 2002.

The vaccine has also been used in France and Hungary. In Canada, the Quebec government announced in the summer of 2001 that meningococcal C conjugate vaccine would be offered to all residents under the age of 20 years.

#### IV. CONCLUSIONS

The success of Hib conjugate vaccines in countries that have immunized the majority of children has been stunning, ranging from elimination of disease in nations with very high immunization coverage to declines of over 95% in countries with somewhat lower immunization rates. Similarly, early data on impact of the meningococcal C conjugate vaccine are impressive. Worldwide use of Hib and meningococcal C conjugate vaccines could lead to elimination of these infections. However, major obstacles stand in the way of achievement of this goal. Conjugate vaccines currently are expensive, and implementation of standard regimens into many national immunization programs schedules poses a daunting challenge for available health care resources, particularly in developing countries. Progress is needed in reducing production and distribution costs. Equally as important is interaction between ministries of health and immunization partners to enhance support for conjugate vaccine immunization programs. Accurate estimates of the burden of disease as well as clearly defined examples of impact are needed to contribute to the political will to use these vaccines. Continued surveillance for disease in countries that have introduced these vaccines is essential, both to identify poorly served populations, and to assess the

impact of different strategies, for example, use of a booster dose of Hib vaccine. Finally, efforts to enhance routine immunization coverage, including improved logistics and decreasing dropout rates of children returning for multidose regimens are critical. Most of these challenges are common to all childhood immunization programs, however, and the existence of these new, effective tools for elimination of a much-feared disease of childhood can contribute to the will to overcome these obstacles for all vaccines.

### I. EPIDEMIOLOGY AND IMPLICATIONS FOR VACCINE DEVELOPMENT

Few infectious pathogens match the global impact of *Streptococcus pneumoniae* infections. In industrialized countries, *S. pneumoniae* is the most common identified bacterial cause of hospitalization for pneumonia, meningitis, and acute otitis media [1–3]. Invasive pneumococcal infections are most common among the very young (generally, 100–200 cases per 100,000 persons aged <2 years per year) and the elderly (45–90 per 100,000 persons aged >65 years per year) (Figure 1) [4–9]. Attack rates for persons aged 85 years and older are similar to those in infants [6]. These numbers translate into 106,000–175,000 hospitalizations and 7000–12,500 deaths in the United States annually [10]. Certain racial and ethnic groups, such as American Indians and Alaska Natives, are at increased risk for serious pneumococcal infections, as are individuals with underlying illnesses such as human immunodeficiency virus (HIV) [4,5,7–9,12,13].

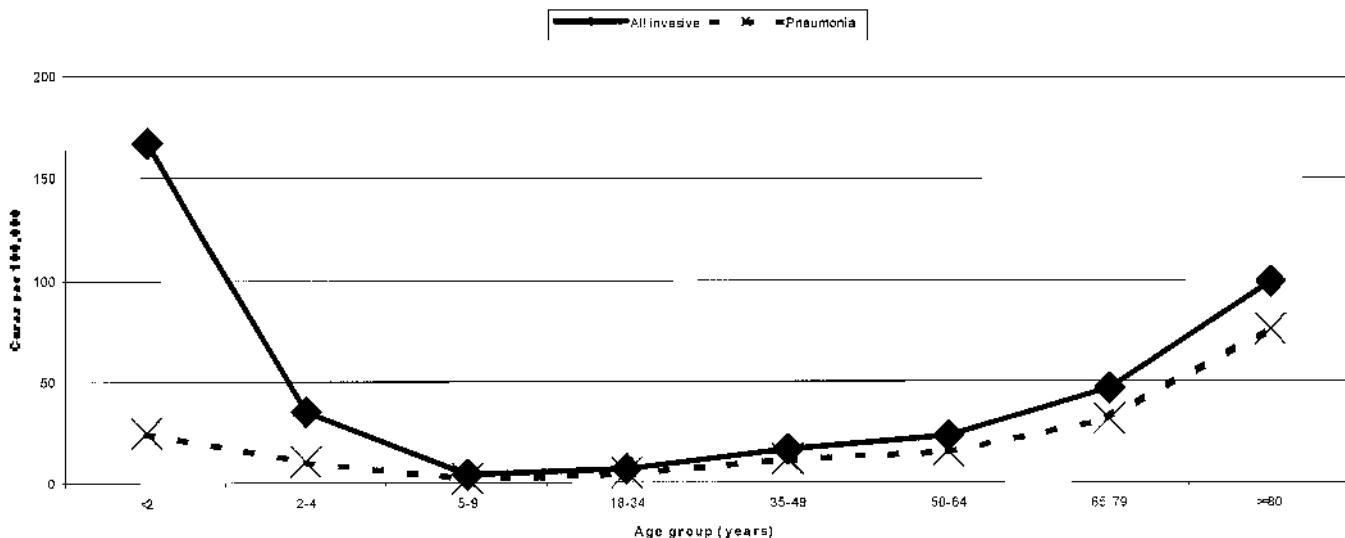

In developing countries, pneumococcal infections are a major cause of morbidity and mortality among infants and young children. The World Health Organization (WHO) estimates that >1 million young children die annually of pneumococcal infections [14]. Greater than 90% of these deaths occur in the developing world and most of these deaths are attributed to pneumococcal pneumonia. Pneumococcal meningitis is severe, with a high case fatality rate (up to 50%, even with antibiotic therapy) and a high risk (~20–25%) of long-term disability among survivors [15,16]. The burden of pneumococcal disease among adults in the developing world may also be substantial because acute respiratory infections are the leading infectious causes of adult mortality, *S. pneumoniae* is the leading etiological

agent identified in adults hospitalized with severe pneumonia [17–21], and the prevalence of risk factors known to increase the risk of pneumococcal disease (such as HIV infection and cigarette smoking) is common in many developing countries [11,22].

Estimates of the burden of pneumococcal disease vary, depending on case definition and case finding methodology. The most specific definition of pneumococcal disease is based on the isolation of pneumococci from normally sterile body sites (e.g., blood, cerebrospinal fluid, and pleural fluid). The sensitivity of this definition, though, is low. Therefore, incidence rates based only on isolates from sterile body sites underestimate the overall disease burden. Case finding based on disease syndromes commonly caused by the pneumococcus, such as community-acquired pneumonia or acute otitis media, captures a more complete picture of the burden of pneumococcal disease, but these data are quite nonspecific. The accuracy and the specificity of alternative diagnostics, such as sputum Gram stain and culture, pleural fluid and urine antigen testing, polymerase chain reaction (PCR), and serological assays, are limited and can be unacceptably low among patients who are merely colonized with *S. pneumoniae* [23–33]. The challenges to accurate measurement of the burden of pneumococcal disease are exacerbated in developing countries [34] where few, if any, laboratory resources are consistently available for diagnosis.

#### A. Serotype Distribution

For vaccines directed against the capsular polysaccharides, the distribution of serotypes causing illness is critically important. For practical and economic reasons, only a limited

**Figure 1** Age-specific incidence of pneumococcal disease in the United States, 1998.

number of serotypes are included in conjugate pneumococcal vaccine formulations [35]. The first licensed pneumococcal conjugate vaccine contains capsular polysaccharides of seven serotypes (4, 6B, 9V, 14, 18C, 19F, and 23F) (Table 1). Other vaccines under evaluation cover 9, 11, or 13 serotypes. To some degree, the relative importance of individual pneumococcal serotypes differs by age group, clinical syndrome, and geographical area, and over time. Optimal vaccine formulations need to target the serotypes that most commonly cause diseases among populations to be vaccinated.

The seven serotypes in the first licensed conjugate vaccine account for >80% of isolates from blood and cerebrospinal fluid of children aged <2 years in the United States compared with <60% of isolates from older children and adults [9]. Vaccine formulations that are based on the most prevalent serotypes among young children may not

provide optimal serotype coverage for the prevention of pneumococcal infections in adults. The addition of four serotypes to the seven-valent vaccine formulation (1, 3, 5, and 7A) would add coverage for <2% of isolates from children aged under 2 years, but would increase coverage by nearly 10% among older children and adults [9].

The distribution of serotypes causing otitis media differs from that of isolates causing bacteremia and meningitis. In national surveillance in the United States, the seven most common serotypes causing bacteremia and meningitis in children aged <6 years, plus serologically related serotypes (6A, 9A, 9L, 18B, and 18F), accounted for only 65% of 314 isolates from middle ear fluid during 1978–1994 [36]. Serotype 3 accounted for 9% of middle ear fluid isolates but <1% of blood or cerebrospinal fluid isolates. More recent data from the United States with a larger number of isolates

**Table 1** The Seven Pneumococcal Serogroups Most Frequently Causing Invasive Disease Among Young Children, by Region

Region	Rank order of isolation frequency						
	First	Second	Third	Fourth	Fifth	Sixth	Seventh
United States and Canada	14 (27.8)	6 (17.0)	19 (14.3)	18 (8.6)	23 (7.4)	9 (6.3)	4 (6.3)
Asia	1 (11.7)	19 (10.8)	6 (9.9)	5 (9.1)	14 (8.0)	7 (6.4)	23 (5.3)
Africa	6 (23.8)	14 (18.9)	1 (12.7)	19 (11.7)	23 (4.2)	5 (4.0)	15 (3.8)
Europe	14 (18.7)	6 (15.4)	19 (12.7)	18 (9.6)	23 (8.1)	9 (6.3)	1 (6.1)
Latin America	14 (22)	6 (13.9)	5 (9.2)	1 (8.2)	19 (7.9)	23 (7.9)	18 (5.5)
Oceania	14 (24.0)	6 (15.9)	19 (14.2)	18 (6.6)	23 (6.4)	9 (6.3)	4 (4.2)

Serogroups included in seven-valent Pnc-CRM<sub>197</sub> are in bold. Numbers in parentheses are the proportion of all sterile site isolates for each serogroup. (From Ref. 45.)

show that the proportion of isolates that would be covered by the current heptavalent vaccine is much higher (>86%) during the first 3 years of life, but falls thereafter [37]. Preliminary data from a large international collaborative study that analyzed isolates obtained from over 3000 children with acute otitis media indicates that serotypes 6B, 14, 19F, and 23F were isolated most frequently among children aged 10–18 months, an age when the incidence of acute otitis media is highest (W. Hausdorff, personal communication). The prevalence of individual serotypes appears to shift slowly over a period of decades rather than years. At the Boston City Hospital, serotypes 1, 2, and 3 accounted for roughly one-half of isolates from all sites prior to 1950, but during 1979–1982, they accounted for <5%, whereas serogroups 4, 6, 14, 18, and 19 became increasingly common [38–41]. Of 3644 isolates from blood collected at 10 U.S. hospitals between 1967 and 1975, serotypes 1, 2, and 3 accounted for 8.5%, 0.3%, and 7.1%, respectively [42]. In contrast, among the >7000 blood isolates serotyped at Centers for Disease Control and Prevention (CDC) from 1978 to 1995, only one was serotype 2. In 1998, the proportion of serotype 1 and serotype 3 isolates from blood submitted to the CDC through population-based surveillance was down to 2.4% and 3.3%, respectively [9]. Factors contributing to the apparent decline in serotypes 1, 2, and 3 invasive diseases and the increases in disease caused by other serotypes are unknown.

Serotypes that most commonly cause invasive pneumococcal infection differ somewhat in various regions of the world. Serogroups 6, 14, and 19 are leading causes of invasive pediatric pneumococcal disease in all regions (Table 1) [43–45]. Serogroup 1 continues to be a common cause of invasive diseases in Asia, Africa, Latin America, and parts of Europe, but is uncommon in the United States, Canada, Oceania, and Scandinavia [45,46]. Differences in the prevalence of serotype 1 among ethnic groups also occur. In southern Israel, serotype 1 accounts for 10–14% of invasive infections among Jewish children compared with 32–38% of infections among Bedouins [47]. In Alaska, serotype 1 caused 7% of invasive infections among Alaska Native children aged <5 years during 1991–1998 but was recovered from only 1 of over 200 non-Native children [12].

Some investigators have suggested that the observed geographical variability in serotype distribution reflects variations in blood culture practices [48]. Prospective studies will be required to test this hypothesis.

The global acquired immune deficiency syndrome (AIDS) epidemic also influences serotype distributions [49,50]. In South Africa, a greater proportion of HIV-positive adults had invasive disease caused by serogroups usually associated with infection in children (6, 14, 19, and 23) compared with HIV-negative adults. Serotype 1 was less common among HIV-infected persons of all ages compared with those without HIV [51,52].

## II. IMMUNOBIOLOGY AND VACCINE DESIGN

Immunization with a polysaccharide covalently coupled to an immunogenic protein elicits isotype switching primarily

to IgG1, a strong memory response, and involvement of T-cell help [53,54]. These features, which are characteristic of T-dependent antigens, make good immunogens in young children and yield booster responses with repeated administration.

The development and production of conjugate vaccines is a complex process. The process must minimize structural, chemical, and stoichiometrical changes to the individual components (carrier protein and polysaccharide) and couple the polysaccharide directly to the protein carrier in a one-step reaction. This procedure also must be optimized for each polysaccharide in the vaccine.

The combination of vaccines into multivalent formulations can result in a decrease in immunogenicity of one or more components. In the case of conjugated vaccines, the underlying mechanism for this suppression is not well understood, but appears to be associated with increasing dosage of the carrier protein [55]—a phenomenon called “carrier-induced epitope suppression.” Some studies have shown that epitope suppression can occur when a subject is immunized with an antigen conjugated to a carrier molecule to which the subject is immunologically experienced [56–58].

Theoretically, protein carrier-induced epitope suppression could prevent the boosting effect for pneumococcal polysaccharide antigens in individuals already primed to the carrier. In humans, carrier-induced epitope suppression may be dependent on vaccine dose, which may be highly antigen-specific and, thus, quite unpredictable in individual volunteers [58]. Preexposure to the protein carrier has, in fact, led to immune enhancement for several protein antigens and for responses to Hib capsular polysaccharide [54]. It will be necessary to determine whether different combinations of each conjugate, when part of multivalent formulations, result in a significant alteration in the immunogenicity of the combination vaccine components compared to the conjugates alone.

## III. ISSUES IN MEASUREMENT OF THE IMMUNE RESPONSE TO CONJUGATE VACCINES

Licensure of new pneumococcal conjugate vaccines will need to be based on *in vitro* measures of immune response. This approach was successfully used to license a Hib conjugate vaccine in the United States in the 1990s. Approval was based upon the use of immune correlates of protection to show the comparability of the candidate with previously licensed Hib conjugates. A similar approach will be needed for approval of new pneumococcal conjugate vaccines.

Several issues complicate the establishment of immune correlates of protection. First, there are at least two measures of immune response that can be used to evaluate immunogenicity—serum IgG antibody concentration and opsonophagocytic activity. Second, the amount of antibody or opsonophagocytic antibody needed may vary by serotype, and hence require serotype-specific correlates. Third, the concentrations or titers that correlate with protection against invasive diseases may not be adequate for protection against mucosal infections such as pneumonia, otitis

media, or carriage. Fourth, for the evaluation of vaccines that contain new serotypes not included in any existing licensed vaccine, comparison to licensed vaccines will not be possible.

Typically, pneumococcal conjugate vaccine immunogenicity has been measured as the concentration of specific serum IgG (expressed as µg/mL) antibody following vaccination. Measuring IgG antibody concentrations is useful because these antibodies enhance opsonization, complement-dependent phagocytosis, and killing of pneumococci by leukocytes and other phagocytic cells, and because the assay (an enzyme immunoassay) is relatively straightforward to standardize. Increases in serum IgG antibody concentration following primary vaccination are also generally accompanied by an increase in antibody avidity. Improved antibody avidity indicates immunological maturation and corresponds with the establishment of immunological memory. Immunological memory, not antibody concentration postimmunization, may be the effector mechanism ultimately responsible for protection against invasive disease.

Opsonophagocytic activity is a more rigorous measure of protection provided by antipolysaccharide antibodies. Antibody avidity correlates better with opsonophagocytic activity in vitro than with the concentration of serum IgG antibody [59], and protection against experimental challenge infection correlates better with opsonophagocytic activity than with total antibody concentration [60]. The role of subclass distribution of antibodies, alone or in combination with functional activity, remains to be determined. Attempts to standardize the opsonophagocytic assay among international laboratories are currently underway. An opsonophagocytic assay developed by scientists at the CDC uses the HL-60 tissue culture cell line, and has been validated against the traditionally used human peripheral blood polymorphonuclear leukocytes. This assay is performed by flow cytometry using fluorescently labeled bacteria, and titers to multiple serotypes can be simultaneously estimated [61,62].

#### **IV. CLINICAL EVALUATIONS IN INFANTS AND YOUNG CHILDREN**

##### **A. Safety**

Pneumococcal conjugate vaccines are generally well tolerated among infants and toddlers. Currently, the pneumococcal conjugate vaccine with the most extensive safety evaluation is a seven-valent vaccine (Pnc-7 CRM<sub>197</sub>, Prevnar™; Wyeth Vaccines, Pearl River, NY). Each dose of Pnc-7 CRM<sub>197</sub> contains 2 µg each of capsular polysaccharides from serotypes 4, 9V, 14, 19F, and 23F; 2 µg of oligosaccharide from serotype 18C; and 4 µg of polysaccharide from serotype 6B, conjugated to approximately 20 µg of a recombinant diphtheria toxinoid, cross-reactive material (CRM) 197. Pnc-7 CRM<sub>197</sub> has been licensed and routinely used since 2000 in the United States. With this vaccine, local and systemic reactions such as swelling, redness, and fever are less frequently observed than with diphtheria–tetanus–whole cell pertussis (DTwP) vaccines, but more frequent than with

hepatitis B or diphtheria–tetanus–acellular pertussis (DTaP) vaccines [63,64]. In a large randomized trial, vaccination with Pnc-7 CRM<sub>197</sub> was not associated with an increased risk of outpatient visits for allergic reactions, asthma, wheezing, shortness of breath, or breath holding within 3 days of any dose. Further evaluation of the long-term safety of pneumococcal conjugates is ongoing.

##### **B. Immunogenicity**

The antibody response varies by serotype and is potentially influenced by the type and dose of saccharide used, the protein carrier to which the saccharide is conjugated, the type of protein–saccharide linkage used, and the simultaneous coadministration of other vaccines. Immunogenicity studies in infants illustrate the effect of different types of saccharides. Daum et al. [65] examined the response of infants to three different antigen concentrations of multivalent polysaccharide and oligosaccharide vaccines containing up to five different serotypes. For nearly all serotypes included in the vaccine, the antibody concentrations following three doses of vaccine were greater in the infants who received the polysaccharide formulation compared to those who received the oligosaccharide formulation (Table 2) [65]. No significant differences were noted for any of the local reactions or measured adverse events associated with the two prototype vaccines. The polysaccharide formulation may be more immunogenic than a comparable oligosaccharide design because it displays more epitopes [66]. Further Phase II and Phase III studies have used the polysaccharide formulation.

The effect of the dose of protein–saccharide seems to vary by vaccine type. In the study by Daum et al. [65], the differences between doses (0.5, 2.0, and 5.0 µg) were minor in comparison to the differences between polysaccharide and oligosaccharide preparations (Table 2). With a four-valent PncT vaccine candidate, the antibody responses appeared to be inversely associated with the dose used [67]. The antibody concentrations were highest in the group that received 1 µg compared to groups that received 3- or 10-µg formulations.

The kinetics of the antibody response vary according to serotype. With a candidate five-valent Pnc-CRM<sub>197</sub> vaccine, increased antibody concentrations were seen after one dose for serotypes 18C and 19F and after two doses for serotypes 14 and 23F, but antibodies to 6B did not increase substantially until after three doses (Table 2) [65]. Similarly, an immunogenicity study of a quadrivalent vaccine manufactured by conjugating pneumococcal polysaccharides to outer membrane proteins of group B meningococcus (Pnc-OMP) infants showed good antibody responses to serotypes 14 and 19F following one or two doses of vaccine, but antibody increases were more gradual for serotypes 6B and 23F, with substantial concentrations not appearing until two or three doses [68].

The simultaneous administration of other vaccines also can impact the antibody response to some pneumococcal conjugate vaccines. Specifically, administration of acellular pertussis (aP) vaccine significantly reduces the immunogenicity of simultaneously administered pneumococcal saccha-

<sup>a</sup> Approximately 50 subjects were enrolled per group and immunized at 2, 4, and 6 months of age.

<sup>b</sup> Received combination diphtheria–tetanus–whole cell pertussis–Hib conjugate vaccine.

<sup>c</sup> Polysaccharide at 5.0, 2.0, or 0.5  $\mu\text{g}$  per serotype.

<sup>d</sup> Oligosaccharide at 5.0, 2.0, or 0.5  $\mu\text{g}$  per serotype.

rides conjugated to tetanus toxoid (T-conjugates), but not those conjugated to diphtheria toxoid (D-conjugates) [69]. The exact biological mechanism for this observation is unclear, but it is possible that wP vaccines provide a powerful adjuvant effect that is needed by the T-conjugates, but not the D-conjugates.

### C. Efficacy

#### 1. Seven-Valent Pnc-CRM<sub>197</sub>

Three large-scale, randomized, controlled trials of this vaccine have been conducted in northern California, Finland, and the Apache and Navajo nations of the southwestern United States (Table 3).

*Kaiser Permanente, Northern California.* This individually randomized, controlled, double-blinded trial of efficacy served as the pivotal trial for the licensure of this vaccine [64]. The study was conducted among children enrolled in a large managed care plan, the Northern California Kaiser Permanente group. The trial was designed to assess the efficacy of a four-dose regimen for the prevention of culture-proven invasive pneumococcal disease in young children. A total of 37,868 infants were randomly assigned to receive either Pnc-7 CRM<sub>197</sub> or an investigational meningococcal serogroup C conjugate vaccine containing CRM<sub>197</sub> at the ages of 2, 4, 6, and 12–15 months.

Infants were followed in blinded fashion for a period of 3.5 years. In the intention-to-treat analysis, 49 cases of

culture-confirmed invasive pneumococcal diseases due to vaccine serotypes were observed among the control vaccine recipients versus three cases among the pneumococcal conjugate vaccine recipients for an efficacy of 93.9% (95% CI: 79.6, 98.5). The per-protocol analysis showed that only 1 of 40 cases occurred among recipients of the pneumococcal conjugate vaccine for an efficacy of 97.4% (95% CI: 82.7, 99.9). Subsequent analyses showed that partially vaccinated children (e.g., <3 doses of vaccine) were significantly protected against invasive disease.

Serotype specific efficacy was 100% for the serotypes 14, 18C, and 23F components, and 84.6% for serotype 19F. Data were not sufficient to determine efficacy for serotype 6B, 9V, or 4, or to determine whether there was significant cross-protection against other serotypes in the same serogroup (e.g., serotype 6B vaccination providing protection against serotype 6A disease).

The majority of invasive pneumococcal diseases detected during this trial were bacteremia without an obvious focus (30 of 52 cases detected). There were five cases of pneumococcal meningitis and six cases of sepsis in control vaccine recipients, with no cases of meningitis and one case of sepsis among the pneumococcal vaccine recipients. These results are encouraging, but effectiveness against the most severe manifestations of pneumococcal disease will most likely be documented through postlicensure surveillance studies.

In addition to the primary endpoint of invasive disease, Black et al. [64] were able to assess the vaccine's efficacy

**Table 3** Results of Randomized, Controlled Trials of Pneumococcal Conjugate Vaccine Efficacy

Trial site	Vaccines		Efficacy (95% LL, UL)				
	Pneumococcal	Control	N	Vaccine-type pneumococcal invasive disease	Vaccine-type otitis media	All pneumococcal otitis media	Radiographic pneumonia with consolidation
Northern California, USA	Seven-valent-CRM <sub>197</sub>	MenC-CRM <sub>197</sub>	37,868	97% (83, 100)			19% (6, 30)
Navajo and Apache Nations, USA	Seven-valent-CRM <sub>197</sub>	MenC-CRM <sub>197</sub>	8,292	77% (-9, 95); 83% (21, 96) <sup>a</sup>			-3% (-60, 33)
Finland	Seven-valent-CRM <sub>197</sub>	Hepatitis B	1,662		57% (44, 67)	34% (21, 45)	
Finland	Seven-valent-OMP	Hepatitis B	1,666		56% (44, 66)		
South Africa	Nine-valent-CRM <sub>197</sub>	Placebo	~40,000	HIV-negative: 85% (32, 98); HIV-positive: 58% (-1, 84)			
					HIV-negative: 22% (0, 40); HIV-positive: 6% (-21, 27)		

<sup>a</sup> Intention-to-treat analysis

against clinically defined otitis media. In the intention-to-treat analysis, there were 17 cases of spontaneously ruptured tympanic membranes among controls and six cases among vaccinees for a point estimate of efficacy of 64.7% ( $P = 0.035$ ). Of note, all the positive cultures among vaccinees were serotype 19F. The vaccine showed significant protection against endpoints that are more frequent but less specific than pneumococcal otitis media, including protection against clinically defined otitis media and ventilatory tube placement.

The efficacy against pneumonia with x-ray evidence of consolidation was also assessed in this study. The vaccine reduced the incidence of pneumonia with consolidation by 19% (95% CI: 6, 30).

*Finland.* An individually randomized, double-blinded, controlled trial of the efficacy of a four-dose regimen of the seven-valent Pnc-CRM<sub>197</sub> conjugate vaccine was conducted in three areas of Finland [63]. This trial's primary objective was to determine the efficacy of the vaccine for the prevention of acute otitis media due to pneumococcal serotypes included in the vaccine. Over a 3.5-year period, 1662 children were enrolled into the trial. Equal numbers of children received Pnc-CRM<sub>197</sub> vaccine or a control regimen of hepatitis B vaccine. This study was designed as a three-arm trial, with an equal number of children also receiving a candidate seven-valent vaccine using a different protein, the outer membrane protein of serogroup B *Neisseria meningitidis* (seven-valent Pnc-OMP). (For details of the results with the Pnc-OMP vaccine, see below.) Children were vaccinated at the ages of 2, 4, 6, and 12 months.

A standardized definition of acute otitis media was developed, which included signs, symptoms, and the appearance of the tympanic membrane. For the prevention of clinically defined episodes of acute otitis media, the protective efficacy estimate was 6% (95% CI: -4, 16). For the prevention of recurrent otitis media—defined as at least three episodes in 6 months, or four or more episodes in 12 months—the vaccine's efficacy was estimated at 16% (95% CI: -6, 35).

A unique feature of the Finnish trial was its ability to routinely carry out myringotomy to collect middle ear fluid for bacteriological culture from patients with acute otitis media. This allowed the study to assess the efficacy of the vaccine for the prevention of ear infections due to *S. pneumoniae*. The study showed significant protection against acute otitis media episodes due to pneumococci of serotypes included in the vaccine (VE = 57%; 95% CI: 44, 67), and also, significant protection against certain pneumococci of the same serogroup but of a different serotype—6A, 9N, 19A, 18B, and 23A (VE = 51%; 95% CI: 27, 67). Of note, there was a 33% increase in the risk of otitis media due to nonvaccine type pneumococci among vaccinees, which was of borderline statistical significance (VE = -33%; 95% CI: -80, 1). This finding of an increased risk of nonvaccine-type otitis media is not surprising given that other studies have shown that the vaccine reduces the prevalence of colonization with vaccine serotypes, but often is associated with an increase in colonization with nonvaccine serotypes (see below).

*Navajo/Apache Nations.* In this high-incidence population, a uniquely designed efficacy trial was conducted [70]. Unlike the other trials, where individual infants were randomized to a vaccine group, this study randomized on the basis of community units on an Indian reservation. This community-randomized trial of the efficacy of a four-dose regimen of the seven-valent Pnc-CRM<sub>197</sub> conjugate vaccine was unique among the trials with this vaccine because of its ability to measure the indirect (i.e., herd immunity) effects of vaccination. The control communities received the investigational meningococcal C conjugate vaccine; all participants and investigators were blinded to vaccine group allocations. The study's primary objective was to measure the effectiveness of community-wide vaccination for the prevention of invasive pneumococcal disease. Secondary objectives included an assessment of the impact of vaccination on pneumococcal carriage among vaccinees and the impact on transmission in households.

The trial enrolled 8292 infants from 8 randomization units. Enrollment and surveillance were truncated by the licensure of the vaccine in February 2000. In the per-protocol analysis, there were eight cases of vaccine-type invasive disease among control vaccinees and two cases among pneumococcal conjugate vaccinees (VE = 76.8%; 95% CI: -9, 95); the intention-to-treat analysis included three additional cases in the control group for a vaccine efficacy estimate of 82.6% (95% CI: 21, 96) [71].

## 2. Seven-Valent Pnc-OMP

*Finland.* This candidate vaccine's efficacy against serotype-specific otitis media was evaluated in the same randomized, controlled trial as the seven-valent Pnc-CRM<sub>197</sub> vaccine (see "Seven-Valent Pnc-CRM<sub>197</sub>" for detailed information) [72]. In all, 835 children were enrolled in the Pnc-OMP group as compared to 831 in the hepatitis B vaccine group. Infants were vaccinated with Pnc-OMP at the ages of 2, 4, 6, and 12 months, except for the last 187 enrolled infants who received unconjugated pneumococcal polysaccharide vaccine at the age of 12 months.

The vaccine regimen was associated with a 56% reduction in acute otitis media due to vaccine serotypes (95% CI: 44, 66). Serotype-specific efficacy estimates ranged from a low of 37% (95% CI: 1, 59) for serotype 19F to a high of 82% (95% CI: 12, 96) for serotype 9V. Overall, the vaccine reduced the incidence of pneumococcal acute otitis media by 25% (95% CI: 11, 37). The overall frequency of acute otitis media, however, did not differ between the two groups.

## 3. Nine-Valent Pnc-CRM<sub>197</sub>

*South Africa.* A randomized, placebo-controlled efficacy study was conducted in Soweto, an urban area near Johannesburg, South Africa. The trial was designed to assess the efficacy of a three-dose, accelerated regimen of vaccination (ages of 2, 3, and 4 months) for the prevention of invasive disease and x-ray-confirmed pneumonia in HIV-

positive and HIV-negative infants and children. The preliminary results of the study were presented in May 2002 at the International Symposium on Pneumococci and Pneumococcal Diseases in Anchorage, AK.

In HIV-infected children, the vaccine provided 58% efficacy versus invasive pneumococcal diseases of vaccine serotypes (per-protocol analysis, 95% CI: -1, 84). The vaccine did not show a significant reduction in the incidence of pneumonia with consolidation (VE = 6%; 95% CI: -21, 27), but this finding is not surprising considering the substantial role of *Pneumocystis carinii* and other organisms as agents of pneumonia in HIV-infected children.

In HIV-uninfected children, the vaccine demonstrated highly significant efficacy against invasive pneumococcal diseases due to vaccine serotypes (VE = 85%; 95% CI: 32, 98). Against pneumonia with x-ray evidence of alveolar consolidation, the vaccine efficacy estimate was 22% (95% CI: 0.1, 40) ( $P = 0.049$ ). Of relevance for public health purposes, in the per-protocol analysis, the vaccine prevented three times as many cases of x-ray pneumonia with consolidation (33 cases) as it did culture-confirmed invasive pneumococcal disease (11 cases), indicating that most of the cases of pneumococcal diseases prevented by this vaccine will be undetected by routine culture methods.

*The Gambia.* A randomized, placebo-controlled trial design is testing the efficacy of the nine-valent pneumococcal conjugate vaccine for the prevention of severe pneumococcal diseases including culture-confirmed invasive disease and x-ray-confirmed pneumonia [73]. The trial population includes infants born in two rural divisions of The Gambia. With a per-capita GNP of \$300, a high infant mortality rate (~80/1000 live births), endemic malaria transmission, and limited health care access, the situation is typical of much of rural Africa. Results should be available by 2005.

#### 4. Eleven-Valent Pnc-D/T

*Bohol, Philippines.* This trial is designed to evaluate the efficacy of Aventis' 11-valent pneumococcal conjugate vaccine for the prevention of radiographic pneumonia in an urban area of the Philippines on the island of Bohol. This vaccine is manufactured by linking pneumococcal polysaccharides with either diphtheria or tetanus toxoids. This randomized controlled trial aims to enroll ~12,000 infants. It is anticipated that the results of this trial will be available by 2005. Although Aventis does not plan to proceed with the licensure and commercialization of this pneumococcal vaccine, nevertheless, the trial will provide important information on the burden of pneumococcal pneumonia and the value of pneumococcal vaccination in an Asian setting.

#### 5. Eleven-Valent Pnc-Protein D

*Czech Republic.* Glaxo SmithKline developed an 11-valent pneumococcal vaccine using, as a recombinant, a nonlipidated form of protein D (a highly conserved cell surface lipoprotein obtained from either capsulated or

unencapsulated strains of *Haemophilus influenzae*) as the carrier protein [74].

This vaccine is being evaluated in a Phase III field trial in the Czech Republic that aims to enroll 5000 infants with vaccinations given at the ages of 3, 4, 5, and 12–15 months. The infants also receive diphtheria–tetanus–acellular pertussis vaccine at the same visit. The study is designed to determine efficacy against culture-proven otitis media due to vaccine serotypes. The results of the study are expected to be available by 2004.

### V. CLINICAL EVALUATION IN THE ELDERLY

Persons over 65 years of age are at increased risk for contracting, or dying from, pneumococcal infection. Higher rates of pneumococcal disease in the elderly may be related to immunosenescence (age-related declines in immune function) resulting in losses of opsonizing antibody concentrations and functions in the elderly [75,76].

Two studies in adults examined the immunogenicity of a five-valent candidate pneumococcal CRM<sub>197</sub> vaccine containing serotypes 6B, 14, 18C, 19F, and 23F [93,95]. The first study randomly assigned 46 “generally healthy” older adults age 50–85 years to either a conjugate vaccine (CRM<sub>197</sub>) or a licensed polysaccharide vaccine [77]. Similar postvaccination geometrical mean antibody levels were reached for serotypes 6B, 14, and 18C for both vaccines. The conjugated vaccine tended to elicit lower levels of antibody to 19F and higher levels to 23F compared to the polysaccharide vaccine, but none of these differences was statistically significant [77]. The second study compared the same conjugate vaccine to a licensed polysaccharide vaccine in younger (age <45 years) and older (age >60 years) adults [78]. There were no statistically significant differences in antibody responses between the vaccines in either age group.

### VI. CLINICAL EVALUATION IN PERSONS WITH UNDERLYING MEDICAL CONDITIONS

In 2000, the Advisory Committee on Immunization Practices (ACIP) of the U.S. Public Health Service issued guidelines on the use of conjugate and polysaccharide pneumococcal vaccines in persons with immunocompromising conditions. The ACIP did not recommend the use of pneumococcal conjugate vaccine in immunocompromised persons aged 5 years and older. There are currently no data from randomized trials assessing the efficacy of pneumococcal conjugate vaccine among persons immunocompromised by medical conditions or medications, but a number of studies have been conducted to determine the safety and immunogenicity of conjugate vaccines in these groups. These studies compare responses to conjugate pneumococcal vaccines among immunocompromised persons compared with healthy controls, assess responses to conjugate vaccines compared with responses to polysaccharide vaccines, and determine booster responses to conjugate or polysaccharide

vaccines among immunocompromised persons previously vaccinated with a conjugate vaccine.

#### A. Sickle Cell Disease

Effective vaccines are needed for the prevention of life-threatening pneumococcal infections in infants and young children with sickle cell disease and related hemoglobinopathies [79,80]. The risk of pneumococcal infection increases dramatically within the first 6 months after birth, well before T-cell-independent immune responses to polysaccharide vaccines are developed. Infants with sickle cell disease who were vaccinated with Pnc-CRM<sub>197</sub> at the ages of 2, 4, and 6 months developed antibody responses comparable to those seen in infants without sickle cell disease [81]. Children aged 2 years and older with sickle cell disease who were primed with two doses of Pnc-7 CRM<sub>197</sub> 8 weeks apart responded with higher antibody concentrations to polysaccharide vaccine than did those who were previously unimmunized [82]. Antibodies induced by the booster dose of polysaccharide vaccine after priming with conjugate vaccine may have more functional activities than do antibodies that are present before vaccination [83]. Local reactions were not more common following the booster dose of polysaccharide vaccine compared to the priming doses of conjugate vaccine, even among patients with high prebooster antibody concentrations [81,82].

#### B. Human Immunodeficiency Virus-Infected Patients

In general, immune responses to pneumococcal conjugate vaccines are impaired in HIV-infected persons, particularly with more advanced HIV infection [84,85]. One exception is found in data from a study of 18 HIV-infected and 33 uninfected children aged 2–24 months where geometrical mean antibody concentrations were similar in the two groups 1 month after completing a three-dose primary series with a five-valent Pnc-CRM<sub>197</sub> vaccine [86].

No clear advantage of pneumococcal conjugate vaccine over polysaccharide vaccine has been identified for HIV-infected persons aged 2 years and older. The HIV-infected children aged 2–19 years responded to a five-valent Pnc-CRM<sub>197</sub> vaccine with greater antibody concentrations for some serotypes than did children receiving 23-valent polysaccharide vaccine [87]. Better responses to a single dose of conjugate vaccine compared with a single polysaccharide vaccine for selected serotypes have been found in some studies of HIV-infected adults with CD4<sup>+</sup> lymphocyte counts >200 [88] but not in others [85]. Among adults with more advanced AIDS (CD4 count <200), the response to 19F as part of a five-valent vaccine was inferior to that elicited by a 23-valent polysaccharide vaccine [85]. However, until immune correlates of protection disease are determined, it is unclear whether even statistically significant differences in an immune response are clinically relevant. Although more local reactions (primarily tenderness at the injection site) have been reported for HIV-infected adults

after vaccination with conjugate vaccines as compared with polysaccharide vaccine, serious untoward effects have not been reported in either group [85,88]. In addition, no changes in viral load during 24 weeks of follow-up were observed among 33 patients receiving one or two doses of the seven-valent Pnc-CRM<sub>197</sub> vaccine [89].

Incremental increases in antibody concentration and functional activity after a second dose of conjugate vaccine are limited in HIV-infected adults [84,88]. However, these data are considered inadequate at this time to justify the additional costs and efforts of the widespread use of pneumococcal conjugate vaccine.

#### C. Hodgkin's Disease

Patients treated for Hodgkin's disease are particularly susceptible to life-threatening pneumococcal infections. Although patients with Hodgkin's disease respond well to pneumococcal immunization before treatment, immune responses to polysaccharide vaccines are impaired for up to 2 years after treatment [90]. Responses to polysaccharide vaccine two or more years after a diagnosis of Hodgkin's disease do not differ from those of healthy controls [91]. Responses to a single dose of seven-valent Pnc-OMP vaccine in these patients were inferior to those elicited by polysaccharide vaccines [91]. However, the conjugate vaccine recipients responded better to a dose of 23-valent polysaccharide vaccine 1 year later than did patients who had not received conjugate vaccines, suggesting a possible role for conjugate vaccines for the immunological priming of patients with Hodgkin's disease [92].

#### D. Bone Marrow Transplant Patients

Opportunistic pneumococcal infection among persons undergoing allogeneic bone marrow transplantation occurs most commonly in the late recovery phase (>100 days after transplantation) [93]. Antibodies to pneumococcal capsular polysaccharides can be depressed for several years after transplantation [94]. IgG antibody responses to pneumococcal polysaccharide vaccine during the first 2 years after bone marrow transplantation are depressed and have low functional activity [95,96]. Prolonged depression of antipneumococcal antibodies and poor responses to pneumococcal polysaccharide vaccine are a particular problem for patients with graft-versus-host disease [97]. Antibody responses in a small number of patients vaccinated with a seven-valent OMP conjugate vaccine 1 year after bone marrow transplantation were similar to responses to pneumococcal polysaccharide vaccine [98].

Administering *H. influenzae* type b (Hib) conjugate vaccine to patients undergoing autologous bone marrow transplantation led to better anticapsular antibody responses to posttransplantation doses of Hib conjugate vaccine compared with patients who were not vaccinated before harvest [99]. Likewise, pretransplantation vaccination of stem cell donors with Hib conjugate vaccine produced higher total anti-polyribosylribitol phosphate (PRP) responses in allogeneic stem cell transplant recipients compared with

recipients with unvaccinated donors [100]. Future work will assess similar strategies using pneumococcal conjugate vaccine for pretransplantation immunization.

## VII. IMPACT OF ROUTINE IMMUNIZATION ON TRANSMISSION AND DISEASE

### A. Effect of Conjugate Vaccination on Nasopharyngeal Colonization

Pneumococcal conjugate vaccines reduce colonization with vaccine serotypes. Klugman [101] reviewed four published and six unpublished studies of the effect of pneumococcal conjugate immunization on subsequent carriage of pneumococci in the nasopharynx (NP) [102–105]. These studies included seven different vaccine formulations, ranging from five-valent to 11-valent, given to infants or toddlers in five different schedules, and investigators collected NP specimens 1 month to 2 years after immunization. The effect on colonization by pneumococcal serotypes included in the vaccine was remarkably consistent. In all but one study, which measured colonization 2 years after primary immunization [101], pneumococcal conjugate vaccination was associated with significantly reduced colonization by vaccine serotypes.

Notably, in five of the studies reviewed by Klugman [101], pneumococcal conjugate vaccinees were significantly more likely to be colonized with nonvaccine pneumococcal serotypes [102–104]. In a large randomized trial of nine-valent Pnc-CRM<sub>197</sub> vaccine among toddlers in Israel, vaccination reduced colonization with several serotypes included in the vaccines (6B, 9V, 14, and 23F) but not 19F [106].

The increase in nonvaccine serotype pneumococcal colonization raises the question of whether the increase is due to “replacement” colonization by nonvaccine serotypes, or is the result of “unmasking” of existing nonvaccine type subpopulations [107]. Replacement occurs when vaccinated individuals, who are protected against colonization by vaccine serotypes, become relatively more susceptible to colonization by nonvaccine types, perhaps by allowing nonvaccine serotypes to compete more successfully for resources in the absence of competition from vaccine serotypes.

Unmasking implies that the observed increase in nonvaccine serotype carriage after vaccination is actually due to an increased likelihood of detection after the decline in the number of vaccine-type organisms. Most NP colonization studies are performed by directly plating specimens onto agar plates and then by selecting one or a few colonies for serotyping. This technique is sensitive for identifying the presence of any pneumococci, but insensitive for detecting colonization by multiple serotypes. Because individuals may be colonized with multiple serotype populations (e.g., one vaccine serotype and one nonvaccine serotype) and, in some cases, the minority serotype may account for only 10% or less of all pneumococci, the effect of vaccination may be to simply unmask the nonvaccine serotype populations by decreasing the density of vaccine serotypes on the agar plate [108]. Differentiating between serotype replace-

ment and unmasking can be difficult, but a recently developed statistical test by Lipsitch [109] helps to determine the likelihood of true replacement in the context of clinical trials.

Although pneumococcal conjugates were expected to be highly efficacious against systemic infections, it was largely a surprise to find that this parenterally administered vaccine protected against the acquisition of *S. pneumoniae* at mucosal surfaces. The mechanisms that mediate protection against mucosal infection are unclear. Typically, protection on mucosal surfaces is thought to be due to secretory IgA. However, the response to pneumococcal conjugates is overwhelmingly serum IgG antibody, with only low levels of salivary IgA demonstrable following primary immunization with pneumococcal conjugates [110,111]. Some authors have proposed that the effect on colonization is due to the production of high-serum IgG levels, which transude onto the mucosal surfaces, providing short-lived protection immediately following immunization [112] and, indeed, salivary IgG concentrations following immunization correlate with serum IgG concentrations [110]. It is likely that both IgA and IgG antibodies play a role in vivo [110].

Routine pneumococcal conjugate vaccination will likely have substantial indirect effects, which may be beneficial, detrimental, or both, at the individual and population levels. At the individual level, vaccination will likely reduce the risk of colonization by vaccine serotypes but also increase the risk of colonization, and perhaps disease, by nonvaccine serotypes. At the population level, widespread vaccination is likely to reduce the transmission of vaccine serotypes and hence induce herd immunity (i.e., reduce the risk of disease due to vaccine serotypes among vaccinated and unvaccinated persons). There is also the possibility that increases in colonization with nonvaccine serotypes will lead to increased transmission of the disease due to these types. Mathematical models by Lipsitch [107] indicate that replacement colonization and transmission are likely to occur, and that the extent to which they occur will be mediated by vaccination coverage, the efficacy of the vaccine against vaccine serotype colonization, and the degree of competition between vaccine and nonvaccine serotypes.

The overall impact of vaccination on pneumococcal disease rates will be a balance of these direct and indirect effects. In vaccinated children, an increased risk of acute otitis media caused by nonvaccine serotypes has been reported [63], but data from controlled trials do not indicate a greater risk of invasive disease from nonvaccine serotypes. Black et al. [113] reported that following the introduction of routine infant immunization with seven-valent Pnc-CRM<sub>197</sub> vaccine, the incidence of invasive disease due to vaccine serotypes decreased far greater than expected based on immunization coverage alone. For example, in the first year of routine vaccination, the incidence of disease among infants <1 year old decreased by 87% even though the proportion of infants fully vaccinated did not exceed 30% at any point and <67% of infants had received any pneumococcal conjugate vaccine dose. No increase in nonvaccine serotype invasive disease was reported. Postlicensure surveillance studies are needed to detect any clinically signifi-

cant increased risk of invasive disease caused by nonvaccine serotypes.

### B. Effect of Conjugate Vaccines on Nasopharyngeal Colonization with Antibiotic-Resistant Strains

Conjugate pneumococcal vaccines may reduce antibiotic-resistant infections by protecting infants from drug-resistant strains, by disrupting the transmission of drug-resistant organisms, and, perhaps, by lessening the selective pressure for antibiotic-resistant pneumococci by reducing antibiotic use in vaccinated children. During the 1990s, antimicrobial drug resistance was most common among the serotypes that are included in the seven-valent conjugate vaccine [114,115]. Although replacement by nonvaccine serotypes raises questions about the efficacy of conjugate vaccine in reducing overall transmission, drug resistance has been less common in the nonvaccine serotypes recovered from vaccinated children [101,103,105,116]. Thus, pneumococcal conjugate vaccines should reduce person-to-person transmission of drug-resistant strains. Ongoing surveillance and additional studies will be necessary to determine whether the emergence of antimicrobial resistance in nonvaccine serotypes will pose future challenges to the treatment of pneumococcal infections.

Results of a randomized, double-blinded trial in Israel show how pneumococcal conjugate vaccination may reduce the selective pressure of antibiotics that drives drug resistance [106]. Day care center attendees aged 12–35 months were randomized to vaccination with a nine-valent CRM<sub>197</sub> pneumococcal conjugate vaccine or a control vaccine (*N. meningitidis* group C CRM<sub>197</sub> conjugate) and followed monthly to bimonthly with nasopharyngeal swabs for 2 years. The history of illnesses and antibiotic use during the period since the previous visit were obtained during interviews with parents. Children receiving pneumococcal conjugate vaccine had fewer reported episodes of upper respiratory tract infections, lower respiratory problems, and otitis media than did control recipients. More importantly, the group receiving pneumococcal vaccine had 17% fewer days on antibiotics, including reductions of 10% for antibiotics taken for upper respiratory infections, 20% for otitis media, and 47% for lower respiratory tract problems.

### C. Serotype Switching in Response to Immunological Pressure

The overwhelming majority of penicillin-resistant, multi-drug-resistant *S. pneumoniae* isolates are associated with only a select few (e.g., types 6B, 14, 19F, and 23F) of the 90 different capsular types that may decorate the surface of the organism. These same four serotypes are the predominant players that cause invasive disease in infants. The restriction of these dangerous drug-resistant organisms to such a few key serotypes provided hope that the development of conjugate vaccines, which include these serotypes, would control some of the most dangerous strains of *S. pneumoniae* that cause widespread disease [117].

Recent work, however, has led to the discovery that multidrug-resistant strains could overcome the protective effects of a conjugate vaccine by acquiring DNA molecules from other pneumococci that allow expression of new capsular types [118]. In an outbreak among AIDS patients in New York, a multidrug-resistant pneumococcal clone, which represented a serotype 23F strain that had acquired the genes to express the capsule of serotype 3, was identified, thereby converting the strain to serotype 3 [119].

## VIII. ISSUES FOR USE OF PNEUMOCOCCAL CONJUGATE VACCINES IN DEVELOPING COUNTRIES

With an estimated 1 million childhood deaths due to pneumococcal disease each year, the routine use of pneumococcal conjugate vaccines could substantially improve child health in developing countries. The successful introduction of these vaccines into developing countries will require efforts to overcome some major obstacles. The introduction process begins with researchers who generate an evidence base in developing countries, which shows the importance of pneumococcal disease, especially pneumococcal pneumonia, and the safety and effectiveness of the vaccines. This must in turn generate a local appreciation for the importance and value of vaccination. Experience with Hib conjugate vaccines has shown that the lack of local disease burden data was one of the major obstacles to the vaccine's uptake in developing countries [120].

Epidemiological differences and limitations in financial and programmatic resources limit the ability to extrapolate data from studies conducted in industrialized countries to developing countries. For example, efficacy studies conducted in industrialized countries have evaluated a four-dose regimen in which the second dose of vaccine was not given until at least the age of 4 months. In many developing countries, however, pneumococcal pneumonia among very young infants (i.e., less than 3 months old) is a major problem and most developing country programs give only three doses, not four, in the primary vaccination schedule. Studies of immunization regimens tailored to the epidemiology in developing countries are needed.

Pneumococcal conjugate vaccines will likely cost more than the vaccines that are currently part of the routine immunization program. The economic impact of pneumococcal disease and the cost-effectiveness of immunization must be assessed. Even with these efforts, substantial external assistance will be needed to make the vaccine available to the countries that need it the most—those countries with high infant and child mortality and few economic resources. The creation of the Vaccine Fund of the Global Alliance for Vaccines and Immunization (GAVI) represents a major step forward in this respect. The acceleration of pneumococcal vaccine use in these countries will be a major test for the alliance, and its success, or failure, will likely have major implications for vaccine development in the future.

## Pneumococcal Common Proteins and Other Vaccine Strategies

David E. Briles and Susan K. Hollingshead

The University of Alabama at Birmingham, Birmingham, Alabama, U.S.A.

James C. Paton

University of Adelaide, Adelaide, Australia

### I. DEVELOPMENT OF NOVEL VACCINES TO PNEUMOCOCCAL ANTIGENS

*Streptococcus pneumoniae* expresses a number of molecules, aside from capsular polysaccharide, that are able to elicit protection. Figure 1 is a cartoon of the pneumococcal surface depicting many different pneumococcal surface structures. All of the labeled structures, except the cell membrane and cell wall, are able to elicit protective responses. Data for some of these molecules are stronger than those of others. Although the data demonstrating protection by antibody to IgA1 protease are limited, its high sequence diversity suggests that the antibody to this protein has a protective effect in man [1].

### II. PHOSPHOCHOLINE/TEICHOIC ACIDS

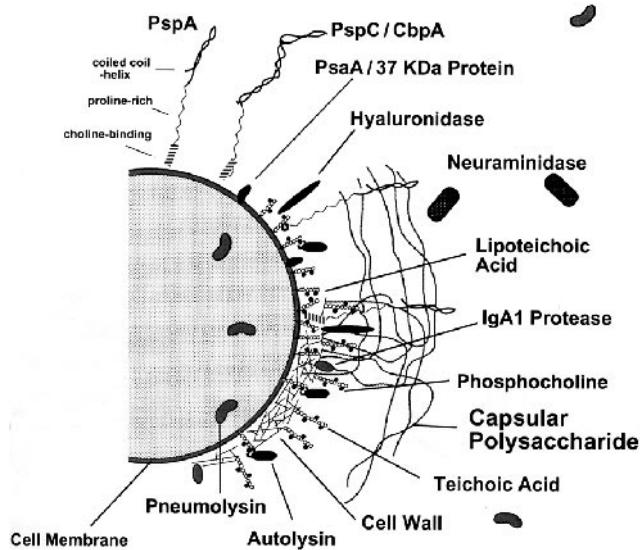

Antibodies to the phosphocholine (PC) epitope of the teichoic and lipoteichoic acids of the pneumococcus are protective [2–6]. Although most of the work has been conducted with mouse antibodies, human antibody to PC protects in a mouse challenge model [3]. Phosphocholine is a common epitope on other respiratory bacterial pathogens [4,5]. Human C-reactive protein, which recognizes PC, protects mice against pneumococci [6] and *Haemophilus influenzae* [7]. Phosphocholine is considered an attractive vaccine candidate because it is invariant in structure and it is found on all pneumococci [8,9]. Shortcomings include the fact that it does not elicit memory responses, and antibodies to PC are less protective on a one-to-one basis than those to capsule [10]. Isolated phosphocholine-containing teichoic acid is not highly immunogenic in mice or humans. Purified lipoteichoic acid (F-antigen), however, is immunogenic [11,12] and can

protect mice (Moon Nahm, manuscript in preparation). Immune responses to teichoic acids are readily elicited by immunization with killed intact pneumococci [13].

### III. PNEUMOCOCCAL PROTEIN VACCINE ANTIGENS

One alternative to using polysaccharides or polysaccharide-protein conjugates is to develop a vaccine composed of protection-eliciting pneumococcal protein(s) [2]. Infants generally make good responses to protein antigens, and the immunogens of all successful nonliving pediatric vaccines are either proteins themselves, or make use of protein carriers. By including a few selected virulence proteins in a protein-based vaccine, it should be possible to target more than one virulence and invasion mechanism. Indeed, immunization with mixtures of pneumococcal proteins can be more protective in mice than individual proteins [14,15]. A protein vaccine would also have the advantage in that the recombinant proteins can be produced relatively inexpensively, a possibility that might make such vaccines more affordable worldwide.

Several pneumococcal proteins, PspA, PsaA, pneumolysin, neuraminidase, autolysin, and PspC, elicit protective immunity in mice against pneumococcal infection [16–23,15,24,25]. Each of these proteins is a virulence factor [2,24,25]. The capsule has long been believed to be required for virulence [26–28]. Studies with genetic exchange mutants have confirmed these expectations [29]. Based on the analysis of the pneumococcal genome and the use of in vivo gene selection systems, many additional protein vaccine candidates have been proposed [30–32].

**Figure 1** Cartoon showing the pneumococcal cell membrane, cell wall, and nine different components that are considered likely to be able to elicit protection against pneumococcal infection, invasion, or colonization. These molecules include the carbohydrates, capsular polysaccharide, teichoic acids, and lipoteichoic acid; as well as the protein PspA, PspC (CbpA), PsaA, pneumolysin, neuraminidase, hyaluronidase, and IgA1 protease.

### A. PspA

Pneumococcal surface protein A (PspA) is expressed by all pneumococci [33] and, so far, is the only purified pneumococcal protein that has been used to immunize human volunteers [34]. Human antibodies elicited by immunization with rPspA protect mice from fatal sepsis with pneumococci [23]. As for size, PspA molecules from different strains range from about 65 to about 95 kDa [35]. The N-terminal half of the molecule is thought to have an  $\alpha$ -helical antiparallel coiled coil structure [36,37].

The center of the molecule contains about 80 residues, which are about 40% proline, and in some molecules there is a 30-residue highly conserved, nonproline containing region in the center of the proline-rich region. The C-terminal end of the molecule is composed of 9–10 highly conserved, choline-binding repeats of 10 amino acids, each with a highly conserved 17 amino acid tail. The choline-binding domain attaches PspA noncovalently to the phosphocholine residues of the lipoteichoic acid (and possibly cell wall teichoic acid). Much of the  $\alpha$ -helical domain of the molecule is highly immunogenic and exposed at the bacterial surface. Antibodies elicited by the  $\alpha$ -helical domain protect against infection and the 100 amino acids near the C-terminal end of the  $\alpha$ -helical domain is where major cross-protective epitopes of Rx1 (clade 2, family 1) PspA have been mapped [36,38–40,35].

Although PspA exhibits much structural variability [35], protective antibodies to it are quite cross-reactive

[38,23,24]. Much of the cross-protection appears to be elicited by epitopes encoded by the most C-terminal 100 amino acids of the  $\alpha$ -helical region. Based on the amino-acid sequence of this region of PspA, we have divided all PspAs into six clades which comprise three families [35]. We have examined over 2000 strains of pneumococci collected from around the world and have found that at least 98% are in families 1 and 2, which are composed of clades 1 and 2, and 3 through 5, respectively (Hollingshead, manuscript in preparation). Although in strains of many capsular types the isolates are predominantly of members of a single PspA family, both major PspA families have been found in all major capsular types. Antibodies to PspA produced by five mammalian species were shown to be able to protect mice against intravenous infection with pneumococci expressing either family 1 or family 2 PspA [22–24]. Table 1 shows the results obtained when antibody PspA elicited in a monkey were used to passively protect mice (J. Monde and D. E. Briles, unpublished results). At least, some cross-protective immunity exists even between different PspA families, and makes it likely that a PspA vaccine need not contain more than one or few PspAs [22–24].

Although several biological properties of PspA are known, the relative importance of these properties in virulence is not known. It is important to resolve these questions if we are to have confidence that antibody to PspA will be as efficacious in man as it is in mice. Understanding PspA's mechanism of action should help us understand the pathogenesis of pneumococcal disease. Understanding the mechanism by which an antibody to PspA protects should aid in the development of a useful surrogate assay for evaluating human responses to PspA vaccines.

Pneumococcal surface protein A is probably not important for any metabolic or transport function. The net growth of pneumococci in media or in C3-deficient mice is not dependent on the expression of PspA [41]. Moreover, antibodies to PspA do not alter the growth or cause death of pneumococci in media [42], heparinized blood [3], or in C3-deficient mice (Briles and Szalai, unpublished results).

**Table 1** Serum from a Rhesus Monkey Immunized with PspA Can Protect Mice from Fatal Infection with Capsular Type 3 *Streptococcus pneumoniae*

Immunogen	Dilution of serum	Numbers of mice		<i>P</i> vs. preimmune
		Alive	Dead	
No serum	No serum	0	3	
Preimmune	1/20	1	5	
	1/40	0	6	
	1/80	0	6	
	1/20	6	0	
Immune	1/40	6	0	
	1/80	4	2	<0.0001

0.1 ml of passive serum given i.p. 1 hr before i.v. challenge with > 10 LD<sub>50</sub> of *S. pneumoniae*. *P*-value compares alive vs. dead mice via Fisher's Exact Test.

Pneumococcal surface protein A is required for full virulence of pneumococci [18,41,25]. Mice can be protected against pneumococcal sepsis and death with passive MAb and polyclonal anti-PspA [3,17,18,40] as well as by immunization with native and recombinant PspA [23,24,43,44], or with DNA vaccine encoding PspA [45,46].

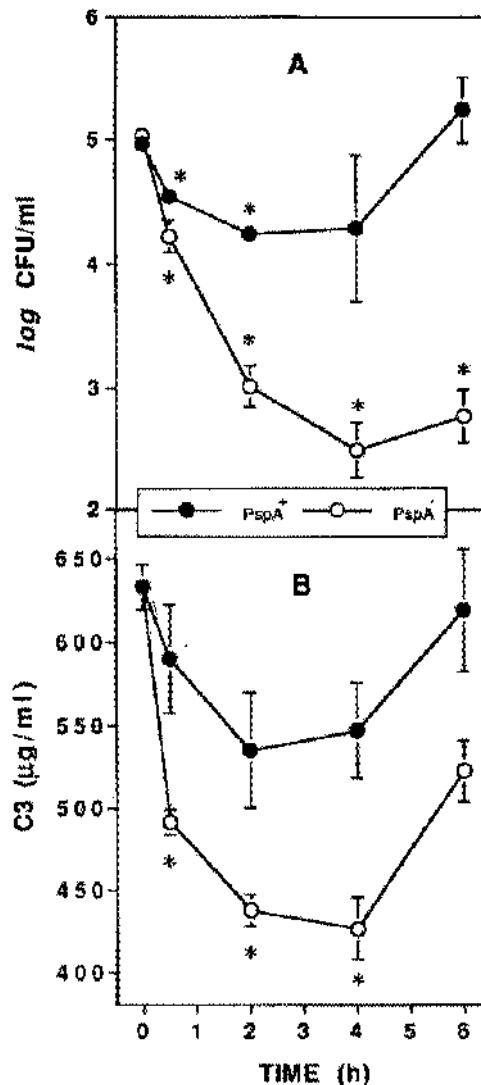

Pneumococcal surface protein A is expressed on the surface of encapsulated pneumococci [47,37,42], but is measurably more exposed on nonencapsulated, as on encapsulated pneumococci (Hakansson and Briles, manuscript in preparation). Antibodies to PspA are not able to opsonize pneumococci for opsonophagocytosis and killing in vitro using standard techniques [3] (Briles, unpublished results; Moon Nahm, unpublished results), and they are not able to agglutinate pneumococci [42]. These observations are consistent with the expectation that the surface density and exposure of PspA epitopes is less than that of the repeating epitopes of capsular polysaccharides.

Serious pneumococcal infections are frequently associated with low levels of serum complement [48,49]. Pneumococcal capsular polysaccharides, teichoic acids, and lipoteichoic acids can all fix C' at least weakly through the alternative pathway [50–52]. This pathway of complement activation is required for most of the C' deposition on encapsulated pneumococci exposed to fresh human serum [53].

By use of the bystander C' activation assay, it was shown that one of our PspA<sup>-</sup> mutants activated more C' than PspA<sup>+</sup> pneumococci [54,55]. This has also been observed using Western blots to look at deposited C' fragments [41] and by using ELISA to detect C' deposited on the pneumococcal surface [56]. A most convincing in vitro demonstration that the presence of PspA affects the surface deposition of C' was obtained with a flow cytometry assay using live pneumococci (Ren et al., submitted). Evidence that PspA affects C' deposition in vivo has also come from our studies, where PspA<sup>+</sup> bearing and PspA<sup>-</sup> isogenic strains were injected into mice and the relative levels of C' in their sera were measured [41] (Figure 2). If the virulence function of PspA is to block C' fixation, then Ab-PspA might be able to block PspA's ability to inhibit C' fixation, and should thus increase the level of C' deposited on pneumococci [56].

PspA's ability to decrease C' deposition could explain PspA's effect on virulence, if the C' deposited on PspA<sup>-</sup> pneumococci enhanced opsonophagocytosis and killing in vivo. In mice lacking C3, neither the PspA nor the antibody to PspA affects virulence. These observations are consistent with the expectation that PspA's effect on C' activation may be important to its effect on virulence [57,57a,41]. The effect of PspA on opsonization by complement is further emphasized by the observation that Fc receptors do not appear to be required for the protective effects of antibodies to PspA. Even though the phagocytes of mice lacking Fc receptors Fc $\gamma$ RI, Fc $\gamma$ RIIB, and Fc $\gamma$ RIII [58] fail to bind to IgG1, IgG2 and IgG2b, antibodies to PspA are almost as efficacious in these mice as in wild type-mice (Szalai et al., manuscript in preparation).

In light of the above results, it was a little surprising that the antibody to PspA efficiently mediates the binding of

**Figure 2** Expression of PspA by pneumococci inhibits complement activation and clearance of pneumococci during a bacteremic infection of CBA/N mice with  $10^5$  colony-forming units of PspA<sup>+</sup> or PspA-pneumococci. Blood was collected to quantitate bacteremia (A) and serum C3 (B). Data are presented as means  $\pm$  standard errors of the means from a total of 15 mice per group. Asterisks indicate significant decreases ( $P < 0.05$ ) in bacteremia or serum C3 concentrations compared to 0-hr (pre-infection) values. (Adapted from Ref. 41.)

capsular type 3 pneumococci to phagocytes [55,59–61]. We refer to this binding as Ab-dependent adherence of bacteria to phagocytes (AABP). We have observed that AABP can be mediated by a normal human serum but that it is not observed using PspA<sup>-</sup> capsular type 3 pneumococci, suggesting that PspA might be a major mechanism by which this is mediated in nonimmune human sera (Briles and King, unpublished results). AABP with the pneumococcus occurs in both the presence or absence of C' [61] (Briles et al., unpub-

lished results) and does not lead to killing of the opsonized pneumococci even when the C' levels of about 1/10 normal serum are used in the assay. Whether the attachment of pneumococci to phagocytes by anti-PspA may play a role in the killing, or clearance, of pneumococci in vivo is not known.

All PspA families and clades bind lactoferrin avidly and specifically [42,62] (Mirza, Hollingshead and Briles, unpublished results). The binding site for lactoferrin is within the clade-defining region of the  $\alpha$ -helical domain [35,42]. This same region of PspA is also responsible for most of the cross-protective Ab elicited by PspA/Rx1 [38,22]. The ability of lactoferrin to bind to PspAs of different clades, despite the differences in sequences of different PspAs, suggests that lactoferrin's binding has functional significance. The extensive sequence differences within the region of PspA that binds lactoferrin suggest that the binding of PspA to lactoferrin may be dependent on protein conformation, rather than specific linear protein sequences. Our observation that Ab–PspA can inhibit the binding of lactoferrin to PspA (Mirza and Briles, unpublished results) indicates that whatever advantage pneumococci gain by binding lactoferrin, it can probably be blocked by the antibody to PspA.

Lactoferrin is present in all body secretions at concentrations ranging from 0.1 to 7 mg/mL [63]. It is produced by neutrophils during inflammation, and can reach blood levels of 0.2 mg/mL, with even higher local concentrations [63]. Lactoferrin effectively sequesters iron from most pathogens [64,65], including pneumococci [66]. Apolactoferrin (lacking iron) is bactericidal for many bacteria [67] including pneumococci. Killing by lactoferrin may be important within phagocytes [67] and possibly in secretions, but not in the blood, as its bactericidal effects are inhibited by serum (Mirza et al., manuscript in preparation). Lactoferrin has also been reported to enhance [68] or inhibit [69,70] C' activation, depending on the system studied. Thus it is possible that the binding of lactoferrin to PspA may enhance PspA's anticomplementary activity. It is also possible that the presence of PspA on pneumococci may interfere with lactoferrin-mediated killing.

At present, only indirect data support the contention that PspA antibodies protect against pneumococci in humans. If human antibody to PspA is protective, it should also select for variants in the antigenic structure of PspA. The bulk of the diversity of PspA is in the exposed portions of the molecule, not in the choline-binding domain. The extensive diversity of the exposed portions of the molecule suggests that in its primary host, man, immunity to PspA must reduce the chance that the pathogen is able to successfully colonize/infect and be transmitted to a new host.

Immunity to PspA could act at one or more steps in the infection process. Antibody to PspA is initially acquired transplacentally from the mother, and children subsequently develop their own titers of anti-PspA; this occurs rather slowly in children in response to pneumococcal carriage and infection [71–73]. However, the appearance of substantial levels of antibodies to PspA in children corresponds to the period of time in which young children begin to be relatively resistant to pneumococcal infection [74]. Some data indicate that invasive pneumococcal disease may be more frequent in children with low antibody levels to PspA than in those with

high levels of antibody to PspA [73]. In a human carriage challenge model, establishment of carriage leads to elevated PspA antibody levels. The same studies suggest that elevated antibody levels may protect against carriage in adults [75].

## B. PspC

Another pneumococcal surface protein, variously called PspC, CbpA, SpSA, or Hic [76–81], plays a role in adherence and colonization [25,78], C3 binding [82], secretory IgA binding [77,80,81], factor H binding [83–85], and inhibition of alternative pathway C3 activation [85]. The multiple names for PspC has ensued partly because of the different activities of the protein, and partly because PspC is a variably mosaic protein which has allelic variants with significant differences in their domain structure [79,83,86]. The term "PspC" was the first name given to this family of allelic genes in gene bank, on September 26, 1996 [54,76,79]. The alleles of *pspC* that were originally described encoded a domain structure very similar to that of PspA. PspC consists of a choline-binding repeat and proline-rich domains that are indistinguishable from those of PspA. The size of the  $\alpha$ -helical domain of PspC is within the range observed for the  $\alpha$ -helical domain of PspA, and some PspC molecules have  $\alpha$ -helical domains that are highly homologous to portions of the alpha helical domain of some PspA molecules [79].

While the PspC produced by about 75% of pneumococci have a choline-binding region indistinguishable from PspA [77,79] other pneumococci produce a PspC in which the choline-binding region is replaced by an LPXTG amino acid sequence motif, which is associated with attachment to the cell wall peptide cross-bridge by the enzyme sortase [83,86]. Eleven major groups of PspC proteins exist, and a nomenclature based on differences in the domain structures of the encoded proteins has been proposed [86].

Immunization with purified rPspC elicits protection against fatal sepsis, as well as nasopharyngeal carriage in mice [25,79]. Studies are needed to evaluate the breadth of protection afforded by this molecule and to compare the virulence roles and protection elicited by the different forms of PspC.

## C. Pneumolysin

Pneumolysin is produced by virtually all strains of *S. pneumoniae*, and was one of the first pneumococcal proteins proposed as a vaccine antigen [87]. It is a member of a family of toxins referred to as the thiol-activated cytolsins (strep-tolysin-O and listeriolysin-O also belong to this group). These toxins initially interact with cholesterol in host cell membranes, after which they insert into the bilayer and oligomerize to form transmembrane pores, thereby bringing about cell lysis [88]. The ubiquity of cholesterol in animal cells accounts for the broad range of detrimental effects attributable to these toxins, many of which occur at sublytic concentrations. For pneumolysin, these effects include inhibition of the bactericidal activity of leukocytes, blockage of proliferative responses and Ig production by lymphocytes, reduction of ciliary beating of human respiratory epithelium,

and direct cytotoxicity for respiratory endothelial and epithelial cells [89].

Pneumolysin is a bifunctional toxin that, in addition to its cytotoxic properties, binds the Fc region of human IgG and activates the classical complement pathway (with a concomitant reduction in serum opsonic activity) [90,91]. Thus pneumolysin may interfere with both phagocytic and ciliary clearance of pneumococci, by blocking humoral immune responses, and by aiding penetration of host tissues. Pneumolysin also directly induces inflammatory responses [92] and, under certain circumstances, can alter the inflammatory responses so that they are less protective than normal [93]. Injection of purified pneumolysin into rat lungs induces severe lobar pneumonia, histologically indistinguishable from that seen when virulent pneumococci are injected [94].

Defined pneumolysin-negative mutants of *S. pneumoniae* exhibit significantly reduced virulence in mouse models of sepsis and pneumonia [95]. When compared to the wild-type strain, intranasal challenge with pneumolysin-negative mutants results in a less severe inflammatory response, a reduced rate of multiplication within the lung, a reduced capacity to injure the alveolar–capillary barrier, and a delayed onset of bacteremia [96,97].

Although native pneumolysin is a protective immunogen in mice, it is not suitable as a human vaccine antigen, because of its toxicity. To overcome this, mutations have been introduced into the pneumolysin gene in regions essential for its cytotoxic and/or complement activation properties, resulting in the expression of nontoxic but immunogenic “pneumolysoids,” which are easily purified from recombinant *Escherichia coli* expression systems [98]. Pneumolysin is a highly conserved protein, and extensive analysis of genes from a wide range of *S. pneumoniae* serotypes has detected negligible variation in deduced amino acid sequence, auguring well for broad coverage. Indeed, immunization of mice with a pneumolysoid carrying a Trp433–Phe mutation resulting in >99.5% reduction in cytotoxicity (designated as PdB) provided a significant degree of protection against all nine serotypes of *S. pneumoniae* that were tested [99].

Humans develop antibody to pneumolysin as a result of natural exposure to *S. pneumoniae*, and purified human antipneumolysin IgG passively protects mice from challenge with virulent pneumococci [100]. Thus it is anticipated that the various pneumolysoids will be immunogenic in humans. However, pneumolysoid may not provide a sufficient degree of protection to be an effective standalone human vaccine antigen. Pneumolysin is not displayed on the surface of the pneumococcus. Rather, it is located in the cytoplasm and released into the external milieu when pneumococci undergo spontaneous autolysis in some strains [21]. It also appears to be released by an as yet uncharacterized export mechanism in other pneumococci [101].

Antibodies to pneumolysin presumably impart protection by neutralization of the biological properties of the toxin, thereby impeding the kinetics of infection, rather than by stimulating opsonophagocytic clearance of the invading bacteria. Thus protein-based vaccines combining pneumolysoid with pneumococcal surface proteins capable of eliciting opsonic antibodies would be expected to be more effective (see Section 5).

#### D. Pneumococcal Surface Antigen A (PsaA)

Pneumococcal Surface Antigen A, a highly conserved 37-kDa surface protein produced by all pneumococci, was initially thought to be an adhesin based on sequence homology with putative lipoprotein adhesins of oral streptococci. It is actually metal-binding lipoprotein component of an ATP-binding cassette (ABC) transport system with specificity for Mn<sup>2+</sup> [102]. Defined PspA<sup>-</sup> mutants of *S. pneumoniae* are virtually avirulent for mice and exhibit markedly reduced adherence in vitro to human type II pneumocytes [103]. This is presumed to be a consequence of a requirement for Mn as a cofactor, or for regulation of expression of other virulence factors (e.g., adhesins), and/or growth retardation due to an inability to scavenge this metal in vivo [104]. The avirulence of PspA-pneumococci might also be due, at least in part, to the fact that they are highly susceptible to oxidative stress [105].

Immunization of mice with purified PsaA confers partial protection against intraperitoneal challenge with *S. pneumoniae*, although it is less efficacious than either pneumolysoid or PspA [15]. The dimensions of PsaA (approximately 7 nm at its longest axis) [106] are such that if it is anchored to the outer face of the cell membrane via its N-terminal lipid moiety, it is unlikely to be exposed on the outer surface of the pneumococcus. Thus the observed protection is presumably attributable to in vivo blockade of ion transport, which necessitates the diffusion of antibody through the capsule and cell-wall layers. Penetration of antibody may well be influenced by the thickness of the capsule, which is believed to be upregulated during invasive infection. In contrast, pneumococci colonizing the nasopharynx are thought to downregulate capsule expression [107], thereby facilitating the interaction between surface adhesins and the host mucosa. Consistent with this hypothesis, the intranasal immunization of mice with PsaA significantly reduces the nasopharyngeal carriage of *S. pneumoniae* [14].

#### E. Autolysin

Autolysin, a *N*-acetylmuramoyl-L-alanine amidase [108], has been shown to be primarily responsible for pneumococcal autolysis, which follows pneumococcal death at the end of the growth phase in vitro. Isolated autolysin elicits protective immune responses [109] and is a virulence factor [110,111]. Observations that antibodies to autolysin and pneumolysin did not have synergistic protective effects led to the hypothesis that the virulence mechanism of autolysin was the autolytic release of pneumolysin, and that pneumolysin carried out the virulence functions [109]. This hypothesis was supported by the observation that, in capsular type 2 strain D39, mutations in either autolysin or pneumolysin reduced virulence in a lung inoculation model [111]; mutations in autolysin reduce virulence in this model more than mutations in pneumolysin.

#### F. Neuraminidase and Hyaluronidase

*S. pneumoniae* produces a large number of hydrolytic enzymes, some of which may play a role in degradation of

host glycoproteins or extracellular matrix, and many of which are associated with surface expression [112]. A few of these are known virulence factors, including the neuraminidases and the hyaluronate lyase [113,114]. Neuraminidases cleave sialic acid from host surfaces, particularly in the liver and the kidney, and thus, may significantly impede the host's ability to efficiently recover from an infection. Injected neuraminidase is toxic to mice, and *nanA* mutant strains are more efficiently cleared from the lung [115]. Immunization with *NanA* could extend the life of mice [13]. Hyaluronate lyase is predicted to be a surface-bound protein in the pneumococcus, contrary to its secreted status in several other organisms. It degrades hyaluronic acid, a component of basement membranes and connective tissue; a *hya* mutant exhibited virulence in a mouse bacteremia model [114].

One less-characterized member of the hydrolase surface protein group is SpuA [116], a pullulanase which has an alpha-1,6-glucanohydrolase activity that could be involved in scavenging carbohydrate or in uncovering receptors for adhesion. None of the hydrolytic class of proteins has been fully tested for their ability to elicit protective antibody, but some could prove useful as components of a multivalent protein vaccine.

### G. PavA

Among the more suitable vaccine candidates are the newly described adhesins. Antibodies to adhesins may limit colonization and carriage in the nasopharynx, and may decrease invasiveness by interfering with adhesion in the lung or middle ear. One newly defined adhesin is pneumococcal adhesion and virulence (PavA), which appears to be present at the bacterial cell surface, even though it lacks any known signals for transport or for surface attachment [117].

### H. PhtA, B, C, and D

A family of histidine triad proteins, designated as PhtA, B, C, and D, are also potential vaccine candidates [31]. Their exact function unknown, these proteins are surface-exposed and may be surface-attached through a lipoprotein attachment site. Antibodies to PhtA and PhtD are found in human convalescent sera, and rabbit antisera raised to recombinant proteins protect in passive immunization experiments in mice. Some of the recombinant proteins elicit immunity against systemic challenge with pneumococci [31]. An additional histidine triad protein, PhpB, is initially a 79-kDa protein that is processed to a 20-kDa protein which has a putative human complement C3-proteolytic activity. Antibodies elicited by the 79-kDa recombinant protein protect CBA/N mice against death and bacteremia, and reduce nasopharyngeal colonization, but immunization with the 20-kDa portion of the PhpA protein does not protect mice [118].

### I. PiuA and PiaA

PiuA and PiaA are lipoproteins that form as components of iron uptake transporters of *S. pneumoniae*. PiuA and PiaA are antigenically cross-reactive, and immunity to these pro-

teins is reactive with pneumococci of nine different *S. pneumoniae* serotypes. Immunity to PiuA and PiaA protects mice, and immunity to both PiuA and PiaA is more protective than immunity to either protein alone [119].

### J. IgA1 Protease

IgA1 protease is a cell surface-associated enzyme of *S. pneumoniae* that cleaves human IgA1, but not IgA2. IgA1 is the IgA isotype most common in human secretions. It is assumed that cleaving human IgA1 improves the ability of pneumococci to successfully colonize the human host [120,121]. Pneumococcal IgA1 protease does not cleave mouse IgA. IgA1 protease is highly variable [1,121], suggesting that human protective responses to IgA1 protease have selected for variability in the structure of IgA1 protease. Animal tests of this potential vaccine antigen await the development of an IgA knockout mouse expressing transgenic human IgA1 under the control of the mouse promoter for the IgA in murine secretions. Determining the possible usefulness of IgA1 as a vaccine antigen will depend in part on whether or not it contains any highly cross-reactive protection-eliciting epitopes.

## IV. COMBINATION PROTEIN VACCINES

Virtually all of the pneumococcal proteins under consideration as vaccine antigens are directly or indirectly involved in the pathogenesis of pneumococcal disease. Mutagenesis of some combinations of virulence factor genes, for example those encoding pneumolysin and either PspA or PspC [141], or PspA and PspC [25], has been shown to synergistically attenuate the pneumococcal virulence in animal models, implying that the respective proteins function independently in the pathogenic process. Such results suggest that immunization with combination of these antigens might provide additive protection. Moreover, the individual antigens differ in their capacity to protect against various *S. pneumoniae* strains [17,99]. Thus a combined pneumococcal protein vaccine may elicit a higher degree of protection against a wider variety of strains than any single antigen. To date, only a limited number of combination experiments have been performed. The combination of pneumolysoid PdB and PspA clearly provides enhanced protection against systemic infection and pneumonia [15,24], whereas the combination of PspA and PsaA provides additive protection against carriage [14]. Thus the present data suggest that, for elicitation of protection against sepsis, pneumonia, and carriage, a vaccine containing PspA, pneumolysoid, and PsaA might work well. As additional antigens are examined, some may be found to be of significant value for use in new vaccine formulations.

## V. PNEUMOCOCCAL PROTEIN AS POSSIBLE CARRIERS FOR POLYSACCHARIDES

Pneumococcal proteins could be used in combination with PS-protein conjugates or as carriers for conjugation of pneumococcal polysaccharides. By including cross-reac-

tive protection-eliciting proteins to a vaccine containing pneumococcal polysaccharides or polysaccharide-protein conjugates, the spectrum of protection elicited by the polysaccharide and conjugate vaccines could be broadened. Preparing pneumococcal polysaccharide conjugates using pneumococcal proteins rather than proteins of other species, such as diphtheria or tetanus toxoid, should also have an advantage in terms of anamnestic responses elicited by a pneumococcal infection. If the vaccine stimulates T-cell memory that can be boosted upon infection, a better anamnestic antibody response may be achieved than when the carrier in the vaccine is not presented by infecting pneumococci. The speed with which anamnestic antibody is elicited is probably especially critical in the most susceptible human hosts, because it is in individuals with rapidly progressing disease that death is most likely to occur.

Using pneumococcal proteins as carriers for pneumococcal polysaccharides could also lead to the development of a "hybrid" vaccine containing three or four of the most common polysaccharides conjugated to the three or four most promising cross-reactive proteins. By limiting the number of different polysaccharide-protein conjugates, it may be possible to help control the vaccine's cost.

Pneumolysin [98] and PspA have both been successfully used as carriers for immune responses to polysaccharides in animals. Detoxified pneumolysin mutant PdB conjugated to capsular 9F polysaccharide elicited protection against fatal infection in infant mice challenged with capsular type 19 pneumococci [122]. A conjugate containing PspA and capsular type 14 polysaccharide was immunogenic in mice and elicited good titers of antibodies to the both the polysaccharide and to PspA (Mond, Lees, and Briles, unpublished results). Although conjugated to polysaccharide, PspA was still able to elicit protective immunity. Mice immunized with

the PspA-PN14 conjugate were protected against otherwise lethal challenge with the highly virulent capsular type 2 strain (D39) of *S. pneumoniae* (Figure 3).

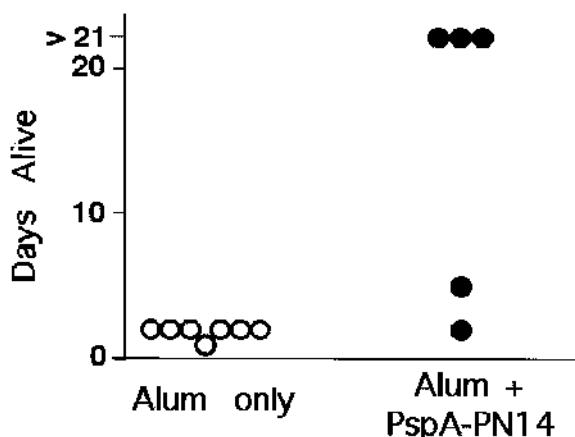

## VI. PROTECTION AGAINST CARRIAGE

It is assumed that to achieve herd immunity against the pneumococcus, it will be important to protect against carriage of pneumococci in the nasopharynx. Immunization to prevent carriage should also protect the immunized individual against invasive disease. Because invasion is invariably thought to be preceded by at least a short duration of carriage [123], protection against carriage should prevent the opportunity for invasion. Whether immunity to carriage is elicited by mucosal or systemic immunization, it is expected that there will also be high levels of systemic antibody, which should also protect against invasive disease [124,125].

Intramuscular immunization with appropriate pneumococcal proteins may also protect against carriage. However, mouse studies indicate that mucosal immunization may be more effective at preventing carriage than systemic immunization. In the mouse, mucosal immunization elicited better protection against carriage than systemic immunization, although the systemic immunization elicited higher serum titers of IgG antibody. In the mouse, mucosal antibody was detected by intranasal, but not by systemic, immunization [125].

## VII. MUCOSAL IMMUNIZATION WITH WHOLE, KILLED VACCINE

In an effort to develop a pneumococcal vaccine for developing countries, the use of killed pneumococci for intranasal immunization has been investigated [126]. The rationale for this approach is that no preparation of isolated antigen, conjugated antigen, or bacterial DNA would be required, thus permitting the vaccine to be produced at relatively low cost and, therefore, perhaps more accessible to children in these countries. By using a nonencapsulated pneumococcus as immunogen, it is hoped to maximize the immune responses to the cross-reactive somatic antigens [126]. The earliest studies of this type were conducted in the first third of the 20th century, and demonstrated that parenteral immunization with nonencapsulated killed pneumococci could elicit protection against systemic infection with encapsulated virulent organisms [127]. Bull and McKee demonstrated in 1929 that intranasal immunization of rabbits with whole killed pneumococci could protect against carriage and invasion through the nasal route [128]. More recent studies in mice demonstrate that immunization of mice mucosally with heat-killed pneumococci elicits mucosal and systemic antibody that protects against systemic infection [129] and against nasopharyngeal carriage [130]. Alcohol-killed pneumococci are more immunogenic than those killed by heat. Immunization with alcohol-killed pneumococci protects rodents against carriage and invasive disease [126]. Malley et al. prepared their heat-killed vaccine using nonencapsulated pneumococci that were also autolysin negative [126]. The absence of the autolytic activity facilitates reproducible

**Figure 3** Immunity to PspA elicited by PspA-PN14 conjugate. CBA/N mice were immunized on days 1, 14, and 28 with 1.2 µg of PspA-PN14 conjugate on alum or with alum alone. Fourteen days after the last boost, they were challenged i.v. with 250 CFU of capsular type 2 strain D39. The greater protection of the PspA-PN14 immunized mice was significant at  $P=0.018$  by comparison of days to death using a two tailed Wilcoxon two-sample rank test.

growth and harvesting of the bacteria, because autolysis is largely avoided [101].

### VIII. SUMMARY

In the last 20 years, the approach to pneumococcal vaccination has evolved from a single focus on the polysaccharide antigen to the multiple approach that now includes the cell surface and cell-released protein antigens of the pneumococcus. This evolution in thinking has also extended to the use of mucosal immunization, as well as the possibility of using the mucosal route for immunization with killed pneumococci. It is likely that one or more of these new immunization strategies will play a role in the control of the pneumococcus in the future.

## Polysaccharide-Based Conjugate Vaccines for Enteric Bacterial Infections: Typhoid Fever, Nontyphoidal Salmonellosis, Shigellosis, Cholera, and *Escherichia coli* O157

Shousun C. Szu, John B. Robbins, Rachel Schneerson, Vince Pozsgay, and Chiayung Chu

National Institutes of Child Health and Human Development, National Institutes of Health,  
Bethesda, Maryland, U.S.A.

### I. INTRODUCTION

Although a variety of vaccines to prevent typhoid fever and cholera (caused by *Vibrio cholerae* O1) are licensed in many countries, there are no licensed vaccines against nontyphoidal *Salmonella*, *Shigella*, *V. cholerae* O139, and *Escherichia coli* O157. We investigated the protective antigens and the host components that confer immunity against this latter important group of diseases to devise safe and effective vaccines [1]. The long experience with vaccines composed of either inactivated or attenuated strains of bacterial pathogens was based largely upon Pasteur's idea for vaccine development: that convalescence from disease induces immunity. But inactivated or attenuated strains of bacteria are not good immunogens when administered in a clinically acceptable form, and convalescence from many enteric infections, such as shigellosis, does not reliably confer a high degree of immunity of long duration [2].

We have exploited the *similarities* in the pathogenesis of and immunity to enteric and respiratory pathogens for the development of enteric vaccines. The surface polysaccharides (PS) of many bacterial pathogens are both essential virulence factors and protective antigens, including the capsular polysaccharides (CP) of respiratory pathogens such as pneumococci, *Haemophilus influenzae* type b, and meningococci, and the Vi CP of the enteric pathogen *Salmonella enterica* serovar *typhi* (*S. typhi*) [3–5]. For most other Gram-negative enteric pathogens, the O-specific polysaccharide (O-SP) domain of their lipopolysaccharides (LPS), including nontyphoidal *Salmonella*, *Shigella*, *V. cholerae*, *E. coli*, etc., serves the same role as a CP [4,6]. Surface PS shields the bacterium from the protective actions of serum complement (lysis for Gram-negatives and opsonophagocytic killing by polymorphonuclear leukocytes). A critical level of serum IgG antibodies to these surface PS confers immunity to diseases by initiating these protective actions. Serum IgG anti-

PS transudes onto the surface of respiratory or intestinal epithelium, where it induces complement-mediated lysis of the inoculum containing the pathogen [7,8].

### II. *S. TYPHI* AND OTHER ENTERIC FEVERS

#### A. *S. Typhi*

Three types of typhoid vaccines are currently licensed: parenterally administered inactivated whole cell vaccines [9,10], orally administered attenuated *S. typhi* strain Ty21a [11], and parenterally administered CP Vi vaccine [12–14a]. These three vaccines confer ca. 70% protection in older children and adults. In children less than 5 years of age, these vaccines are either poorly immunogenic and protective (e.g., Vi), or insufficient data are available to draw conclusions about their efficacy (e.g., Ty21a) [14b]. Notably, it has been shown that in some endemic areas, the highest incidence of typhoid may be seen in children <5 years of age [15].

*S. typhi* is covered by the Vi CP, which serves as a virulence attribute. An early-generation Vi PS vaccine candidate was prepared in the early 1950s, which involved treatment with 1 N acetic acid at 100°C for 24 hr. This early Vi vaccine failed to protect volunteers against experimental challenge with *S. typhi* [16], and it was subsequently discovered that the harsh treatment with acid denatured the Vi. Vi prepared by modern technology results in a nondenatured PS product that is safe, easily standardized, and, following administration of a single dose, confers immunity to typhoid fever for subjects living in areas of high incidence (albeit only to individuals over the age of 5 years). In double-blinded, randomized, controlled trials in areas of high endemicity, Vi elicited 65–75% efficacy in Nepal, South Africa, and China [12–14a]. The efficacy declined to 55% over 3 years of follow-up, paralleling the decline in Vi antibody levels [13]. Vi is

licensed in more than 80 countries and has been highly successful in reducing the incidence of typhoid (H. H. Yang, personal communication).

Although Vi is immunogenic in older children and adults, it does not elicit protective levels of antibodies in infants and young children, nor does it give a booster response (age-related and T-cell-independent). Rejection of Vi in adults was safe, but it only restored Vi antibody levels to the peak postprimary injection levels [17]. These deficiencies were overcome by applying the discoveries of investigators at the Rockefeller Institute in the 1920s and 1930s [18], who showed that the immunogenicity of pneumococcal type 3 CP could be increased by binding these substances to a protein to form a conjugate. The *H. influenzae* type b CP was the first conjugate to be clinically useful, and its widespread introduction has virtually eliminated this most common cause of meningitis in infants and children [5]. Accordingly, the conjugate technology was adapted to the pneumococcus, meningococcus, *S. typhi*, and *Shigella*.

Vi is a linear homopolymer of (1–4) $\alpha$ -D-galacturonic acid, C3-O-acetylated, and C2-N-acetylated; it has no vicinal hydroxyls; and its carboxyl is relatively inaccessible [20,21]. Nevertheless, a safe and highly immunogenic Vi conjugate was devised, which elicited high levels of IgG antibodies and provided memory for booster responses in 2- to 5-year-olds [20–23]. In a randomized, double-blinded, placebo-controlled trial in the Mekong Delta region of Vietnam, involving about 5000 vaccinees and an equal number of controls, the Vi conjugate elicited 91.1% protection over 27 months of active surveillance [24]. With additional passive surveillance for 19 months, there have been 17 cases in the controls and three in the vaccinees [25]. Over the ensuing 19 months, the efficacy declined slightly to 82% (91.1% vs. 82%,  $P < 0.2$ ). The efficacy for the whole study period (46 month) is 89%. This efficacy is among the highest reported for any typhoid vaccine and was achieved in an age group for which there was no effective vaccine. Based upon the antibody data of the whole study period, we estimate the protective level of IgG anti-Vi to be about 0.35 g/mL (the titer of the younger age group at 46 months after immunization) [25]. It is a safe prediction that the Vi conjugate will be close to 100% protective after one injection in individuals older than 5 years.

#### The Efficacy of Vi-rEPA in 2- to 5-Year-Old Children in Vietnam Was Determined by Active (1–27 Months) and Passive Surveillance (28–46 Months)

	Vaccinees	Placebos	Efficacy
1–27 months	5991	6017	
Typhoid fever ( $n =$ )	5	56	91.1%
28–46 months	5383	5420	
Typhoid fever ( $n =$ )	3	17	82.3%
0–46 months	5991	6017	
Typhoid fever ( $n =$ )	8	73	89.0%
	91.5% vs. 89.0%	82.3%	NS

The immunogenicity of the Vi conjugate at lower dosages or administered to infants concurrently with DTP is under study. Should the Vi conjugate induce levels of IgG

anti-Vi comparable to those in the 2- to 5-year-olds, this new typhoid vaccine could be incorporated into the World Health Organization's Expanded Program on Immunization schedule, which targets routine vaccination [26].

#### B. Nontyphoidal *Salmonella* Conjugates

The TAB vaccine, composed of inactivated *S. typhi*, *S. paratyphi* A, and *S. paratyphi* B, was removed as a licensed product because of the lack of data on the efficacy of the paratyphoid components and the frequent and severe adverse reactions observed. Currently, there are no licensed vaccines to prevent nontyphoidal *Salmonella* infections, including paratyphoid fevers [27,28]. *Salmonella* groups A, B, and D share the same LPS backbone [29]:

According to the Kauffmann–White scheme, the backbone is designated as factor 12. The serogroup specificity lies on the 3,6-dideoxyhexoses branch linked (1→3) to the mannose:paratose for group A (factor 2) [30], abequose for group B (factor 4), and tyvelose for group D (factor 9) [30]. The rhamnose is partially O-acetylated at C3 for *S. paratyphi* A [31]. The galactose for group B linked (1→6) with glucose (factor 1) and abequose is partially O-acetylated at C2 (factor 5) [29].

#### 1. *S. Paratyphi* A Conjugate Vaccine

*S. typhi* and *S. paratyphi* A are inhabitants and pathogens of humans only, and can be considered as clones. The second most common *Salmonella* infection in the southeast Asia is *S. paratyphi* A. In the 1990s, approximately one-tenth of *Salmonella* cases in Indonesia, India, and Vietnam were *S. paratyphi* A. There is an increase of *S. paratyphi* A infections in the southwest region of China. This region had a high incidence of typhoid prior to the implementation of massive immunization with Vi in 1997. *S. paratyphi* A has become the most common *Salmonella* infection in this region (private communication).

The LPS of *S. paratyphi* A has two O-acetyls that are essential for the immunogenicity of the O-SP. Removal of the O-acetyls eliminated the immunogenicity of the O-SP [32]. The O-SP and tetanus toxoid conjugated vaccines were prepared using schemes that preserved the O-acetyl groups [32]. The immunogenicity data from Phase I and Phase II studies in Vietnamese adults and children are shown [33]:

#### IgG LPS Antibodies Elicited *S. paratyphi* A O-SP–TT Conjugate

Age (years)	Number of injections	<i>n</i>	IgG anti-LPS (ELISA units)			
			0 day	42 days	70 days	180 days
18–44	One	20	1.47	18.5	—	6.00
13–17	One	108	1.69	15.1	—	7.05
2–4	One	63	0.91	19.3	11.7	3.47
2–4	Two <sup>a</sup>	47	0.77	16.7	11.9	4.08

<sup>a</sup>The second dose was injected 42 days after the first dose.

There were no significant adverse reactions. After one injection, 75% of adults, 85% of teenagers, and 90% of young children responded with more than a fourfold rise of IgG anti-LPS. After 6 months, the antibody levels were approximately 3.8–4 times higher than the preimmune levels. The bactericidal titer was roughly related to the IgG anti-LPS level: the absorption of specific LPS removed most of the bactericidal activities. An efficacy trial in a highly endemic area is being planned.

## 2. *S. Typhimurium* Conjugates

The most common *Salmonella* infection in developed countries is caused by *S. typhimurium*. In 2001, the National *Salmonella* Center in the Netherlands reported an increase in *S. typhimurium* H8380 phage-type DT104 isolations from humans [34–36]. The DT104 strains were resistant to ampicillin, chloramphenicol, streptomycin, sulphonamides, and tetracyclines. Strains were also found to be resistant to fluoroquinolones, trimethoprim, and ciprofloxacin. Most cases were in 0- to 5-year-olds and the clinical course of the DT104 infection was severe with many unusual extraintestinal complications [37].

The *S. typhimurium* infection of mice is a suitable animal model. Serum LPS antibodies, whether actively induced or passively administered, confer protection to mice [38]. Monoclonal antibodies identified the abequose side chain (factor 4) as the most important protective epitope [39]. We prepared conjugate vaccines with the O-SP purified from an *O*-acetyl negative strain of *S. typhimurium* TML (*O*:4,12) linked to cholera toxin or tetanus toxoid [40]. In outbred young mice injected subcutaneously without adjuvant, the conjugates elicited antibodies: reinjection induced booster responses of both IgG and IgM anti-LPS. Most mice produced group B-specific antibodies (abequose or factor 4). Passive administration of conjugate-induced anti-LPS antibodies conferred protection.

About half of the disease isolates contain another antigenic epitope (factor 5): the *O*-acetyl in glucose. The cross-reaction between the *O*-acetyl-positive and *O*-acetyl-negative strains is limited. For example, antibodies raised against factors O4,05 do not cross-react with the O: 4,12 strains [40]. Vaccines containing both *O*-acetyl-positive and *O*-acetyl-negative LPS may be necessary for the optimal protection against *S. typhimurium* infections. The complexity of the group B O-SP of *S. typhimurium* will require a surveillance of this pathogen prior to any efficacy trial.

## III. SHIGELLA

An estimated 200 million people worldwide suffer from shigellosis with 650,000 deaths annually [41,42]. The highest incidence, morbidity, and mortality occur in children 1–4 years of age [43]. In developed countries, attendance at day care centers and chronic care institutions poses a major risk factor for sporadic cases and small outbreaks. *Shigella* is the most frequent cause of *dysentery* (diarrhea with gross blood and mucus in stools) in developing

countries. Dysentery often results in stunted growth [44]. Because of the low infectious dose (~100 organisms), person-to-person transmission is frequent in young children and in overcrowded living conditions. Antibiotics can shorten the duration of fecal excretion but treatment has become increasingly difficult due to the multiantimicrobial resistance of *Shigella*. For these reasons, the World Health Organization (WHO) has assigned a high priority to the development of a vaccine against shigellosis [41].

The genus *Shigella*, Gram-negative nonmotile bacilli that do not ferment lactose, includes groups A (*Shigella dysenteriae*), B (*S. flexneri*), C (*S. boydii*), and D (*S. sonnei*) [44]. From the taxonomic perspective, some contend that *Shigella* and *E. coli* can be considered members of the same genus based on their DNA homology [43,45].

Parenterally injected inactivated *Shigella* vaccines elicited serum antibodies but did not prevent shigellosis. But whole cell vaccines administered once or twice intramuscularly to humans elicit low levels of IgG anti-LPS of short duration [46,47a,47b].

The LPS of *Shigella* is both an essential virulence factor and a protective antigen. The virulence of *Shigella* requires a full expression of their LPS. The outer domain of LPS, the O-SP, shields the bacterium against the protective action of serum complement [48]. Serum O-SP antibody is required to initiate protection against complement actions [49]. Shigellosis confers LPS-specific immunity of limited duration [48]. A significant correlation was shown between the level of serum IgG LPS antibodies and the resistance to shigellosis among Israeli soldiers [49]. Seroepidemiological data provide evidence of serum IgG O-SP antibody-mediated immunity to *Shigella* [50]. The rarity of shigellosis in newborns and young infants and middle-aged and older adults argues for serum IgG O-SP antibody-mediated immunity. Much of this IgG antibody is elicited by cross-reacting bacteria, as shown by serum IgG anti-LPS in most adults, even in countries such as Sweden where shigellae such as *S. dysenteriae* type 1 have not been present during this century [50,51]. Ashkenazi et al. [52a], Shears [52b], and Passwell et al. [53] have shown a similar age-related development of serum IgG anti-LPS for *S. sonnei*. These “natural” antibodies may explain in part why both newborns, young infants, and adults are relatively immune to shigellosis.

It is hypothesized that IgG LPS antibodies inactivate the *Shigella* inoculum as it reaches the intestine. Once the organism has multiplied and becomes intracellular, vaccine-induced serum IgG anti-LPS is ineffectual. A randomized, double-blind, vaccine-controlled study showed that the *S. sonnei* rEPA elicited 74% protection ( $P = 0.001$ ) in Israel Defense Forces recruits [54,55].

Cases occurred in three companies about 3 months after vaccination. This immunization also conferred 43% ( $P = 0.04$ ) protection in one company against an outbreak occurring 1–17 days following vaccination. This preliminary observation suggests that our *Shigella* conjugates might be of value in controlling epidemics. Efficacy in this study was correlated with the level of conjugate vaccine-induced serum IgG anti-LPS [55].

Culture-Proven Infection in Israel Army Recruits Following Vaccination with *S. sonnei* Conjugates

Cohort	Vaccine groups					
	<i>S. sonnei</i> rEPA		EcSf 2A-2 and meningococci		Percent efficacy	
	n/total	%	n/total	%	P	95% CI
A	1/32	3.1	7/48	14.6	0.135	75
B	0/32	0	3/48	6.2	0.271	100
C	3/115	2.6	13/72	18.1	0.073	65
Total	4/179	2.2	23/168	13.7	0.006	84
D	15/127	11.8	40/93	20.7	0.039	(2–82)

The safety and the immunogenicity of similar *Shigella* conjugates were demonstrated in children of ages 4–7 and 1–4 years in Israel [56]. The fold rise in anti-LPS was similar in adults and children, but the level of anti-LPS elicited by the conjugates was lower in young children:

Age-Related Serum IgG Geometric Mean (GM) Anti-LPS Responses in Vaccines Elicited by O-Specific PS Conjugates

Conjugate	Age of vaccinees					
	Adults		4–7 years		1–4 years	
	Pre	Post	Pre	Post	Pre	Post
<i>S. sonnei</i> rEPA	1.64	48.0	0.32	8.05	0.16	2.86
<i>S. flexneri</i> 2a rEPA	6.28	113.0	1.25	48.0	0.59	40.0

The table above compares the GM of IgG anti-LPS 2 weeks following the second injection of *Shigella* O-SP conjugates in studies undertaken in adults, 5- to 7-year-olds, and 1- to 4-year-olds.

The O-SP of *S. dysenteriae* type 1 is a tetrasaccharide repeating unit: 3)- $\alpha$ -L-Rhap-(1 $\rightarrow$ 3)- $\alpha$ -L-Rhap-(1 $\rightarrow$ 2)- $\alpha$ -D-Galp-(1 $\rightarrow$ 3)- $\alpha$ -D-GlcNAc-(1 $\rightarrow$ ). This saccharide is a hapten and must be conjugated to a protein to induce serum antibodies. The O-SP of *S. dysenteriae* type 1 (natural product) was bound to human serum albumin by multiple point attachment (O-SP-HSA) [57]. Saccharides, corresponding to the O-SP, have been synthesized including tetrasaccharides, octasaccharides, dodecasaccharides, and hexadecasaccharides with a spacer at their reducing end, bound to the protein by single point attachment: the molar ratios of the saccharides to HSA ranged from 4 to 24. In mice, except the tetramer, conjugates of the octamer, dodecamer, and hexadecamer elicited IgG LPS antibodies after the second injection, a statistically significant rise (booster) after the third injection, and higher levels than those vaccinated with O-SP-HSA ( $P = 0.0001$ ). The highest GM levels of IgG

anti-LPS were elicited by the hexadecamer with nine chains or 9 mol of saccharide/HSA (15.5 ELISA units) followed by the octamer with 20 chains (11.1 ELISA units) and the dodecamer with 10 chains (9.52 ELISA units).

The superior immunogenicity of the conjugate prepared with the synthetic saccharides may be explained by assuming that there is a ratio and saccharide-to-protein length that permit optimal stimulation of B cells and T cells [58]. Poly-saccharides or their degradation products are comparatively heterogenous and have not allowed such precise synthesis as has been achieved with synthetic saccharides. Clinical trials of *S. dysenteriae* type 1 conjugates prepared with synthetic saccharides are planned.

#### IV. *V. CHOLERAE* O1 AND O139 CONJUGATE VACCINES

In the United States, the parenteral *V. cholerae* whole cell vaccine was withdrawn because of frequent adverse reactions and short duration of protection. Although the vast majority of clinical infections worldwide are caused by *V. cholerae* O1, in some parts of Asia, 5–20% of cases are caused by serogroup O139; strains of both serogroups can secrete cholera toxin. *V. cholerae* O1 has two LPS types, designated as Inaba and Ogawa, composed of a linear homopolymer  $\alpha$ 1 $\rightarrow$ 2 linked perosamine glycerol-tetronic acid [59]. Serotype Ogawa, in addition, has a methyl group on its C2 at the nonreducing terminal saccharide. *V. cholerae* O139 has a CP composed of a hexasaccharide repeating unit that consists of a trisaccharide backbone and two branches [60]. Our vaccine program for cholera is based upon the following:

- A) The causative agent is confined to the intestinal lumen. Bacteremia and systemic complications such as fever or shock are rarely encountered in cholera patients.
- B) The severe watery diarrhea of cholera gravis is largely mediated by cholera toxin and the disease can be mimicked by feeding the purified protein to volunteers. But neither serum nor intestinal secretory antitoxin confers long-lived protection to cholera in humans [61].
- C) Only the level of serum vibriocidal antibodies has been correlated with resistance to cholera caused by *V. cholerae* O1: the attack rate varies inversely with the serum vibriocidal titer and is rare in individuals with a titer of >1:160 [62].
- D) Most serum vibriocidal activities from convalescent sera can be absorbed by LPS for *V. cholerae* O1, or by CP for *V. cholerae* O139 [63].
- E) Newborns and infants, independent of breast feeding, have a low attack rate of cholera than older children, suggesting that maternally derived serum IgG confer immunity [64].

##### A. Inaba and Ogawa Serotypes of *V. Cholerae* Serogroup O1

*V. cholerae* O1 Inaba conjugates made with hydrazine-treated LPS were evaluated in adult volunteers and the level

of serum IgG anti-LPS was compared with that elicited in parenteral whole cell killed cholera vaccine containing  $4 \times 10^9$  mL<sup>-1</sup> serotypes Inaba and Ogawa [65–67]. Both conjugates and the cellular vaccine elicited vibriocidal antibodies. The correlation coefficient between IgG anti-LPS (ELISA) and 2-mercaptoethanol (2-ME)-resistant vibriocidal antibodies was 0.81 ( $P < 0.0004$ ) and vibriocidal activities were absorbed by LPS.

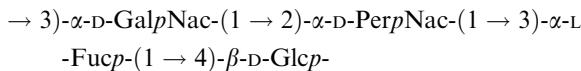

### B. Serogroup O139

The CP from *V. cholerae* O139 was not immunogenic. A conjugate synthesized with CP from O139 was prepared with the mutant diphtheria toxin, DT-H21G [68,69]. Mice injected with conjugates elicited vibriocidal antibodies toward *V. cholerae* O139, but not serotype O1. Treatment with 2-ME reduced (~4-fold) but did not eliminate their vibriocidal activity, indicating that much of this activity was mediated by IgG anti-CP.

We have also inspected convalescent sera from *V. cholerae* O1 patients in Mexico and *V. cholerae* O139 patients in Thailand. The vibriocidal activities for both serotypes were specific toward the surface PS and largely mediated by IgM; the vibriocidal activities were nearly all removed by treatment with 2-ME. The whole cell oral vaccine mimics the pathway of the disease and also induced more IgM than IgG. Conjugate vaccines elicited IgG vibriocidal antibodies that persist longer and can better penetrate into the intestinal fluid than IgM. The evaluation of these conjugates in endemic areas is being planned.

### V. E. COLI O157

In 2001, ~70,000 people in the United States were infected with *E. coli* O157, up from 20,000 cases in 1999 [70–72]. The natural reservoirs of *E. coli* O157 are in cattle, sheep, and deer. Cattle can be infected with the organism for a period from 1 week to 1 month without symptoms. Contaminated beef hamburgers, dairy products, water, vegetable, and fruits are common sources of *E. coli* O157. The ingested infectious dose may be as low as a few hundred organisms. *E. coli* O157 can cause severe clinical disease including hemorrhagic colitis and hemolytic uremic syndrome (HUS) in 5–10% of infected pediatric patients; a subset of HUS patients experiences severe kidney damage. We propose that bactericidal antibodies against the O157 O-SP will lyse the inoculum in the jejunum. The O-SP of *E. coli* O157 consists of four neutral sugars:

where perosamine (4,6-dideoxy-L-mannosamine) is the immunodominant sugar and is found in many cross-reacting organisms [73,74]. The O-SP was conjugated to protein by several schemes. A Phase I evaluation of these investigation-vaccines was conducted in healthy adults at Carolina Medical Center (Charlotte, NC) [75,76]. The conjugates were safe and elicited statistically significant rises of IgG anti-LPS levels at 4 weeks and up to 26 weeks follow-

ing vaccination: 80% responded with at least a fourfold rise in the anti-LPS IgG level within 1 week, and 100% responded at 6 weeks. These sera precipitated in immunodiffusion with LPS from *E. coli* O157 but not with LPS from *E. coli* O55 or strain K-12, indicating that the antibodies are directed against the O-SP region and not the core region of the LPS. Postvaccination sera had bactericidal activity [76]:

IgG LPS Antibodies Elicited in Adult Volunteers by *E. coli* O157 O-SP-rEPA Conjugates

Conjugate	Preimmune	Anti-LPS IgG (GM, ELISA units)		
		1 week	4 weeks	26 weeks
O-SP-rEPA	0.47	7.93	61.9	32.8
DeALPS-rEPA <sup>a</sup>	0.51	5.73	46.3	31.2
DeALPS-rEPAv	0.54	4.12	36.6	33.1

<sup>a</sup>DeALPS LPS was prepared by treatment with anhydrous hydrazine. (From Ref. 76.)

There were 29 volunteers in each group; each volunteer received one injection containing 25 µg of PS. A high-titer postvaccination serum was used as standard and assigned a value of 100 ELISA units. The postimmune sera were bactericidal and their titer was related to their content of IgG anti-LPS as measured by ELISA. Currently, the safety and the immunogenicity of O-SP-rEPA are being evaluated in 2- to 5-year-old children. Preliminary results showed that conjugate vaccine is safe and induces more than a 10-fold rise of IgG anti-LPS 6 months after the first injection; booster responses were detected after reinjection.

The anti-LPS bactericidal activity from the conjugate vaccines could theoretically release Shiga toxin [77]. Accordingly, we synthesized conjugates of *E. coli* O157 O-SP bound to the nontoxic B subunit of Shiga toxin 1 (Stx1B). We modified our conjugation scheme to retain the immunogenicity of the Stx1B and to accommodate the smaller molecular weight of Stx1B (7300 kDa). The conjugates elicited both neutralizing antitoxin (titer 1/10,000) and induced the bacteriolysis of *E. coli* O157 [78].

Clinical isolates of *E. coli* O157 from HUS patients mostly contain the gene that encodes Stx2 [79]. Furthermore, from our experience with cholera toxin conjugates, the immunogenicity of holotoxin provided higher neutralization activity than the B-subunits. Thus, a recombinant nontoxic Stx2 as the carrier protein will be more desirable [80].

### VI. SUMMARY

The surface PS of respiratory and enteric bacterial pathogens are essential virulence factors and protective antigens. These CP or O-SP exert their virulence by shielding the bacteria from complement. A critical (protective) level of antibodies, most importantly of the IgG isotype, confers

immunity to these pathogens by killing the inoculum. Protein conjugates of these PS enhance the immunogenicity and prolong the duration of antibody synthesis. This approach to develop vaccines has provided the first vaccine for typhoid that protects young (2- to 5-year-old) children, and preliminary data indicate that O-SP conjugates will prevent shigellosis. Conjugate vaccines are also being developed to prevent *E. coli* O157 and *V. cholerae* disease. Preliminary clinical data show these conjugates to be safe and immunogenic. We are enthusiastic about the potential of synthetic saccharides to replace the natural product for conjugate vaccines.

## Attenuated Strains of *Salmonella enterica* serovar Typhi as Live Oral Vaccines Against Typhoid Fever

**Myron M. Levine, James Galen, Carol O. Tacket, Eileen M. Barry, Marcela F. Pasetti, and Marcelo B. Sztein**  
*University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.*

### I. TARGET POPULATIONS

Typhoid fever is exceedingly uncommon in modern industrialized countries where populations are served by treated, bacteriologically monitored water supplies and by sanitation that removes human fecal waste. In contrast, in less-developed countries where populations commonly lack such amenities, typhoid fever is often endemic and, from the public health perspective, typically constitutes the most important enteric disease problem of school-age children [1]. Systematic clinical, epidemiological, and bacteriological surveillance for typhoid fever carried out in relation to field trials of the efficacy of candidate vaccines has provided more precise data on the incidence of typhoid in many populations [2–9]. The incidence rates recorded were much higher than predicted based on nonsystematic surveillance. Systematic household and health center-based surveys have also demonstrated a surprisingly high frequency of bacteremic (but in general clinically mild) typhoid infection among febrile infants and toddlers in endemic areas [10,11].

Besides school-age children in less-developed countries, travelers [12] and clinical microbiologists [13] represent other groups at increased risk of developing typhoid fever. Among U.S. travelers, the risk is highest in the Indian subcontinent [12,14]. Because of increased exposure to *Salmonella enterica* serovar Typhi (*S. Typhi*), clinical microbiologists, even in industrialized countries, constitute a high-risk group [13,15].

### II. MULTIRESTANT *S. Typhi* STRAINS

Since 1990, strains of *S. Typhi* resistant to most of the antimicrobials that previously were clinically effective have spread aggressively throughout the Middle East, the Indian subcontinent, and Southeast Asia [16–18]. The few antibiotics that remain effective against these multiresistant strains, such as ciprofloxacin and ceftriaxone, are relatively expensive and not readily available in rural areas of less-developed countries. The dissemination of these multiresistant

*S. Typhi* strains in many less-developed countries constitutes a public health crisis that has rekindled interest in the development of improved oral typhoid vaccines [19].

### III. CURRENTLY LICENSED LIVE ORAL TYPHOID VACCINE Ty21a

Ty21a, an attenuated strain of *S. Typhi* that is safe and protective as a live oral vaccine, was developed in the early 1970s by the chemical mutagenesis of pathogenic *S. Typhi* strain Ty2 [20]. The characteristic mutations in this strain include an inactivation of *galE* (which encodes UDP-galactose-4-epimerase, an enzyme involved in LPS synthesis) and an inability to express Vi capsular polysaccharide. Whereas Ty21a has been remarkably well tolerated in placebo-controlled clinical trials, it is not clear precisely what mutations are responsible for the stable, attenuated phenotype of this vaccine.

Ty21a provides significant protection without causing adverse reactions. Results of three double-blind, placebo-controlled studies that utilized active surveillance to assess the reactogenicity of Ty21a in adults and children show that adverse reactions are not observed significantly more often in vaccinees than placebo recipients for any symptom or sign [9,21,22]. In large-scale efficacy field trials with Ty21a, involving approximately 530,000 schoolchildren in Chile and 32,000 in Egypt, and approximately 20,000 subjects from 3 years of age to adults in Indonesia, passive surveillance failed to identify vaccine-attributable adverse reactions [2,3,5,9,23].

Notably, results of controlled field trials of Ty21a emphasize that the formulation of the vaccine, the number of doses administered, and the spacing of the doses markedly influence the level of protection that can be achieved [1–5,9,24,25]. In the first field trial of Ty21a in Alexandria, Egypt, 6- to 7-year-old schoolchildren received three doses of vaccine (suspended in a diluent) on Monday, Wednesday, and Friday of 1 week [24]; to neutralize gastric acid, the

children chewed a 1.0-g tablet of NaHCO<sub>3</sub> several minutes before ingesting the vaccine or placebo. During the 3 years of surveillance, 96% protective efficacy against bacteriologically confirmed typhoid fever was observed [24].

A more recent formulation that has been a commercial product since the mid-1980s consists of lyophilized vaccine in enteric-coated, acid-resistant capsules. In a randomized, placebo-controlled field trial in Santiago, Chile, three doses of this enteric-coated formulation given within 1 week provided 67% efficacy during the first 3 years of follow-up [3] and 62% protection over 7 years of follow-up [26]. Four doses of Ty21a in enteric-coated capsules given within 8 days are significantly more protective than two or three doses [25]. When Ty21a was licensed in the United States by the Food and Drug Administration in late 1989, it was with a recommended schedule of four doses given at an every-other-day interval; other countries use a three-dose immunization schedule.

In the mid-1980s, the Swiss Serum and Vaccine Institute (currently Berna Biotech) succeeded in preparing for large-scale field trials a “liquid suspension” formulation of Ty21a that was amenable to large-scale manufacture. The new formulation consists of two packets: one containing a dose of lyophilized vaccine and the other containing a buffer. Contents of the two packets are mixed in a cup containing 100 ml of water and the suspension is then ingested by the subject to be vaccinated. A fourth field trial was initiated in Santiago, Chile [3] and a parallel trial was carried out in Plaju, Indonesia [9] to compare directly this new liquid formulation (that somewhat resembles what was used in the Alexandria, Egypt field trial) with the enteric-coated capsule formulation. Vaccine administered as a liquid suspension was superior to vaccine in enteric-coated capsules. In the Santiago trial, the difference was highly significant. Ty21a given as a liquid suspension protected young children as well as older children [2]. In previous trials with enteric-coated vaccine, young children were not as well protected as older children [5]. The “liquid formulation,” which is now available in a number of countries, is not only superior in efficacy to the enteric-coated capsule formulation but is more practical for administering vaccine to toddlers and preschool children. Although there are no field trial data to document the efficacy of Ty21a in children below 3 years of age, nevertheless, the liquid formulation is well tolerated and strongly immunogenic in toddlers and preschool children [27,28]. In contrast, an attempt to prepare a liquid suspension of Ty21a by emptying the contents of an enteric-coated capsule into a mixture of milk containing 0.5 g of NaHCO<sub>3</sub> resulted in an ineffective mixture that was poorly immunogenic [29]. Despite its pioneering role and positive attributes, recognized drawbacks of Ty21a include the lack of a molecular basis for its attenuation, relatively modest immunogenicity, and, most importantly, the need to administer at least three spaced doses in order to confer protection.

#### IV. CORRELATES OF PROTECTION OF LIVE TYPHOID VACCINES

Although Ty21a is only modestly immunogenic and requires three or four spaced doses to elicit protection, the efficacy is

surprisingly long-lasting, enduring for 5–7 years [26]. Two immunological assays were found to correlate with the protection conferred by different formulations and immunization schedules of Ty21a in field trials. These include serum IgG O antibody seroconversions [4] and enumeration of gut-derived IgA O antibody-secreting cells (ASCs) detected among peripheral blood mononuclear cells (PBMCs) [30]. The identification of these measurements as immunological correlates of protection provides an invaluable tool for use in early clinical trials of new attenuated *S. Typhi* strains as possible live oral vaccines.

#### V. NEW GENERATIONS OF ATTENUATED *S. Typhi* AS LIVE ORAL VACCINES

Investigators in various laboratories worldwide have undertaken to engineer new candidate vaccine strains that are as well tolerated as Ty21a yet are more immunogenic, such that a single oral dose will elicit protective immunity. One attempt was made to increase the immunogenicity of Ty21a by restoring its ability to express Vi antigen [31]. Following other strategies (Table 1), candidate vaccine strains have been prepared by inactivating genes encoding various biochemical pathways [32,33], global regulatory systems [34], heat shock proteins [35], other regulatory genes [36,37], and putative virulence properties [38,39]. An elucidation of the sequence of the complete genome of wild-type *S. Typhi* strain CT 18 has provided an important resource for the development of attenuated *S. Typhi* strains.

The relative attenuating potential of various mutations has typically been assessed by feeding *S. Typhimurium* strains harboring these mutations to mice and by observing the result, in comparison with isogenic wild-type strains. Regrettably, the behavior of attenuated *S. Typhimurium* strains in mice has not proven to be reliable for predicting the behavior of homologous *S. Typhi* mutants in humans. There exist several examples where specific mutations that successfully attenuate *S. Typhimurium* for mice failed to adequately attenuate *S. Typhi* for humans [32,40,41]. These observations underscore the critical importance of careful clinical trials. The availability of the complete *S. Typhi* genome sequence has assisted in the identification of target sites to introduce attenuating mutations [42,43].

##### A. Vi-Positive Ty21a

A derivative of Ty21a was constructed by introducing *viaB*, which encodes the enzymes required for the synthesis of Vi polysaccharide, from wild-type strain Ty2 into the chromosome of Ty21a and by demonstrating the expression of Vi capsular polysaccharide [44]. Tacket et al. [31] fed this Vi-positive Ty21a strain with buffer to healthy North American adults in single liquid suspension doses containing  $5 \times 10^5$ ,  $5 \times 10^7$ , and  $5 \times 10^9$  colony-forming units (cfu); an additional group of subjects received three  $5 \times 10^9$  cfu doses and buffer (every-other-day interval between the doses). The Vi-positive variant was well tolerated and most subjects who received three doses developed rises in serum IgG antibodies and IgA ASCs against *S. Typhi* O antigen. However, no

subject manifested rises in serum IgG anti-Vi or exhibited ASCs that secrete IgA anti-Vi [31].

### B. 541Ty and 543Ty

Hoiseth and Stocker [45] and Edwards and Stocker [46] popularized the concept of making auxotrophic mutants of *Salmonella* with inactivations of genes encoding enzymes in the aromatic amino acid biosynthesis pathway. These mutations render the *Salmonella* nutritionally dependent on substrates (*para*-aminobenzoic acid and 2,3-dihydroxybenzoate) that are not available in sufficient quantity in mammalian tissues; as a consequence, the vaccine remains viable but is severely inhibited in its ability to proliferate.

Edwards and Stocker [46] constructed prototype strains 541Ty and 543Ty (a Vi-negative variant of 541Ty) from CDC 1080, a wild-type strain obtained from the collection of the Centers for Disease Control. It may be of some relevance that the pathogenicity of this strain had never been directly tested in volunteers. In contrast, most other investigators have started with wild-type strain Ty2, the parent of Ty21a [20], in their attempts to engineer new attenuated strains. The pathogenicity of Ty2 has been established in volunteer studies [47].

Strains 541Ty and 543Ty also harbor a deletion mutation in *purA*, which results in a specific requirement for adenine (or an assimilable compound such as adenosine) [46]. A third mutation in *hisG*, leading to a histidine requirement, does not affect virulence but provides an additional biochemical marker to clearly differentiate the vaccine strain from wild *S. Typhi*. Strains 541Ty and 543Ty were quite well

tolerated in dosages up to  $5 \times 10^{10}$  cfu in Phase I studies but were notably less immunogenic than Ty21a in stimulating humoral antibody responses [48]. For example, only 11% of subjects developed serum IgG anti-O antibodies [48].

### C. Attenuated *S. Typhi* Strain CVD 908

The first vaccine strain that proved to be well tolerated and impressively immunogenic following administration of a single oral dose in Phase I clinical trials in humans is strain CVD 908 [41,49], which harbors precise deletion mutations in *aroC* and *aroD* [50]. CVD 908 was the first engineered *S. Typhi* vaccine candidate shown to be highly immunogenic yet well tolerated. At a well-tolerated dose of  $5 \times 10^7$  cfu, 92% of CVD 908 recipients manifested IgG O antibody seroconversions and showed evidence of priming of the intestinal immune system (IgA ASCs) [49]. Moreover, vaccinees exhibited lymphoproliferative responses and their PBMCs were shown to secrete cytokines (in particular gamma interferon) upon exposure to *S. Typhi* flagella [51]. CVD 908 also stimulates cytotoxic lymphocytes that recognize targets (Epstein–Barr virus-immortalized prevaccination B lymphocytes) expressing *S. Typhi* antigens on their surface [52].

One possible drawback observed in the Phase I clinical trials with CVD 908 is that 50% of subjects who ingested this vaccine strain at a dose of  $5 \times 10^7$  cfu and 100% of subjects who received a  $5 \times 10^8$  cfu dose manifested silent bacteremias wherein vaccine organisms were recovered from blood cultures collected at one or more time points between days 4 and 8 after vaccination. The blood cultures were collected systematically in these individuals within hours after they

ingested the vaccine and then on days 2, 4, 5, 7, 8, 10, 14, 20, 27, and 60. No blood cultures from any vaccinee were positive prior to day 4 nor after day 8. The vaccinemas appeared to have no clinical consequence (e.g., they were not associated with fever) and they were short-lived, spontaneously disappearing without the use of antibiotics. There is a precedent for the licensure and mass use in public health of live vaccine strains that cause short-lived vaccinemas. For example, viremia occurs in many recipients of attenuated rubella vaccine strain RA27/3 [53] or attenuated poliomyelitis vaccine (mostly serotype 2 component) [54,55]. Thus, if licensure of CVD 908 was to be pursued, sufficient empirical data would have to be generated to document that the vaccinemas are not associated with any untoward reactions, as was done for the licensure of attenuated rubella and oral polio vaccines. Pursuing an alternative strategy, it was decided to introduce additional mutations into CVD 908 to yield a derivative that would remain well tolerated and immunogenic yet would not manifest vaccinemas.

#### D. CVD 908-htrA

Chatfield et al. [35] found that the inactivation of *htrA*, a gene encoding a stress protein that functions as a serine protease, attenuates wild-type *S. Typhimurium* in the mouse model. Moreover, mice immunized orally with  $\Delta htrA$  *S. Typhimurium* are protected against subsequent challenges with a lethal dose of wild-type *S. Typhimurium*. Levine et al. [56] thereupon introduced a deletion mutation into the *htrA* of CVD 908, resulting in strain CVD 908-htrA. Tacket et al. [57] fed CVD 908-htrA as a single dose to three groups of subjects who ingested  $5 \times 10^7$  cfu ( $n=7$ ),  $5 \times 10^8$  cfu ( $n=8$ ), or  $5 \times 10^9$  cfu ( $n=7$ ). The CVD 908-htrA strain was as well tolerated as the CVD 908 parent. Only 1 of 22 subjects developed a low-grade fever, which was detected by routine surveillance and was not associated with any complaints of malaise. However, 2 of 22 subjects developed loose stools [57]; mild diarrhea had not been observed in any recipient of CVD 908 [41,49]. The immune response elicited by CVD 908-htrA was excellent: 20 of 22 individuals manifested

significant rises in serum IgG O antibody, and in 100% of subjects, gut-derived IgA antibody-secreting cells were detected, which made antibody to O antigen (Table 2). These responses are virtually identical to what was observed in Phase I clinical trials in subjects immunized with comparable doses of CVD 908. The one striking difference was with respect to vaccinemas. Whereas vaccinemas were detected in 12 of 18 subjects who received a  $5 \times 10^7$  or  $5 \times 10^8$  cfu dose of CVD 908, no vaccinemas were detected in any of the 22 individuals who ingested well-tolerated, highly immunogenic  $5 \times 10^{7-9}$  cfu doses of CVD 908-htrA ( $P < 0.001$ ).

CVD 908-htrA was then evaluated in a Phase II randomized, placebo-controlled clinical trial in a larger number of adult North American subjects to assess the clinical acceptability and immunogenicity of a lyophilized formulation of the vaccine administered following reconstitution. Dosage levels of  $5 \times 10^7$  and  $5 \times 10^8$  cfu were evaluated [58]. There were no differences in the rates of side effects among recipients of either the high dose, the low dose, or the placebo during 21 days of follow-up. The vaccine strain was immunogenic at both dosage levels, although responses were stronger in recipients of the higher dose [58,59].

Vaccine strain ACAM 948-CVD was derived from wild-type Ty2 by introducing the identical mutations as found in CVD 908-htrA. The difference between these strains is that in the construction of ACAM 948-CVD, only bacteriological media devoid of animal products were used. ACAM 948-CVD is in early clinical trials.

#### E. Strain CVD 909, A Further Derivative of CVD 908-htrA that Constitutively Expresses Vi Capsular Antigen

From the results of two large-scale field trials, it is known that parenteral administration of non-denatured purified Vi polysaccharide confers a moderate level of protection against typhoid fever (55% vaccine efficacy over 3 years of follow-up) by stimulating serum Vi antibodies [6,7,60]. Results of other field trials show that attenuated strain Ty21a, which lacks Vi capsular polysaccharide, also confers

**Table 2** Leading Live Oral Typhoid Vaccine Candidates Based on Results of Early (Phase I or II) Trials Assessing the Clinical, Immunological, and Bacteriological Response of Adult Volunteers Following Ingestion of a Single Dose of Vaccine

Vaccine strain and dosage (cfu)	Formulation	Number of subjects	Positive cultures		Fever			Immunological responses			References
			Stool	Blood	$\geq 38.2$	$\geq 39.5$	Diarrhea	Serum IgG O antibody	IgA O ASCs	References	
CVD 908-htrA ( $10^{7-9}$ )	Freshly harvested	22	17 (77%)	0	1 (5%)	0	2 (9%)	20 (91%)	22 (100%)	[57]

Ty800 ( $10^{7-10}$ )	Freshly harvested	11	10 (91%)	0	0	0	1 (9%)	6 (55%)	10 (91%)	[62]	
$\chi 4073$ ( $10^{7-9}$ )	Freshly harvested	10	3 (30%)	0	0	0	0	9 (90%)	9 (90%)	[61]	
ZH9 ( $10^{7-9}$ )	Frozen in glycerol	9	3 (33%)	0	0	0	0	5 (56%)	6 (67%)	[39]	

a moderate level of protection and achieves this by eliciting cell-mediated and humoral immune responses other than the stimulation of Vi antibodies [3,5,26]. Levine et al. [4] hypothesized that a live oral vaccine may achieve a much higher level of protection against typhoid fever if it stimulated anti-Vi antibody, in addition to stimulating antibody responses to other antigens and eliciting cell-mediated immunity. Regrettably, the new generation of attenuated *S. Typhi* vaccine strains—exemplified by strains such as CVD 908, CVD 908-*htrA*, Ty800, and X4073, which are well tolerated and more immunogenic than Ty21a in eliciting serum O and H antibodies [41,49,57,61,62]—only rarely stimulate serum Vi antibodies in subjects. Because Vi expression is highly regulated and appears to be turned off when *S. Typhi* gains its intracellular niche, Wang et al. [63] engineered CVD 909, a further derivative of CVD 908-*htrA* that constitutively expresses Vi. CVD 909 was constructed by replacing the native promoter of *tviA* with the strong constitutive promoter *P<sub>tac</sub>*. Constitutive expression of Vi was thereby achieved. In mice immunized mucosally (intranasally) with a single dose of vaccine, CVD 909 stimulated a significantly higher GMT of serum Vi antibodies than CVD 908-*htrA* [63].

#### F. Derivatives of Wild-Type Strain CDC 1080 with Mutations in *aro* and *htrA*

Deletions were introduced in *aroA* and *aroD* (encoding enzymes in the aromatic biosynthetic pathway) in wild-type strain CDC 1080 to produce vaccine candidate PBCC 211. Three different formulations of PBCC 211 were tested in Phase I clinical trials [64]. Among subjects who ingested either of two lyophilized formulations, a proportion developed fever. At the highest dosage levels tested, some vaccinees manifested silent self-limited vaccinemas on days 4–5 after ingesting a single dose of vaccine [64]. A deletion in *htrA* was introduced into strain PBCC 211 to derive vaccine strain PBCC 222 [64]. A lyophilized formulation of PBCC 222 contained in sachets was tested in Phase I clinical trials in subjects who received dosage levels of  $10^7$ – $10^9$  cfu [64]. No vaccinemas were detected in recipients of this further derivative but some who ingested the highest dosage level developed fever, chills, and headache, leading to abandonment of further clinical trials.

#### G. Strains with Mutations in *cya,crp* or *cya,crp,cdt*

Curtiss et al. demonstrated that in *Salmonella*, *cya* (encoding adenylate cyclase) and *crp* (cyclic AMP receptor protein) constitute a global regulatory system that affects many genes and operons. They showed that an *S. Typhimurium* strain that harbors deletions in *cya* and *crp* [34] is attenuated compared to its wild-type parent, and that oral immunization protects mice against challenge with virulent *S. Typhimurium*.

Curtiss et al. constructed vaccine candidate strain χ3927, a *cya,crp* double mutant of *S. Typhi* strain Ty2. In Phase I clinical trials, Tacket et al. [41] demonstrated that χ3927 was attenuated compared to wild type but insufficiently so to serve as a live oral vaccine in humans because

occasional subjects developed high fever and typhoidlike symptoms. Several subjects also manifested vaccinemas. In order to achieve a greater degree of attenuation, Kelly et al. [65] introduced into the *cya,crp* mutant a third deletion mutation in *cdt*, a gene that affects the dissemination of *Salmonella* from gut-associated lymphoid tissue to deeper organs of the reticuloendothelial system such as the liver, spleen, and bone marrow. The resultant *cya,crp,cdt* triple mutant strain χ4073 was fed to healthy adult North Americans, with buffer, in single doses containing  $5\times 10^5$ ,  $5\times 10^6$ ,  $5\times 10^7$ , or  $5\times 10^8$  cfu. The strain was well tolerated except for one individual in the  $5\times 10^6$  cfu group who developed diarrhea [61]. No subjects manifested vaccinemia. Four of five subjects who ingested  $5\times 10^8$  cfu exhibited significant rises in serum IgG O antibody and had ASCs that made IgA O antibody [61] (Table 2).

The *cya,crp,cdt* mutant strain χ8110, derived from wild-type strain ISP 1820, was fed to volunteers at dosage levels of  $10^5$ ,  $10^6$ ,  $10^7$ , and  $10^8$  cfu [66]. No subjects developed fever, one of four who ingested the highest dosage level developed diarrhea, and two of eight who received  $10^{7-8}$  cfu manifested vaccinemia [66].

#### H. Strains with Mutations in *phoP/phoQ*

Hohmann et al. [62,67] constructed two candidate *S. Typhi* strains harboring deletions in *phoP/phoQ*. Strain Ty445, which also harbors a deletion in *aroA*, was found to be overly attenuated and only minimally immunogenic [67]. In contrast, strain Ty800, a derivative of Ty2 deleted only in *phoP/phoQ*, was generally well tolerated and immunogenic when evaluated in dosage levels from  $10^7$  to  $10^{10}$  cfu in a small Phase I clinical trial involving 11 subjects [62] (Table 2). At the highest dosage level, one of three vaccinees developed diarrhea (10 loose stools). It is difficult to compare the immune responses of subjects who received Ty800 with those observed in recipients of CVD 908-*htrA* and χ4073 because some of the immunological assay techniques were different and, even where the same assay was used (e.g., IgA ASCs that make O antibody), considerable variation is known to occur between laboratories. Nevertheless, for purposes of comparison, the data from the clinical trial with Ty800 are summarized in Table 2 along with data from clinical trials involving comparable dosage levels of CVD 908-*htrA*, χ4073, Ty800, and ZH9.

#### I. Strain ZH9 with Mutations in *aroC* and *ssaV*

*Salmonella* Pathogenicity Island 2 (SPI 2) encodes a type III secretion system that is necessary for *S. Typhimurium* to manifest full pathogenicity in the mouse model [68,69]. *S. Typhimurium* strains harboring deletions in SPI 2 do not manifest a full-blown systemic infection and show a diminished ability to replicate in macrophages. SPI 2, which is activated under intracellular conditions, translocates effector proteins from the vacuole containing the *Salmonella* across the vacuolar membrane to the cytosol of the host cell (e.g., macrophages). *ssaV* forms part of the SSP 2 secretin, the needlelike bacterial structure that transports proteins

across the inner and outer bacterial membranes. *S. enterica* derivatives harboring mutations in *ssaV* are crippled in their ability to secrete SPI 2 effector proteins. Deletion mutations in *aroC* and *ssaV* were introduced in wild-type strain *S. Typhi* strain Ty2 to derive vaccine candidate ZH9 [39].

In a small Phase I clinical trial that included nine adult subjects, ZH9 was well tolerated and elicited anti-Typhi immune responses in the majority of vaccinees (Table 2). The vaccine strain was recovered from stool cultures in only three subjects.

### J. Mixing and Matching of Attenuating Mutations

If current leading vaccine candidate strains such as CVD 908-*htrA*, χ4073, Ty800, and ZH9 encounter difficulties in the course of Phase II or III clinical trials, a careful review of the clinical and serological data should provide critical feedback to allow investigators to engineer new vaccine candidates that incorporate different combinations of attenuating mutations. The goal would be to choose attractive new combinations of mutations based on the clinical, bacteriological, and immunological data generated in previous trials.

## VI. FUTURE USE OF LIVE ORAL TYPHOID VACCINES

Ideally, an attenuated strain constituting the live oral vaccine of the future will be so well tolerated that it will be possible to administer the vaccine routinely to infants as well as to immunocompromised subjects with AIDS or other immune deficiencies. On the other hand, the ideal live vaccine will be so immunogenic that a single dose will confer a high level of long-term protection that will endure throughout childhood, including during the usual peak risk for typhoid fever during the period of 5–19 years of age. With such properties, it will be possible to pursue the control of typhoid by a strategy involving routine immunization of infants within the Expanded Program on Immunization schedule, perhaps supplemented by school-based immunization campaigns.

An alternative epidemiological approach to control endemic typhoid fever would be to institute only school-based immunization programs. Because peak incidence of typhoid fever in most endemic areas occurs in school-age children 5–19 years of age, and because this is a “captive” population, it should be possible in the future to design control programs to incorporate school-based immunization with a single-dose oral vaccine. Field experiences with Ty21a support such an approach. Even using multiple dose regimens of Ty21a, Ferreccio et al. [5] reported the practicality of school-based immunization in a field trial in 230,000 school children that compared two-dose, three-dose, and four-dose regimens (all within 8 days) of Ty21a. Moreover, Olanratmanee et al. [28] observed a herd immunity effect in geographically separate areas of metropolitan Santiago when large-scale use of Ty21a was carried out in the course of field trials in other areas of the city. Practicality will be

greatly enhanced with the advent of a single-dose live oral vaccine, and herd immunity effects should be even more pronounced with a vaccine that exhibits greater efficacy than Ty21a.

## Vaccines Against Lyme Disease

**Mark S. Hanson\***

*MedImmune, Inc., Gaithersburg, Maryland, U.S.A.*

**Robert Edelman**

*University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.*

### I. INTRODUCTION

In this chapter, we review the progress of Lyme disease (LD) vaccine development, the licensure in 1998 of the first human LD vaccine, the removal of that vaccine from the market in 2002, and the scientific and marketing challenges that lie ahead for the next generation of LD vaccines.

#### A. An Overview of Lyme Disease

Lyme disease, or Lyme borreliosis, presents as a multisystemic inflammatory disease with protean manifestations in humans and domestic animals [1]. The disease is caused by *Borrelia burgdorferi* sensu lato [2], a spirochete transferred from a diversity of wild mammals or birds to humans and animals by the bite of *Ixodes* spp. ticks. The taxonomic grouping *B. burgdorferi* sensu lato is subdivided into at least 10 species based on DNA–DNA reassociation and biochemical analyses [3]. In this chapter, *B. burgdorferi* sensu lato will be referred to as “Bb” for simplicity, unless otherwise specified. The three species of Bb that have been isolated from humans and well known to cause human disease are *B. burgdorferi* sensu stricto, isolated in North America and Europe, and *B. garinii* and *B. afzelii*, isolated in Europe and Asia including Japan and Taiwan. These three species may have different clinical presentations [1,4]. Many additional related species circulate in environmental reservoirs, and newer evidence suggests that at least some of them may also infect humans [5,6].

Certain manifestations of the clinical entity now called LD has been known in Europe for more than a century (reviewed in Ref. 7). First recognized clinically in the United

States in the 1970s [8], LD is currently the most commonly reported tick-borne disease in the North America and Europe [1,9]. Currently, about 15,000 cases are reported each year in the United States, although the annual incidence is undoubtedly higher [9,10].

After Bb-infected tick saliva is deposited into the skin, Bb proliferates and causes a macular skin rash called erythema migrans within several days at the site of the tick bite. Constitutional symptoms may occur. The organism then enters the blood, circulating for days to weeks, during which time it disseminates to the joints, heart, brain, and other organs. Weeks or months later, meningitis, facial palsy, heart block, or migratory musculoskeletal pain may develop. Episodes of frank oligoarticular arthritis, encephalopathy, polyneuropathy, or acrodermatitis may occur months or years after the infection [1].

The early manifestations of LD, such as erythema migrans, are readily treated by oral antibiotics. By contrast, many patients with late LD, particularly those having arthritis and nervous system symptoms, must be treated with lengthy regimens of oral or parenteral antibiotics, and some of these patients fail therapy altogether [11]. About 10% of individuals with chronic arthritis, particularly those patients with HLA-DRB1\*0401 or related alleles, are refractory to multiple courses of antibiotics and may have persistent joint inflammation [1,12,13].

Serology is used to confirm the clinical diagnosis of Lyme borreliosis [1]. *B. burgdorferi* infection in humans induces specific IgM and IgG antibodies detected by enzyme-linked immunosorbent assay (ELISA), IFA, and Western immunoblot [14], with antibodies to P41/FlaB and OspC antigens among the most prevalent.

## B. Outer Surface Proteins of *B. burgdorferi* as Vaccine Targets

The earliest Bb antigens characterized were proteins presumed to be on the Bb outer surface membrane based on immunofluorescence and were termed “outer surface proteins” (Osp). OspA through OspF are lipoproteins having covalently attached fatty acids. The term *Osp* is sometimes used collectively for all Bb lipoproteins. OspA was the first of these [15] and is the most abundant membrane protein expressed in vitro by the majority of Bb isolates. OspA proteins are similar across each Bb species (>98% identity within *B. burgdorferi* sensu stricto and *B. afzelii*) [16]. OspB is somewhat less abundant than OspA and is structurally more variable [17,18]. OspC proteins are the most heterogeneous, often sharing only 70–80% identity between strains of a particular Bb species [19]. OspC is the most abundant membrane protein in cultures of many *B. afzelii* and *B. garinii* isolates. At least three additional distinct proteins have been designated “Osp,” including OspD, OspE, and OspF. OspA promotes spirochetal adherence to tick gut and colonization of the vector [20]. The functions of the other Osp are less well understood.

## II. JUSTIFICATION FOR LYME DISEASE VACCINES

There are many reasons to develop and utilize vaccines against LD. First, considerable morbidity is associated with *B. burgdorferi* infection [1]. Second, areas exist in the United States and Europe where 1–3% of a population are infected annually, and the infection seems to be growing in range and intensity [9,21,22]. Third, substantial costs result from multiple and unnecessary diagnostic tests, lengthy oral and parenteral antibiotic treatment regimens, loss of work and school, diminished quality of life, decline of tourism and real estate values in endemic communities, and a widespread fear of acquiring the disease. Fourth, practical and environmentally safe methods of tick control are not available [23], and wildlife (deer) management seems futile [24]. Fifth, personal protection, which includes wearing light-colored clothes, tucking pants into socks, applying tick repellents to skin, applying acaracides to clothes, and promptly removing ticks (nymphal ticks are difficult to detect on the body and clothes), has not reduced the incidence of LD [9,25]. Sixth, the infection can be difficult to diagnose, particularly early LD [26], and although uncommon, patients with chronic LD, who are seronegative and thus go untreated, can also be found [27]. Finally, treatment failures of chronic Lyme arthritis and neuroborreliosis are not uncommon [11].

## III. RATIONALE AND EXPERIMENTAL VACCINE DEVELOPMENT

### A. Naturally Acquired Immunity to *B. burgdorferi*

If a naturally acquired infection by a pathogenic organism induces robust protective immunity, it is likely that a vaccine against that infectious agent would be similarly protective. In human LD, naturally acquired immunity has not been formally demonstrated [33]. On the contrary, repeated Bb

infection of patients treated for early LD has been reported [34], although the frequency of such reinfections is unknown.

### B. Initial Studies of Active and Passive Immunity

The first evidence that vaccines will protect mammals was provided by the studies of Johnson et al. [35] who demonstrated that a single injection of a thimerosal-treated, whole cell Bb vaccine protected hamsters in a dose-dependent fashion against cultured Bb-inoculated 30 days after vaccination. In a companion study, hamsters passively immunized with immune rabbit serum were protected against challenge with 1000, 50% infective doses of Bb [28]. Because Bb-infected hamsters developed circulating antibodies that protected recipient hamsters against subsequent challenge but not against established infection [36], and because immune serum infused 18 hr after inoculation of Bb did not prevent infection, early vaccine development with OspA focused on immunoprophylaxis rather than immunotherapy of LD [29].

### C. Immunity to Tick-Borne *B. burgdorferi*

The efficiency of Bb transmission between tick and vertebrate hosts correlates with the duration of attachment of the infected *Ixodes* tick [43]. Although *Ixodes scapularis* ticks feed for 3–11 days, few infectious Bb spirochetes are transmitted to mammals during the first 2 days [37,43]. Transmission increases dramatically thereafter. The 37°C temperature, shift in pH, and unknown nutrients in the imbibed blood activate Bb in the midgut of the tick, which then multiply and pass to the salivary glands. In Europe and Asia, where *I. ricinus* and *I. persulcatus* transmit *B. burgdorferi* sensu stricto, *B. garinii*, and *B. afzelli*, transmission may begin during the first day of tick attachment [38].

The adaptation of Bb as it cycles between its tick and vertebrate hosts involves the expression of many internal and surface-associated molecules [31]. For example, Bb spirochetes in the midguts of unfed ticks express OspA, but the burst of spirochete replication on tick feeding is accompanied by an upregulation of other proteins, in particular OspC, and a loss of OspA [31,32]. This helps explain the more robust antibody response to OspC than to OspA during early LD [13]. Conversely, OspA-negative Bb in vertebrate hosts become OspA-positive after they infect feeding ticks [32].

A seminal discovery, that Bb are destroyed within the midgut of ticks feeding on passively [39] or actively immunized mice [40–42], has molded our concept of how vaccine-induced immunity may protect against LD. Passive immunization with antiserum from rabbits hyperimmunized against cultured Bb protects mice against tick-transmitted spirochetal infection only when the antibody is administered within 24–48 hr after tick attachment [39], the initial lag period before spirochetes are deposited into the skin of the host [37,43]. Passive antibody administered 3 days after tick attachment does not protect mice [39]. This type of immunity, essentially a passive immunization of the vector by the serum of the vaccinated host, is probably uniquely effective against pathogens such as Bb that reside in a metabolically inactive state in the midgut of an arthropod

vector that feeds for several days. Most Bb spirochetes lose OspA expression during transmission from ticks in parallel with their loss of vulnerability to OspA antiserum [44]. For Bb, this has been described as “transmission-blocking immunity.” Malaria vaccinologists have used the same terminology to describe the reverse process when the mosquito’s acquisition of gametocytes from a parasitic host is blocked. The effectiveness of this novel mechanism of protection depends on the maintenance of circulating Bb antibodies at protective levels in mammals during tick transmission season.

*B. burgdorferi* expresses OspC during transmission from ticks and during early infection in mammals, and may be vulnerable to OspC immunity at both vector and host stages. Supporting this hypothesis, an OspC monoclonal antibody (mAb) that prevents tick-borne Bb infection of mice also blocks the migration of blood meal-activated Bb from the tick gut to the salivary glands [45]. OspC may be another target of transmission-blocking antibody. Successful therapy of Bb-infected mice with OspC antibody has also been reported [46].

Additional antigenic targets against tick-borne Bb undoubtedly exist. Mice infected by tick bite with Bb strain B31, then administered a curative regimen of tetracycline 30 days postinfection, were immune to subsequent reinfection by tick-borne Bb B31 for 10 months. Immunity occurred in the absence of OspA antibodies and did not correlate with OspC antibody levels [47].

#### 1. Cross-Protection Among *B. burgdorferi*

##### Senso Lato

Studies evaluating the passive immunization of irradiated hamsters with Bb polyvalent antiserum [48], severe combined immune-deficient mice with OspA mAbs [49], or immune-competent mice with OspA or decorin-binding protein A (DbpA) hyperimmune serum [50] suggested that monovalent subunit vaccines may be effective against only cultured isolates within a single Bb species, but not between species. OspC cross-protection is even more restricted. Active immunization with OspC from one *B. burgdorferi* sensu stricto isolate failed to protect mice against challenge with other cultured Bb sensu stricto isolates [51]. Cross-protective immunity among *B. burgdorferi* senso lato has been successful in some tick-borne challenge studies [52] but not all [53]. The murine immune response to Bb infection protected against reinfection challenge with homologous, but not heterologous, *B. burgdorferi* sensu lato species [54]. From the foregoing experiments, we predict that an antigen from the three major clinically relevant Bb species will be required for a Lyme vaccine to be effective worldwide. Such a trivalent OspA vaccine has, in fact, protected mice against challenge with a wild population of ticks harboring infections with *B. burgdorferi* sensu stricto, *B. afzelii*, and *B. garinii* [55].

#### D. Borreliacidal Antibody

The observations that passive transfer of immune antiserum, but not immune cells, protected scid mice from Bb challenge provided evidence that immunity is antibody-mediated. In

vitro assays have been developed for detecting and quantifying functional antibodies having borreliacidal [56] or growth-inhibiting [17,57] properties. The Bb form surface blebs and lyse within 30 min to 2 hr [17] after exposure to immune sera or mAb in the presence [17,56] or absence [58] of complement. Remarkably, Bb can be directly killed in vitro even by Fab fragments of borreliacidal antibodies [57], a vulnerability shared by few other pathogens. Opsonizing antibody, with subsequent phagocytosis and intracellular killing, may also contribute to protection [61]. Cell-mediated immunity is insufficient for protection; in fact, CMI mechanisms, including pro-inflammatory cytokines and CD4+ T cell mediation, seem to enhance destructive arthritis [62]. Antibodies against OspA are the best characterized. A key mechanism of protection results from the development of high-titered antibodies to a conformational epitope in the C-terminal end of OspA [63]. The protective epitope is identified by the murine mAb LA-2 in competitive inhibition enzyme immunoassays [64]. A good correlation exists between LA-2-equivalent antibody titers and a bactericidal assay [65].

Antibodies against OspC also can protect against Bb infection. Although some studies have failed to detect borreliacidal activity for OspC antibodies [45,46,66], others have been successful [67].

#### E. Preclinical Development of Lyme Disease Subunit Vaccines

Recombinant proteins expressed in *Escherichia coli* have been the focus of LD vaccine development efforts because it is expensive or impractical to purify vaccine antigens from Bb cultures. Table 1 lists the Bb antigens examined as targets for protective immunity. Most works have concentrated on the OspA lipoprotein and, to a lesser extent, on OspB and OspC lipoproteins. Many preclinical studies in mouse models of human Lyme borreliosis [29,30,63,68] documented that an OspA vaccine was feasible. The lipoprotein OspA initially developed by Connaught Laboratories (now Aventis Pasteur) [69] and SmithKline Beecham (now GlaxoSmithKline, GSK) [42] provided promising first-generation Lyme vaccines for humans [70,71], as discussed in “Clinical Development of Human Lyme Disease Vaccines” below.

### IV. CLINICAL DEVELOPMENT OF CANINE LYME DISEASE VACCINES

#### A. Canine Whole Cell Vaccine

Spurred by the veterinary need and by the early success of an experimental thimerosal-inactivated whole cell vaccine candidate [35], a “chemically inactivated” whole cell vaccine comprised of a proprietary strain of Bb adjuvanted with a proprietary polymer-based system was developed for dogs (LymeVax® *B. burgdorferi* Bacterin; Ft. Dodge Laboratories, Ft. Dodge, IA). Based on its favorable safety profile, the U.S. Department of Agriculture gave LymeVax conditional license in 1990 and full licensure in 1992. The vaccine has been popular and is used widely by veterinarians and dog owners, particularly in Lyme-endemic areas in the United States.

**Table 1** Protective Immunity Associated with *B. burgdorferi* Antigens

Name	Antigen			<i>B. burgdorferi</i> inoculum protection <sup>a</sup>				References

## 1. Immunogenicity and Protective Efficacy

Two years after conditional licensure, a laboratory-based immunogenicity and efficacy trial of Lymeavax in dogs was reported [72]. Only 1 (3%) of 30 vaccinated dogs developed lameness compared to 15 (63%) of 24 control dogs, a statistically significant result. The favorable laboratory results were confirmed by a field study conducted in three veterinary practices in New York and Connecticut among 1969 vaccinated and 4498 control dogs [73]. Lymeavax prevented 78% of clinically apparent cases of Lyme borreliosis, although the study was unblinded and potentially biased.

## 2. Safety

Serious adverse reactions or immune-mediated diseases were not detected in any of the 1969 dogs vaccinated with Lymeavax and followed in some instances for 20 months. Despite this safety profile, laboratory results have raised the possibility of autoimmune reactions to components of the whole cell Bb vaccine. Severe destructive arthritis was evoked by vaccinating inbred hamsters with a whole cell preparation of formalin-inactivated Bb in alum or Freund's incomplete adjuvant, and then by challenging the hamsters with the homologous strain of Bb via syringe before high levels of protective borreliacidal antibody developed [74]. The destructive arthritis in hamsters was induced by the interaction

of vaccine-specific T lymphocytes with viable spirochetes and not dead spirochetes [75]. It is unclear if this hamster model mimics the arthritis seen in other animal models or human LD.

Theoretical concerns of molecular mimicry have been raised by the antigenic cross-reactivity and the protein sequence homology that exist between non-OspA Bb antigens and human tissues [76,77]. The risk of destructive immune-mediated reactions by whole cell vaccines has helped to fuel the development of subunit Osp vaccines for both dogs and humans. Nonetheless, a second-killed Bb bacterin, the bivalent Galaxy® Lyme (Schering Plough Animal Health), has been licensed and marketed in the United States and Canada for canine use.

## B. Canine OspA and OspB Subunit Vaccines

Immunization with several recombinant OspA or OspB vaccine formulations, singly and in combination, designed for dogs appear safe, immunogenic, and protective [78]. OspA was superior to OspB, and QS-21, a purified saponin component, was superior to alum at eliciting functional antibody response [79]. Although QS-21 formulations are promising, they have not been licensed. A recombinant OspA-containing bacterial extract, Recombitek™ Lyme

(Merial, Ltd.), has been licensed and marketed in the United States and Canada for dogs.

## V. CLINICAL DEVELOPMENT OF HUMAN LYME DISEASE VACCINES

### A. OspA Vaccines

#### 1. LYMErix™ (GlaxoSmithKline)

*Clinical Trials.* The GSK rOspA vaccines initially tested in rhesus monkeys [80] performed well in Phase I and Phase II clinical trials conducted in adults [64,65] and later in children [83–85].

The pivotal efficacy trial of the LYMErix vaccine was conducted by Steere et al. [70] at 31 clinical sites during the winter of 1995. The study involved 10,936 volunteers between 15 and 70 years of age who were at risk of acquiring LD. Volunteers were randomized into two groups, with 5469 participants receiving one to three injections of vaccine (at 0, 1, and 12 months) and 5467 volunteers receiving a placebo. Volunteers were followed up in a blinded fashion for 20 months. Cases of LD were confirmed by cultures of skin lesions, polymerase chain reaction (PCR) tests, or serological tests.

In the first year, after two injections, 22 persons in the vaccine group and 43 in the placebo group contracted definite LD ( $P = 0.009$ ). Vaccine efficacy was 49%. In volunteers followed up for 20 months, by which time they had received the third injection of vaccine, 16 vaccine recipients and 66 placebo recipients contracted LD ( $P < 0.001$ ), and vaccine efficacy was 76%. The efficacy of the vaccine in preventing asymptomatic infection was 83% after two injections, and 100% after three injections. Antibody levels to the protective epitope of OspA (LA-2-equivalent antibody [64,65,86]) were measured in 938 participants followed at one study site (Yale University). At 1 month after the second injection, 95% of the vaccinees had positive test results for LA-2-equivalent antibody; 1 month after the third injection, 99% had positive test results associated with a marked anamnestic response to OspA. The higher protective antibody titers after three injections were associated with greater protective efficacy after three injections. Based largely on this pivotal trial, the LYMErix vaccine was licensed by the Food and Drug Administration (FDA) on December 28, 1998. The Public Health Service's Advisory Committee on Immunization Practice (ACIP) [87] and the Committee on Infectious Diseases of the American Academy of Pediatrics have published specific recommendations for vaccine use [88].

*Limitations of LYMErix.* Many unresolved issues surround the use and safety of the LYMErix vaccine. They include the durability of protection, a shortened schedule for primary immunization, an approved schedule of booster doses, the cost-effectiveness of vaccinating against LD, the use of LYMErix in persons younger than 15 years of age and older than 70 years of age, confusing serological cross-reactions engendered by the vaccine, and, most importantly, the possible induction of arthritis and post-LD syndrome in genetically susceptible persons.

*Alternative primary vaccine schedules and booster doses.* Data indicate that a 0–1–6 months primary immu-

nization schedule [81] and a 0–1–2 months schedule [82] both result in high-enough antibody levels 1 month after the third vaccination to provide protective immunity for 1 year in >90% of vaccinees. Although this antibody level is achieved with the currently approved three-dose primary immunization schedule and the two shorter schedules, levels decay rapidly. In an open-label continuation trial, individuals from the LYMErix Phase III trial received booster doses of vaccine at 24 and 36 months after the three-dose primary series. Data supplied by GSK in a safety letter show no adverse impact on vaccine safety associated with administration of a fourth or fifth dose [89].

*Cost effectiveness.* Several pharmaco-economic studies of the LD vaccine have been published [90–92]. The authors of two studies conclude that economic benefits will be greatest when vaccination is used based on individual risk, particularly in persons whose probability of contracting LD is >1% annually [90,92]. All studies conclude that the vaccine should not be used universally. The Institute of Medicine (IOM) report estimates that it would cost more than US\$100,000 per QALY (cost per quality-adjusted life-year) saved if the vaccine were given “to resident infants born in, and immigrants of any age to, geographically defined high risk areas” [91]. In fact, the IOM report ranked the LD vaccine among the lowest priority for vaccine development. Lyme anxiety has fueled a virtual epidemic of overdiagnosis and overtreatment of LD and, until recently, has helped drive public demand for the vaccine [93,94].

*Pediatric trials.* The safety and immunogenicity of LYMErix have been evaluated through pediatric trials in Europe and the United States [83–85]. Trials in the Czech Republic administering LYMErix to children 5–15 years of age on a 0–1–2 months schedule [83], or children 2–5 years old administered a more preferred two-dose schedule at 0 and 1 months, demonstrated that the 15- and 30-µg doses of LYMErix were well tolerated and immunogenic [84]. The 38-µg dose produced antibody levels predictive of protection in 100% of children at 2 months, and protective levels persisted in 93% of the cohort for 6 months (one tick season).

The third pediatric trial was multicenter, double-blind, placebo-controlled, and randomized; it involved 4087 children 4–18 years of age vaccinated at 17 clinical sites in the United States [85]. This large trial employed the 0–1–12 months schedule approved for use in adults. As in European children, the vaccine was safe and highly immunogenic, with 100% of U.S. children attaining a presumptively protective antibody level by 1 month after the third injection. LYMErix induced threefold higher antibody titers in these children and adolescents than in adults previously tested [70]. No efficacy trials in children have been reported. In the fall of 1999, GSK filed a supplement for the use of LYMErix in children <14 years old, which was pending before the FDA until the vaccine was withdrawn by GSK on February 25, 2002 [95].

#### Safety

*Commonly reported adverse events.* A summary of adverse reactions to LYMErix was published in the Physicians' Desk Reference [96]. Clinical trials involved 6478 individuals who received a total of 18,047 doses, including 5469 vaccinated individuals who participated in the randomized, placebo-controlled Phase III trial [70]. LYMErix was

generally well tolerated, with pain at the injection site being the most common adverse event (AE), reported more often in vaccine than placebo recipients. These local inflammatory reactions were usually mild, generally resolved spontaneously, and did not increase with subsequent injections.

In all trials combined, systemic reactions occurred in up to 40% of individuals, with headache and fatigue being the most frequent. Most systemic symptoms were rated as mild, spontaneously resolved within 72 hr, and, like local reactions, did not increase with subsequent vaccinations [96]. There were no significant differences in the incidence of clinical arthritis or musculoskeletal inflammation. The original cohort of vaccinees from the Phase III LYMErix trial has shown no pattern of late-onset vaccine-related serious AEs after 36 months of follow-up [89].

As with any biological product or drug, previously unrecognized AEs may occur during postlicensure use in a larger number of individuals [97]. Therefore AEs reported to the Vaccine Adverse Event Reporting System (VAERS) during the first 19 months of the vaccine's licensure were evaluated for unexpected patterns in age, gender, time to onset, dose number, and clinical characteristics [98]. Over 1,400,000 vaccine doses were distributed, and 905 AEs were reported to VAERS. Except for the 22 hypersensitivity reactions, the AEs reported to VAERS were consistent with AEs noted during the Phase III clinical trial.

**Uncommon adverse events—evidence for induction of arthritis.** There is a theoretical, albeit serious, concern that an OspA-based vaccine for LD might induce chronic inflammatory arthritis in genetically susceptible individuals through a molecular mimicry mechanism [13,62,99,100]. The arguments for [1,89] and against [101] molecular mimicry have been published. To summarize, antibiotic-resistant arthritis is a chronic inflammatory joint disease that follows Bb infection in ~10% of patients [102]. Major histocompatibility complex (MHC) class II HLA-DR4 alleles are associated with an increased risk of chronic antibiotic-refractory arthritis. During the treatment-resistant phase of the disease, these individuals often develop high titers of IgG antibodies against OspA, especially the C-terminal epitope of OspA [13]. This epitope is present in LYMErix vaccine. This immunodominant T-cell epitope of OspA ( $\text{OspA}_{165-173}$ ) and human lymphocyte function-associated antigen 1 (hLFA-1 $\alpha_{L332-340}$ ) cross-react [99]. HLA-DR4-positive patients with chronic Lyme arthritis, but not HLA-DR4-negative patients or HLA-DR4-positive persons without chronic arthritis, mount a strong T-cell response against hLFA-1 [99]. T cells that react to ( $\text{OspA}_{165-173}$ ) are concentrated in the joints of these patients and react with hLFA-1 [104]. In theory, when hLFA-1 $\alpha_{L332-340}$  is processed and presented by the HLA-DRB1\*0401 molecule, this self-peptide may behave as a partial agonist for such OspA-reactive T cells [100].

However suggestive, this example of epitope mimicry cannot yet be considered definitive. First, there is the lack of an adequate rodent model. HLA-DRB1\*0401 transgenic mice injected with OspA responded primarily to the relevant  $\text{OspA}_{165-173}$ , but developed no signs of arthritis [99]. Second, although intense expression of LFA-1 on T cells

among patients with antibiotic treatment-resistant arthritis exists, it is yet unclear if MHC class II molecules in the synovial lesions actually present the LFA-1 $\alpha_{L332-340}$  peptide [103]. Finally, there are no clues as to what precipitates an inflammatory response several months after the borrelian infection [101].

Possible Lyme vaccine-associated chronic arthritis was reported recently in two children and two adults [105]. There were spectra of changes including severe polyarthritis. Such clinical reports need to be confirmed by long-term follow-up of vaccinated individuals as high-priority studies. A more detailed analysis of the theoretical concern of autoimmune induction in vaccinees has been published [89].

Another theoretical safety problem is that the rOspA vaccine may prime some vaccinees to develop arthritis after they receive an infected tick bite, particularly if protective borreliacidal antibodies have waned or have never developed.

**Litigation.** Both class action and individual lawsuits have been filed against GSK alleging that "LYMErix™ effectively introduces high levels of OspA into the blood stream and places HLA-DR4-positive recipients (who make up 30% of the general population) at risk of developing the autoimmune reaction of treatment-resistant Lyme arthritis" [89]. The complaint charges that GSK should advise the general population and physicians to have patients undergo blood testing to assure that they are HLA-DR4-negative before the administration of LYMErix. This suit alleges that the vaccine itself may cause the "autoimmune condition" of "treatment-resistant Lyme arthritis," so the caution printed in the package insert against administering the vaccine to individuals with a history of treatment-resistant Lyme arthritis is inadequate [97]. It must be recognized that about 1.4 million doses of vaccine have been distributed, representing some 400,000 vaccinees, and except for four suggestive cases, all self-limiting and inconsequential in the long run [105], there are no documented cases of vaccine-induced chronic arthritis to substantiate the risk narrated in the complaint: "risk of a chronic, degenerative, and incurable autoimmune disease." Nevertheless, many clinicians are reluctant in the current legal climate to recommend LYMErix for their patients who meet the criteria for its administration.

GlaxoSmithKline initiated a large, FDA-mandated Phase IV study to address unanswered questions about LYMErix-induced arthritis. As of February 2001, only 15% of the targeted 25,000 subjects were enrolled [106]. The target number will not be reached, as GSK removed LYMErix from the market on February 25, 2002 because of dwindling sales, undoubtedly influenced by the concerns presented above.

**Effect of LYMErix on Serological Diagnosis.** The OspA vaccine confounds well-established serological test results by inducing a positive reaction in ELISA assays containing whole Bb organisms [107]. As expected, most persons develop the expected 31-kDa OspA band in response to the vaccine. But some individuals, particularly after multiple doses, unexpectedly develop antibodies reactive with other Bb antigens in their IgG Western blots, such

as to 66-, 41-, 31-, and 21-kDa antigens [107]. Some of these Western blot patterns are broad enough to satisfy the criteria for Bb infection and the diagnosis of LD. These confusing serological results reported after rOspA vaccination have several theoretical explanations, from induction of cross-reactivity to laboratory artifact. An investigational ELISA utilizing recombinant chimeric *Borrelia* proteins devoid of OspA has distinguished persons naturally infected with Bb from OspA vaccinees [108]. Recently, an ELISA based on the Bb peptide *VlsE* C6 was approved by the FDA to differentiate between cases of natural Bb infections and rOspA vaccinees (C6 Bb [Lyme] ELISA; Immunogenics, Cambridge, MA).

## 2. Imulyme™ (Aventis Pasteur)

Two formulations of a lipidated OspA vaccine [69] were studied by Connaught Laboratories (now Aventis Pasteur) in two Phase I trials [59,60]. No preclinical animal studies of the exact human formulation have been reported, although the vaccine prototype was safe and protective in rodents [69]. Two or three 10-µg doses of unabsorbed or alum-absorbed formulations injected at 0, 1, and 6 months were equally safe. The vaccines were immunogenic in 92% of vaccinees. Serum borreliacidal activity nearly disappeared within 5 months, although it was restimulated in all 12 vaccinees tested 1 month after the 6-month booster [59].

In a preliminary report of a Phase II dose-seeking study, two injections of placebo or of 1-, 5-, 10-, or 30-µg doses of the nonadjuvanted lipidated OspA vaccine were administered to 330 adult volunteers [109]. The ELISA seroconversion rates in volunteers varied as a function of vaccine dose, and ranged from 2.4% (1-µg dose) to 97.6% (30-µg dose). Borreliacidal titers were not reported. Both vaccine injections and all vaccine doses were equally safe with minimal side effects observed.

Two efficacy trials of the Connaught Laboratories rOspA vaccine have been conducted [71,110]. The larger trial was conducted in 10,305 persons aged 18–92 years old enrolled at 14 U.S. study sites in five states endemic for LD. Volunteers received two doses of either 30 µg of ImuLyme or placebo given 1 month apart; 7515 volunteers also received a booster dose at 12 months. The volunteers were observed for two tick transmission seasons. Clinical cases were confirmed by serology but not by culture or PCR. The incidence of asymptomatic seroconversion was not determined. The efficacy of the vaccine was 68% in the first year of the study, and 92% in the second year among subjects who received the third injection; persons immunized twice were not protected during the second transmission season. The vaccine was well tolerated. There was no significant increase in the frequency of arthritis or neurological events in vaccine recipients, including persons with and without a prior history of LD.

The second efficacy trial [110], a subset of the larger trial [71], was conducted on 1634 persons (adolescents to 80 years old) recruited at one site in New York State. Vaccine efficacy was 40% during the first year and 37% during the second year. Vaccine efficacy was absent among persons older than 60 years. The reasons for the lower protective efficacy in this single-site study compared to the multisite study are unclear.

Aventis Pasteur filed an application for license with the FDA in 1998 for its ImuLyme vaccine, but the vaccine has not been marketed.

## 3. Live Recombinant Bacille Calmette–Guérin OspA (MedImmune, Inc., Gaithersburg, MD)

A Phase I clinical trial was designed to determine the feasibility of using rBCG as a live bacterial vaccine vector for the outer surface protein A (OspA) of *B. burgdorferi* and as model for other vaccines based on a rBCG vector. Investigators at MedImmune, Inc. developed a rBCG vaccine expressing OspA as a membrane-associated lipoprotein. The rBCG OspA vaccine was safe and immunogenic in several animal species, and protective in a mouse model of Lyme borreliosis [111]. One intradermal injection (0.1 ml) of rBCG OspA was administered to 24 healthy adult volunteers sequentially at one of four dose levels, using a dose escalation design. All volunteers were initially negative for PPD skin test and OspA antibody, and they were monitored for 2 years after immunization. Localized, resolving ulcerations typical of BCG vaccination were observed. Thirteen of 24 vaccinees, principally in the two highest dose groups, converted their PPD skin tests from negative to positive, but notably, none of the 24 volunteers developed OspA antibody [112]. The manufacturer has discontinued the vaccine.

## B. OspC Multivalent Vaccines (Baxter)

The first reported Phase I trial of an OspC vaccine was sponsored by Baxter (formerly Immuno AG) [113]. The trial was performed in 80 volunteers from the Åland Islands (Finland), a population at high risk of contracting LD (>1% incidence per year). Half of the volunteers were seropositive for Bb, and they received three vaccinations at dose levels of 25 or 50 µg. Seronegative volunteers received dose levels of 10, 25, or 50 µg. The vaccine was adjuvanted with aluminum and was pentavalent in design, comprised of recombinant OspC proteins from one strain of *B. burgdorferi* sensu stricto and two strains each from *B. afzelii* and *B. garinii*. Recombinant OspC was expressed as a nonlipoprotein form in the yeast *Pichia pastoris*. The vaccine appeared to be safe and well tolerated at all dose levels. Mild and moderate local and systemic AEs occurred in a dose-dependent manner. Antibody responses were similarly dose-dependent, and seroconversion against the five component antigens was observed in 95% or greater of the formerly seronegative volunteers receiving the highest dose level.

To determine the antigenic composition necessary for the formulation of a pan-European Lyme vaccine, the *ospC* genes of approximately 300 Bb isolates were analyzed for restriction fragment length polymorphisms to estimate the extent of OspC heterogeneity. Sera from several thousand patients with a variety of LD syndromes, and representing 16 European countries, were screened to determine the most clinically relevant OspC serotypes. These analyses predicted that a cocktail of OspC antigens from 14 Bb strains, including two from *B. burgdorferi*, six from *B. afzelii*, and six from *B. garinii*, would provide at least 80% coverage of

the most clinically relevant Bb strains. A Phase II trial testing the safety and preliminary efficacy of this 14-valent OspC vaccine formulation has been completed and its data are being analyzed (Dr. Noel Barrett, Baxter, personal communication).

## VI. NEXT-GENERATION VACCINES

### A. Evaluation of New Subunit Vaccines for Lyme Disease

Much effort has been spent identifying and characterizing the structural and antigenic constituents of Bb. Many of these proteins identified as potential diagnostic antigens, membrane components, or colonization and dissemination factors have also been evaluated as experimental vaccines, usually in mice (Table 1). Their effectiveness as vaccine antigens provides some of the best pieces evidence of their surface exposure on live spirochetes. Direct or indirect evidence indicates that most of these proteins are expressed by Bb in mammalian hosts, and some also in the feeding tick. The functions of most of these antigens are obscure. Bb proteins that bind decorin (DbpA and DbpB), fibronectin (P47/BBK32), and glycosaminoglycans (Bgp) appear to have a role in the adherence of Bb to mammalian extracellular matrix [114–116]. Other than OspA, OspB, and OspC, few of these newer proteins have been successful vaccines. Vaccination with some of these antigens kill Bb in ticks, but only two of these antigens, OspF [117] and P47(BBK32) [118], partially protect mice against tick-borne Bb [41,118]. These two antigens plus VraA and DbpB protect mice against challenge with cultured Bb [119], although the immunity conferred by DbpB is inconsistent [50,119]. Cultured Bb are killed by DbpA antibodies, and spirochetes are killed during the early stages of infection after subcutaneous injection into vaccinated mice [50]. DbpA antibodies also have borreliacidal activity with strain cross-reactivity rivaling that of OspA. However, tick-borne Bb expresses little DbpA, presumably until entering the mammalian host, and transmission-blocking immunity is ineffective [120]. Most Bb anti-gens tested for vaccine effectiveness are biochemically confirmed or presumptive lipoproteins except for one outer membrane-spanning protein (Oms66), which conferred partial immunity against host-adapted Bb [121].

### B. Multicomponent and Chimeric Protein Vaccines

Hypothetically, a combination vaccine composed of Bb antigens upregulated in the tick and in the mammalian host will enhance transmission-blocking immunity and will supplement mammalian-stage immunity against infection or disease. The model combining antigens from multiple stages of infection has its origin in malaria vaccine development. Validation of this approach for Bb has just begun. A combination vaccine comprised of vector-stage OspA and mammalian-stage DbpA was much more effective than either OspA or DbpA alone at protecting mice from cultured Bb, and mice were better protected against heterologous Bb

isolates [122]. OspA–DbpA vaccines remain to be tested against tick-borne Bb.

Vaccination of mice with a DNA plasmid expressing a OspA–OspC chimeric fusion elicited antibodies to both proteins, but protective antibodies appeared to be primarily against OspA, suggesting that further refinement of this strategy is required [123].

### C. Genomics

The complete nucleotide sequence of the large linear chromosome of Bb *sensu stricto* strain B31 and 17 of its 21 plasmids was reported in 1997, and these genomic data were subsequently refined further, including the sequencing of the additional plasmids [124,125]. The relatively small Bb genome has several striking features. First, no homologs of surface proteins, virulence factors, or vaccine antigens from other pathogens are yet recognizable in the Bb genome. Second, the Bb genome encodes at least 132 presumptive lipoproteins, more than any other bacterium to date. Much work remains to screen for vaccine candidates among the additional members of this class of membrane proteins. Third, the existence of multiple paralogs of several lipoprotein genes (such as the *VlsE* locus), either clustered or distributed on multiple plasmids, suggests several potential mechanisms for antigenic variation.

### D. Challenges of *B. burgdorferi* Antigenic Modulation and Phenotypical Heterogeneity

*B. burgdorferi* adapts to the different environments encountered during transmission through the tick vector by changes that include alteration of its surface protein phenotype and consequent antigenic modulation. OspA and OspC are the prototypes of such modulated antigens. Additional temporal or tissue-specific gene expression by Bb also occurs during the infection of mammalian hosts [126,127]. One example is the lipoprotein Arp (ErpT), which is an antigenic target for the resolution of Lyme arthritis in mice, but Arp antibodies do not alter carditis [118]. Another example is DbpA, which is expressed by the majority of Bb, infecting heart tissues of mice, but is expressed by few spirochetes in ear tissues [128].

An important, emerging issue affecting vaccine design and interpretation of data in vaccinated animal models is the striking heterogeneity of Bb phenotypes. As discussed in “Immunity to Tick-Borne *B. burgdorferi*,” initial observations on antigen expression by tick-stage Bb using immunohistochemistry suggested that the spirochete population shifts from expressing OspA to OspC during transmission [31,44]. However, substantial heterogeneity exists within the Bb population at each stage of transmission, including many spirochetes expressing either both OspA and OspC or neither antigen [129]. Another immunohistochemical study has recently detected a heterogeneous expression of protective antigens OspC and DbpA in mice at various sites of disseminated Bb infection [128]. These studies suggest that second-generation vaccines will require either: 1) identification of a new antigenic target that is both constitutively expressed at multiple stages of Bb transmission and infection and is serologically conserved; or 2) different antigens, each induc-

ing immunity against its unique antigenic target expressed at different stages of transmission and infection. Lastly, Bb phenotypical heterogeneity is also present in vitro, even for cloned Bb isolates [122,130], suggesting that partial protection against challenges with cultured Bb need to be reinterpreted; such vaccine candidates may be effective in combination with other antigens.

## VII. CONCLUSION

Less than 20 years elapsed between the 1982 report of the identification and isolation of *B. burgdorferi* and the licensure and marketing in the United States of a prophylactic vaccine against this pathogen. However, the evolving understanding of the agent's antigenic complexity, the elucidation of the unique and unanticipated mechanism of protection of the first-generation vaccine, and the progress on determining LD immunopathogenesis have fueled concerns about autoimmune reactions to the OspA antigen. Such concerns have combined to limit the acceptance of LYMErix and have lead to its withdrawal from the marketplace. Second-generation polyvalent OspC vaccines may overcome some of these concerns, but the precise antigenic components required for efficacy are uncertain. The development of the next generation of novel-antigen or multiantigen LD vaccines is in its infancy.

### I. INTRODUCTION

Diarrheal diseases remain a leading global health problem. It has been estimated that  $(3\text{--}5)\times 10^9$  episodes of diarrhea, resulting in approximately 4 million deaths, occur annually in developing countries with the highest incidence and severity in children below the age of 5 years [1,2]. About half of these diarrheas are caused by bacteria that produce one or more enterotoxins. Cholera, resulting from infection with *Vibrio cholerae* bacteria, is the most severe of these “enterotoxic enteropathies,” while infection with enterotoxigenic *Escherichia coli* (ETEC) is causing the largest number of cases [3,4].

*Vibrio cholerae* of serogroup O1 is the prototype for the enterotoxin-producing bacteria and was first isolated by Robert Koch in 1884. *V. cholerae* O1 can appear as either of two main different serotypes, Inaba and Ogawa. Until the beginning of the 20th century all examined *V. cholerae* O1 isolates were of the same “classical” biotype. In 1906, however, vibrios of a new biotype, El Tor, were isolated, and for many years vibrios of either the classical or El Tor biotype were isolated from cholera cases.

During the early part of the 19th century, cholera started to spread from its likely ancient home in Bengal, and since then seven major pandemics have been described that have affected large parts of the world. The latest pandemic that took its departure from Celebes in 1961 has spread to and become endemic in many countries in Asia and Africa. Beginning in 1991 cholera has also reappeared as a significant health problem throughout most of South and Central America for the first time in more than 100 years [5]. The causative agent in Latin America appears to be identical to the seventh pandemic O1 El Tor organisms isolated from Asia and Africa.

Since 1993, as yet limited to a few countries in Southeast Asia, a new *V. cholerae* serogroup, O139 Bengal, has been

found to cause a variable percentage, usually below 5%, of all cholera cases. If increasing, and even worse, if also spreading to other areas, this new organism may cause yet another major cholera pandemic in parallel with the still ongoing seventh *V. cholerae* O1 El Tor pandemic.

When an epidemic strikes an area where hygiene is poor and health care is not adequate the results can be disastrous, as happened during the refugee crisis in Goma, Zaire, in 1994. An estimated 58,000–80,000 cases and 23,800 deaths occurred within 1 month [6]. Although in endemic areas the highest incidence of cholera is seen in children below 5 years of age, still approximately two-thirds of all *V. cholerae* O1 cases occur in older children and adults in these areas [3,7]. When, on the other hand, cholera has spread to new countries, all age groups have been affected to the same degree. This pattern is probably due to that natural immunity normally develops by age in endemic countries, which is lacking in newly attacked nonendemic areas [8].

The total number of cholera cases annually in the world is uncertain because several affected countries do not monitor or report the disease accurately, in part due to surveillance difficulties but also for fear of economic and social consequences [9]. According to WHO, perhaps only 5–10% of cholera cases are reported. The recent outbreaks of *V. cholerae* O1 in Latin America as well as of *V. cholerae* O139 in Asia have probably resulted in a substantially increased number of cholera cases in the last 5 years. Therefore, the often cited figures of 3–5 million cases and 120,000–200,000 deaths from cholera annually may well be significant underestimates of the present situation.

A cholera-like syndrome can also be seen in some infections with enterotoxigenic *E. coli* (ETEC). ETEC is the most common bacterial cause of diarrhea in developing countries, accounting for an estimated 400 million cases annually. Although many episodes are relatively mild, a sufficient number of cases are severe and it is estimated that

disease caused by ETEC is responsible for 300,000–500,000 deaths a year among children under 5 years of age [2]. In addition, ETEC is also the most common cause of traveler's diarrhea isolated in one-third to one-half of these episodes [10].

The disease caused by enterotoxin-producing bacteria such as *V. cholerae* and ETEC is characterized by watery stools without blood and mucus [4]. In most cases, cholera is characterized by acute, profuse watery diarrhea lasting for one or a few days. In a substantial proportion, however, cholera causes dehydrating disease, and in its extreme manifestations, cholera is one of the most rapidly fatal infectious illnesses known. Within 3–4 hr of the onset of symptoms, a previously healthy person may become hypotensive and may die within 6–8 hr. More commonly, fatal cases progress to hypovolemic shock within 6–12 hr with death following in the next one to several days of dehydrating disease. The most severe cholera cases can purge as much as 15–25 L of water and electrolytes per day, and the mortality rate in severe, nontreated cholera is 30–50%. Persons of blood group O are known to have increased risk of developing severe cholera (cholera gravis) when infected [9].

ETEC disease may vary from mild diarrhea to severe cholera-like disease and is often accompanied by nausea, vomiting, abdominal cramps, anorexia, and more often than in cholera also with significant fever [3,4].

The recommended primary treatment for cholera and ETEC today is with simple, oral rehydration solutions containing salts and glucose, which will save lives when properly administered. If the patient is severely dehydrated on arrival to the treatment center, is unable to drink, or if the rate of fluid loss by diarrhea exceeds what can be compensated by oral rehydration, aggressive intravenous fluid rehydration is necessary. With effective rehydration treatment, the case fatality rate may go down to below 1% even in severe cases of cholera. Antibiotics can be used to shorten the duration of cholera disease and decrease the risk for further spread of the infection. WHO recommends that antibiotics be used only in the treatment of cholera cases with signs of severe dehydration. Whenever possible the sensitivity of the cholera isolate to antibiotics should be assessed. Antibiotics are not indicated in the treatment of milder cases of cholera or for mass prophylaxis and should not be used in the treatment of ETEC diarrhea [9].

In general, vaccines are considered useful tools for controlling bacterial infectious diseases. Effective vaccines, if available and widely used, could prevent a substantial part of the morbidity and mortality in cholera and ETEC infections in developing countries [11]. However, until very recently, no sufficiently effective vaccines for use in humans against either cholera or ETEC diarrhea, or for that matter, other enteric infections, have been available. Thus, previous parenteral cholera vaccines induced at most 50% protection with a duration of only 3 to at most 6 months [12], and vaccines against ETEC and other enterotoxin-producing bacteria have been lacking completely.

The limitations in the protection induced by the previous cholera vaccines could probably to a large part be explained by the parenteral administration route used and in part also by their composition. In cholera infection, both

the bacteria and the toxin they produce exert their action locally in the gut. In accordance with this, local mucosal immunity is of critical importance for protection. The parenteral cholera vaccines have been found to give rise to little, if any immune response locally in the gut in individuals who have not been immunologically primed by previous natural exposure to *V. cholerae*. Also, in the previously primed host, the injection route has been found to be much less efficient than oral immunization [13,14]. In addition, the parenteral cholera vaccines did not stimulate any antitoxic immunity.

Recently, however, the situation has changed for the better with regard to vaccine development against both cholera and ETEC diarrhea. New cholera vaccines are under development, and two oral vaccines are already registered internationally. (See also chapter by Kaper in this volume.) One of these vaccines, which is described in further detail in this chapter, consists of killed whole *V. cholerae* O1 cells in combination with recombinantly produced binding (B) subunit of cholera toxin. This vaccine, which is given in two or three doses in a bicarbonate buffer, is well tolerated and confers a high level (85%) protection against cholera for 6 months [15], and the level of protection is still about 50% three years after immunization in vaccinees who were aged 5 years or older at the time of vaccination [16]. Because of its documented ability to also protect against diarrhea caused by ETEC strains producing cholera-like toxin [17,18], the recombinant cholera B subunit-killed whole cell (BS-WC) vaccine is also registered for use for prophylactic vaccination against ETEC diarrhea. (See also Svennerholm et al., this volume).

## II. MECHANISMS OF IMMUNITY

The development of the oral BS-WC cholera vaccine has to a large extent been based on new insights into the mechanisms of disease and immunity in cholera and related enterotoxin-induced diarrheas gained over the past 30 years [19]. The main findings guiding the modern cholera vaccine development may be summarized as follows:

- (1) The pathogenesis of cholera was shown to critically depend on bacterial colonization associated with toxin production and action locally in the small intestine;
- (2) Therefore, either or both of antibacterial and antitoxic immunity capable of preventing these events were found to protect against disease;
- (3) Both antibacterial and antitoxic immunity were found to depend mainly if not exclusively on locally (mucosally) produced antibodies of the secretory IgA (SIgA) type, and it was shown that intestinal antibacterial and antitoxic antibodies can cooperate synergistically in protection against disease by interfering with the two most important separate pathogenic events in the gut, i.e., colonization and toxin action.
- (4) To stimulate a protective gut mucosal immune response comprising both intestinal antibacterial

and antitoxic antibodies, and for longer-lasting protection also local immunological memory, vaccination by the oral route was found to be superior to parenteral vaccination.

### A. Toxins and Antitoxic Immunity

As stated, the major pathogenic mechanisms of both *V. cholerae* and other enterotoxigenic bacteria include initial bacterial colonization of the small intestine followed by the elaboration of enterotoxin(s) that through specific mechanisms can induce electrolyte and water secretion resulting in diarrhea [19–21]. These enterotoxins, which have a cytotoxic rather than cytotoxic effect on the intestinal epithelium, are believed to stimulate secretion, primarily from the crypt cells in the upper part of the small intestine, by inducing increased formation of cyclic AMP and/or cyclic GMP in the epithelial cells. Cholera toxin (CT) is the prototype enterotoxin and is produced by most *V. cholerae* O1 bacteria of either the classical or El Tor biotype. CT with identical structure to O1 El Tor CT is also formed by the novel *V. cholerae* O139 serogroup [22]. Cholera toxin consists of five identical B subunits forming a ring structure into which a single toxic-active (A) subunit is noncovalently inserted. The toxin binds to cells by each B subunit interacting with a binding receptor identified as a specific glycolipid, the ganglioside GM1 [20]. Binding allows for the translocation into the cell interior of the A subunit, which then through an enzymatic reaction couples ADP-ribose to a subunit of adenylate cyclase and thus causes increased formation and accumulation of cAMP in exposed cells [14]. ETEC bacteria may produce either or both of a heat-labile enterotoxin (LT) and a heat-stable enterotoxin (ST) [19,21]. Of these, LT is closely related to CT with a similar 5B:1A subunit structure and strong structure homology and immunological cross-reactivity in both the A and B subunits [19,23,24]. ST, on the other hand, is of low molecular weight and completely unrelated to LT or CT in structure and function.

Studies in experimental animals have shown a direct correlation between protection against CT-induced fluid secretion and intestinal synthesis of SIgA antibodies and also between protection and the number of SIgA antitoxin-producing cells in the intestine [19]. A protective role of SIgA antitoxin has also been clearly indicated by the direct correlation in breast-fed children in Bangladesh of a reduced risk of developing disease even upon infection with *V. cholerae* O1 and the ingestion of mother's milk with SIgA antitoxin antibodies above a certain level [25]. Furthermore, as will be discussed below, vaccine-induced antitoxic immunity associated with intestinal SIgA antitoxin production in a large field trial in Bangladesh has been shown to confer significant protection against both cholera and diarrhea caused by LT-producing ETEC.

The identification of the AB subunit structure of CT and LT and the roles of the different subunits in pathogenesis and immunity suggested that the isolated CT or LT B subunits (CTB or LTB) could be useful vaccine components to induce protective antitoxic immunity. This notion was further strengthened by findings in animals showing that immunization with highly purified CTB or LTB gave rise to toxin-

neutralizing antibodies that could fully protect against disease also by live challenge in the gut [26,27]. Furthermore, the B subunit pentamers have been found to be particularly well suited as oral immunogens because they are stable in the intestinal milieu and capable of binding to the intestinal epithelium, including the M-cells of the Peyer's patches, properties that are very important for stimulating mucosal immunity and local immunological memory [28].

### B. Colonization Factors and Antibacterial Immunity

The best correlate between protection and naturally acquired immunity in cholera is the level of serum vibriocidal antibodies, which in populations living in cholera endemic areas increase by age in an almost parallel manner to decreased susceptibility to cholera infection and disease [7,12]. However, there is no direct correlation between vibriocidal antibody and protection, especially not after vaccination. Thus, for instance, extremely high vibriocidal antibody levels can be achieved in serum after immunization with parenteral cholera vaccines, but the protection is low because little mucosal immunity is evoked. In contrast, the new oral cholera vaccines whether consisting of killed whole-cell vibrios together with cholera B subunit or of live attenuated vaccine strains induce substantially lower levels of vibriocidal antibodies in serum than achieved with parenteral vaccines, yet provide stronger and more long-lasting protection.

It is well established that *V. cholerae* O1 lipopolysaccharide (LPS) is the predominant antigen inducing protective antibacterial immunity against experimental cholera caused by O1 bacteria [13]. Recent studies have suggested that when it comes to protection against *V. cholerae* O139, immunity is also to a large extent provided by specific antibodies to (O139) LPS. Most of the vibriocidal antibodies in serum are directed against *V. cholerae* LPS, and the extent to which the vibriocidal antibody levels reflect protection probably relates to the degree these antibodies reflect the levels of locally produced, protective IgA antibodies against *V. cholerae* LPS in the intestine.

In *V. cholerae* O1 bacteria of the classical biotype, a toxin-coregulated pilus (TCP) has been shown to be of importance for colonization of the small intestine [29]. There is evidence that also for *V. cholerae* O1 El Tor and O139, an antigenically distinct form of TCP is in an analogous way important for colonization and disease [30]. In addition, *V. cholerae* bacteria have been found to express several other fimbrial structures. One of these is the mannose-sensitive hemagglutinin (MSHA), which is found on O1 El Tor and O139 *V. cholerae* but not on O1 bacteria of classical biotype, and which can mediate bacterial attachment to epithelial cells [31]. The role of these other attachment factors for colonization and infection in humans, however, remains to be defined.

The identification of TCP as an important colonization factor on *V. cholerae* suggests that it should be possible to raise protective antibacterial immunity also against these fimbrial antigens. Indeed, in experimental systems both monoclonal antibodies and polyclonal antisera against

TCP can protect against infection and disease [32]. However, following natural infection, little if any anti-TCP immunity develops. Therefore, as an overall conclusion, it remains to be defined whether mucosal immune responses against TCP and other surface antigens on *V. cholerae* can add significantly to the protective action mediated by antibodies to O1 LPS antigen.

An important observation guiding the design of new cholera vaccines has concerned the cooperation between antitoxic and antibacterial immune mechanisms in protection. Either of the two main protective antibodies against cholera which, as mentioned above, are directed against the cell wall LPS and CTB, can confer strong protection against disease by inhibiting bacterial colonization and toxin binding, respectively [13]. When present together in the gut these antibodies have been shown to have a strongly synergistic protective effect [33].

### C. Immunological Memory

The acute local antibody response to the oral BS-WC cholera vaccine in unprimed individuals normally lasts for up to 6 months [34,35]. However, in accordance with studies in animals showing almost lifelong gut mucosal immunological memory after oral vaccination with CT [36] it has been shown that a long-lasting immunological memory is also induced in humans by the oral vaccine [37–39].

Thus, healthy Swedish volunteers who received a booster vaccination 5 years after an initial two-dose cholera vaccination responded with significantly higher antitoxin and antibacterial serum IgG and IgA antibody levels than previously unvaccinated controls [37]. In another study, the frequencies of CTB-specific antibody-secreting cells (ASCs) extracted from duodenal mucosal biopsies of vaccinated Swedish volunteers were found to be considerably higher after the second than after the first vaccine dose, and the

response to a third booster dose at 5 months fully matched that after the second dose at 2 weeks [39]. Furthermore, circulating ASCs, known to mainly be derived from and reflect the gut mucosal immune response, were higher after either of the second and third vaccine doses than after the first vaccine dose [39]. Almost identical results were obtained in Swedish volunteers given a booster dose 10 months after either two or three initial vaccinations [38].

Taken together, these studies suggest that the oral BS-WC cholera vaccine induces a very long-lasting immunological memory. A stronger and faster immune response than after an initial vaccination can be obtained by a booster vaccination given at any time from 2 weeks up to at least 5 years after the primary immunization. Furthermore, in individuals who have received a fully immunizing two-dose regimen, a single booster immunization given even 5 years later evokes an apparently maximal gut mucosal immune response to the vaccine.

## III. COMPOSITION OF VACCINE

The oral killed BS-WC cholera vaccine (registered under the trademark Dukoral®, SBL Vaccin, Sweden) consists of killed whole *V. cholerae* O1 cells and recombinantly produced CTB. A detailed description of the vaccine composition is given in Table 1. A total of  $1 \times 10^{11}$  heat-killed or formalin-killed *V. cholerae* O1 bacterial cells, comprising both the Inaba and Ogawa serotypes and the classical and El Tor biotypes, are supplied as a suspension mixed with CTB in phosphate-buffered saline. The vaccine is taken together with a bicarbonate buffer provided in the registered vaccine product as a single-dose dry salt preparation, which is dissolved in water and mixed with the vaccine before administration in order to protect the CTB component against stomach acidity.

**Table 1** Composition and Recommended Administration of Oral B Subunit-Killed Whole-Cell Cholera Vaccine

Each dose of vaccine suspension (3 ml) contains:	
<i>Whole-cell component:</i>	
<i>V. cholerae</i> O1 Inaba classic strain (heat inactivated)	$2.5 \times 10^{10}$ vibrios
<i>V. cholerae</i> O1 Inaba El Tor strain (formalin inactivated)	$2.5 \times 10^{10}$ vibrios
<i>V. cholerae</i> O1 Ogawa classic strain (heat inactivated)	$2.5 \times 10^{10}$ vibrios
<i>V. cholerae</i> O1 Ogawa classic strain (formalin inactivated)	$2.5 \times 10^{10}$ vibrios
<i>B subunit component:</i>	
Recombinant CTB	1 mg

The vaccine is produced by SBL Vaccin, Sweden, and currently registered in some 20 countries worldwide under the trade name Dukoral. For immunization, the 3-ml vaccine solution is emptied into a glass of sodium hydrogen carbonate solution and drunk (the buffer salts are supplied in the vaccine package as effervescent granules, which should be dissolved in a glass of cool water, approx. 150 ml; the whole volume is used for vaccinees older than 6 years of age, for younger children only half the volume, ca. 75 ml, is used but still with the full 3-ml dose of vaccine). The recommended primary vaccination comprises two doses of vaccine for adults and children over the age of 6 years and three doses of vaccine to children from 1 to 6 years of age. Doses should be administered at intervals of 1–6 weeks. For maintaining a continuous protection, a booster dose is recommended for adults and children above the age of 6 years after 2 years; children below 6 years of age should receive a booster dose after 6 months.

The first-generation oral cholera vaccine contained CTB subunits purified from CT produced in a fermentor by the wild-type strain 569B. This method made the preparation of this extensively purified component laborious and relatively expensive [40]. These drawbacks were overcome by the development of an efficient recombinant over-expression system for the large-scale production of CTB [41]. These latter procedures now yield more than 1 g of highly purified CTB per liter of fermentor culture even in 1000-L fermentations, which is approximately 100-fold better than the yield obtained with the early nonrecombinant production and isolation of CTB. Since there is no CTA subunit gene present in the production strain used, no active toxin can be formed, which makes the purification processes further efficient and cheaper [41]. No differences have been found in the function of recombinantly produced CTB and toxin-derived CTB as a vaccine component. Immunological and functional studies, including immunogenicity studies in both animals and humans, have not been able to demonstrate any differences in the two molecules or in the immune response they evoke [41,42]. Moreover, the results from an efficacy field trial in Peru with vaccine containing the recombinantly produced CTB [43] were fully consistent with the efficacy results obtained in Bangladesh with first-generation vaccine containing native CTB [15].

#### IV. PROTECTION AGAINST CHOLERA

The first evidence for protective efficacy of a killed oral BS-WC vaccine was seen in a challenge study in North American volunteers in the early 1980s [44]. Immunization with oral killed *V. cholerae* WC vaccine, alone or given with CTB, was evaluated. Vaccinees, who had received three doses of either vaccine, and unvaccinated controls were challenged with  $1 \times 10^6$  *V. cholerae* O1 El Tor organisms to determine the protective efficacy of the vaccines. The combination vaccine provided 64% protection ( $p < 0.01$ ), and the whole cell vaccine without any B subunit provided 56% protection ( $p < 0.05$ ). In addition, illnesses in vaccinees were milder than in controls, and both vaccines gave 100% protection

against more severe disease. This substantial level of protection against challenge with a dose of *V. cholerae* that caused cholera in nearly 90% of controls suggested that these vaccines might provide at least as high a level of protection if given to the population of an endemic area. This prediction has then been tested and confirmed in three large field trials with the combined oral BS-WC cholera vaccine.

The first of these field trials was conducted in Bangladesh in 1985–1990 [15,16,45,46]. The study included nearly 90,000 volunteers 2–65 years of age, and surveillance for cholera was conducted during a 5-year period. The volunteers received three doses of BS-WC vaccine, WC only vaccine, or *E. coli* K12 placebo. The results of the study are summarized in Tables 2 and 3. The overall short-term (4–6 months) protection with the BS-WC vaccine was 85% [15]. The protection in children aged 2–5 years was 100% during this period but declined to 38% for the entire first year and 47% for the second year [Table 2] [46]. Adults were very well protected by the BS-WC vaccine for the first 2 years, 78% and 63% protective efficacy for the first and second year, respectively, while a decline was seen during the third year, 41% protective efficacy [46]. It was also shown that two doses were sufficient for protection giving 77% and 70% protection during the first and second year, respectively (data reanalyzed by SBL, unpublished) [16].

The WC vaccine without any B subunit also provided significant short-term as well as long-term protection against cholera in adults (Table 3). However, the short-term protection, 58% for the initial 4- to 6-month period, was significantly lower than the 85% efficacy of the combined BS-WC vaccine during the same period. This added short-term protection seen with the BS-WC vaccine supports the existence of an independent immunogenic effect of the B subunit component in this vaccine. Indeed, if for calculation of the protective efficacy of the B subunit component one estimates a protective efficacy of BS-WC in comparison with WC by looking at the WC groups as “placebo,” the protective efficacy of the B subunit over the WC component was 73% during this period. The BS-WC vaccine continued to be significantly more protective than the WC-alone vaccine for the first 9 months after vaccination. Thereafter, however, the overall efficacy was similar, approximately 55% during the

**Table 2** Protection Against Cholera by the Oral B Subunit-Killed Whole-Cell (BS/WC) Vaccine in the Bangladesh Field Trial

Follow-up period	Protective efficacy % (95% confidence interval)		
	All ages	Children 2–5 years	Adults and children > 5 years
4–6 months	85 (56–95)	100	76
	First year	38	78
Second year	52 (30–76)	47	63
	Third year	Nil (nil–46)	41

Source: Ref. 46.

**Table 3** Protection Against Cholera by the Oral Whole-Cell Only (WC) Vaccine in the Bangladesh Field Trial

Follow-up period	Protective efficacy % (95% confidence interval)		
	All ages	Children 2–5 years	Adults and children > 5 years
4–6 months	58 (14–79)	35	71
First year	56 (39–76)	31	67
Second year	55 (33–69)	24	73
Third year	41 (7–62)	2	61

Source: Ref. 46.

second year of follow-up and 20–40% during the third year. The protective contribution of the B subunit component appeared to be particularly strong with regard to short-term protection in children less than 5 years of age at the time of vaccination: in contrast to the 100% protective efficacy of the BS-WC vaccine the WC-alone vaccine only provided 35% protection in this age group during the same period [46]. Thus, children 2–5 years were very well protected by the BS-WC vaccine during the first 6 months, but protection declined thereafter, whereas the WC-alone vaccine did not confer sufficient protection to the young children although it protected older children and adults well.

The second randomized, placebo-controlled field vaccine efficacy trial was conducted among Peruvian military personnel in 1992, quite soon after cholera first appeared in Peru (1991) [43]. There were many differences compared with the previous Bangladesh trial; for example, the Peru trial included only high-risk blood group adults who were not exposed to cholera previously, administration of two doses of vaccine only, the use of recombinant CTB rather than native CTB in the vaccine, the fact that all cholera was caused by El Tor biotype, a much smaller population ( $n = 1500$ ), and a very high attack rate in the placebo group. Even so, however, the results of 5 months of follow-up showed 85% protective efficacy (95% confidence interval being 36–97%;  $p = 0.004$  for comparison with the placebo group), which is strikingly similar to the short-term efficacy in the Bangladesh trial.

A third large field trial was also conducted in Peru [47]. It resembled the Bangladesh trial in that it was a large trial (17,000 subjects) and a target population 2–65 years of age. In this study, two primary vaccinations were given to all subjects regardless of age, followed by a third booster dose after 1 year. In contrast to the Bangladesh study, there was active surveillance for cholera and very few cases of cholera seeking treatment at a hospital during the first year of surveillance. The outcome of this study was also in contrast to what was seen previously in that no protection was seen during the first year of surveillance. However, during the second year, when there were also more hospitalized cases,

there was 60% protection against cholera (78% against hospitalized cases), which is in agreement with the results of the Bangladesh trial. The study has been criticized and several possible explanations for this outcome have been proposed [48], including the use of active surveillance for detection of cholera cases with nearly exclusively mild cases during the first year.

## V. CROSS-PROTECTIVE EFFICACY AGAINST ENTEROTOXIGENIC *ESCHERICHIA COLI*

There is ample evidence from preclinical studies that antibodies to CTB can effectively neutralize *E. coli* LT, and that antitoxic immunity induced by either CT or CTB can protect against LT ETEC diarrhea [49].

The first evidence that oral immunization with CTB also provides significant cross-protection against disease caused by LT-producing ETEC in humans was demonstrated in the Bangladesh field trial [17]. The protective efficacy against ETEC diarrhea during the first three months after vaccination, a period in which there was much ETEC disease including strains that produce LT with or without ST, was 67%. Protection was stronger against severe dehydrating disease (86%) than against milder illness (54%). It was not possible to determine the protective efficacy for the following 6 months as there were no ETEC cases, and when the next ETEC season started, 9 months after the last vaccination, no protection was evident. There were no age-dependent differences in protection. Thus, in endemic areas, a good, short-term cross-protection against LT-ETEC disease by the oral BS-WC cholera vaccine, specifically mediated by the CTB component, was shown.

As ETEC is the single most common cause of traveler's diarrhea, it was of interest to study protection in travelers as well. This has been done in two randomized, placebo-controlled studies. The first, and most convincing of these studies, was done on Finnish travelers going to Morocco [18]. In this study, a protective efficacy of 60% was seen against LT-producing ETEC. A second travelers' study was

conducted among U.S. students going to Mexico [50]. The design of this study differed from the Finnish study in that the U.S. students were vaccinated immediately after arrival in Mexico, while the Finnish tourists were vaccinated before departure. Most diarrhea cases occurred during the first two weeks after arrival, when the vaccine could not be expected to protect. When considering only cases occurring more than 7 days after the second vaccination there was 50% (CI: 14–71%) protection against all ETEC diarrhea. The conclusions of the study were that sufficient protection can only be achieved if the vaccine is taken before departure, so that the second dose is taken at least 1 week before arrival, and under these conditions the protection seen in this study supports the previous findings.

## VI. VACCINE SAFETY AND USE IN RISK GROUPS

### A. Overall Vaccine Safety

The oral BS-WC vaccine is generally considered very safe and has been extensively tested in clinical trials involving approximately 240,000 volunteers. No serious adverse events have been associated with vaccination. The most commonly reported adverse events in association with vaccination are mild gastrointestinal symptoms such as abdominal discomfort or pain, loose stools, or diarrhea. In all placebo-controlled trials the frequencies of adverse events, 0–24% of the studied populations, are similar in the vaccine and placebo groups. Both endemic and nonendemic populations have been included in clinical trials, but no differences in adverse reaction rates can be seen [42,51–53].

It has also been suggested that the symptoms are caused by the bicarbonate buffer given together with the vaccine [54]. When the vaccine was given together with a decreased amount of buffer the rate of symptoms decreased, but the antibody responses to CTB also decreased. This implies that although the buffer may be responsible for some gastrointestinal symptoms, it is required for maximum immunogenicity of the vaccine.

In addition to the clinical trials, over 1,000,000 doses of the vaccine have been sold in Sweden and Norway since 1992. During these years the Swedish and Norwegian Medical Products Agencies have received a total of 45 reports describing 63 adverse reactions, which is considered a very low number considering the large number of doses sold.

### B. Children

The safety and immunogenicity aspects of the oral BS-WC cholera vaccine are very well documented for children from 1 to 2 years of age. Protection has been studied in children from 2 years and up, and several additional studies have addressed the safety and immunogenicity of the vaccine in children from 1 year of age [15,16,45–47,51,53,55–57]. In total over 5300 children aged 1–5 years have received the vaccine in clinical trials with strict active surveillance of adverse reactions. In some trials both children and adults have been included, and there is no indication of age-related adverse events.

### C. Pregnant and Breast-Feeding Women

Considering the number of volunteers included in the large field trials with the BS-WC vaccine and the exclusion of pregnancy only by interviews and inspection it could be assumed that an unknown number of pregnant women came to be included. Although an individual follow-up of these women was not done on a systematic basis, there were no reports of pregnancy-related complications or complications in the newborns that were linked to the intake of the vaccine. The experience from Scandinavia, where more than 1,000,000 doses of BS-WC vaccine (Dukoral) have been sold to adults of both sexes, also supports the safety of the vaccine in pregnant women. The Adverse Drug Reaction (ADR) reporting system in Sweden is well developed through the Medical Product Agency (MPA) and there are no ADR reports related to pregnancy or postpartum conditions. In addition, there are no reports of any increased rate of malformation even following cholera infection in the literature. The previous parenteral cholera vaccine was studied in pregnant women and no increase in complications in pregnancy after vaccination was found [58]. Thus, it is extremely unlikely that the oral BS-WC cholera vaccine should have any negative effect when given during pregnancy. The vaccine has been given to a large number of breast-feeding women in several different studies, and no adverse events in relation to breast-feeding have been reported [59,60].

### D. Immunocompromised and HIV-Infected Individuals

There is a wide range of conditions leading to a deficient immune response to infections and vaccinations, with varying degrees of severity. Most of these conditions have not been studied in relation to oral cholera vaccines or cholera disease. However, the immune responses to oral BS-WC cholera vaccine in a group of IgA-deficient patients were studied in relation to vaccination, and it was found that the vaccine caused no adverse reactions and the intestinal IgG and IgM responses to the vaccine in this group were significantly higher than in subjects with normal IgA levels [61]. The potential risk that vaccination of patients with IgA deficiency combined with concurrent gut disease might lead to aggravated disease, due to the absence of anti-inflammatory IgA, has not been confirmed in clinical trials [62].

Three trials have been undertaken with the oral BS-WC cholera vaccine (Dukoral) in HIV-infected subjects in Sweden, Brazil, UK, and Kenya [63–65]. All three trials addressed immunogenicity and safety. The conclusion of these trials with regard to safety is that the vaccine does not cause any other side effects in HIV-infected than in healthy subjects and that there is no HIV disease progression. In general, killed vaccines are not considered a risk to HIV-infected individuals. Today, WHO recommends use of all vaccines included in the Expanded Program of Vaccination (EPI) in HIV-positive individuals, with the exception of BCG and yellow fever vaccines, which should not be given to patients with AIDS [66]. Protective efficacy after oral BS-WC cholera vaccination has not been studied specifically in HIV-infected individuals. However, at least one report has

stated that there is a higher risk ratio for mortality due to cholera in HIV-infected than in uninfected individuals, which underlines the importance of cholera vaccines that are functional also in this group [67].

## VII. PUBLIC HEALTH INDICATIONS AND EXPERIENCE

The main indication for vaccination against cholera is protection of the population at risk in endemic areas. At least 120,000 persons, and probably significantly more, die each year from cholera, reflecting a failure of health system infrastructure and difficulties in implementation of control measures. Nearly 120 countries have reported indigenous cases of cholera since 1991; almost half of them have reported cases for at least 5 out of the past 8 years. Therefore, WHO has recently concluded [9] that although the establishment of adequate personal hygiene, food safety, and sanitation are the mainstay of cholera control, in the short-term drastic improvements in these fields are difficult to achieve in most cholera endemic areas, and there is therefore an urgent need for efficient vaccines as an additional public health tool for cholera prevention. Compared with the parenteral vaccine, the now internationally available cholera vaccines represent significant improvements in terms of protective efficacy duration of protection, safety, and ease of administration [9]. There is an especially high public health need of such vaccines for use in emergency situations with high-risk populations, such as refugees in primitive camps and urban slum residents. WHO emphasizes that the use of cholera vaccines should always be preemptive before an outbreak has started and not reactive as a method of trying to contain an already ongoing epidemic, and that vaccination should always be combined with other preventative control measures currently recommended by WHO. There is also a place for cholera vaccination in civilian and military personnel traveling to highly endemic areas [9].

### A. Attractive Public Health Features of B Subunit-Killed Whole-Cell Vaccine

Results from Phase III efficacy trials do not automatically predict the effectiveness of the same vaccine under conditions of public health use. As opposed to the typical randomized, placebo-controlled efficacy trial, assessment of the public health effectiveness should take into account the impact by vaccination on the population at large, including both vaccinated people and those who for various reasons are not reached by the vaccination. The perceived value of the vaccine and its overall community acceptability are therefore important components in addition to efficacy in determining the public health effectiveness of a given vaccine. Whereas these latter aspects might tend to lower the effectiveness in comparison with the efficacy measured under the more idealized conditions of a placebo-controlled Phase III field trial, the routine public health use of vaccine may also elevate effectiveness above the level expected from efficacy trials through at least two different mechanisms. One of these is the beneficial effects of the so-called "herd immunity" in populations where vaccine coverage is high.

Another less well recognized factor is the generally much higher risk of infection and disease among people who elect to not participate in vaccine trials than among participants [68]. These people may well accept to be vaccinated in public health programs with vaccine that is perceived to be valuable and have few and mild adverse reactions.

The oral BS-WC cholera vaccine has several attractive features for public health use. It has, as described above, an excellent safety profile, does not require a strict cold chain by being stable also at temperatures at or above 30°C (although cold storage is recommended by the manufacturer), and is easy to administer. The BS-WC cholera vaccine is the only internationally registered vaccine with documented efficacy against cholera in endemic countries and is also the only vaccine available with documented protective activity against ETEC diarrheal disease. Consistent with these features and the importance of cholera and ETEC as enteric pathogens in a country like Bangladesh, in addition to their disease-specific efficacy in the Bangladesh field trial, both the BS-WC and the WC vaccines substantially reduced the overall diarrheal morbidity among those vaccinated, resulting in a 51% and 32% reduction in admissions for severe watery diarrhea in the BS-WC and WC vaccinated groups, respectively, as compared with the placebo group during the first year after vaccination [69]. The latter finding provides ample evidence of the public health application potential of the BS-WC cholera vaccine in settings found not only in Bangladesh but also in many other countries, where cholera, ETEC, and other enterotoxic diarrheal diseases account for a large number of life-threatening watery diarrheas and where adequate treatment facilities in rural areas often are scarce [70].

In the first year of follow-up after vaccination in Bangladesh, there was also a dramatic effect of both the BS-WC and WC vaccines as compared with placebo on total mortality [69]. Thus, overall mortality rates were 26% lower in the BS-WC group and 23% lower in the WC group during the first year. Among women vaccinated at ages >15 years those who received BS-WC had 45% fewer deaths ( $p < 0.01$ ) and those who received WC had 33% fewer deaths ( $p < 0.05$ ) than placebo recipients. Several additional findings suggested that this reduction in overall mortality was a specific effect rather than a statistical coincidence: (1) the effect was restricted to the high-cholera season, (2) it was correlated with deaths associated with or preceded by diarrheal disease according to "verbal autopsy" reports by household members, and (3) as mentioned, it was limited to the underprivileged group of women rather than children participating in the study [69]. The effect on total mortality was restricted to the first year. The results suggest that even in a "well-treated" area such as the field site in Matlab there may be a significant number of hidden cholera and severe ETEC diarrhea deaths that might be averted by effective cholera and/or ETEC vaccination programs.

One special aspect studied in the Bangladesh field trial of oral cholera vaccines was the association between breast-feeding and the risk of severe cholera among children under 36 months of age [71]. The results showed that overall, breast-feeding was associated with a 70% reduction of the risk of developing clinical severe cholera and exclusive breast-feeding during infancy appeared to be associated with

nearly 100% protection against severe cholera. Furthermore, maternal vaccination with either the BS-WC or WC oral cholera vaccine was associated with a 50% reduced risk of their nonvaccinated children to develop severe cholera. These results raised a possibility that vaccination of mothers may provide protection to their young children in endemic settings by either or both of two potential mechanisms, i.e., interrupting maternal-child transmission of cholera and/or increasing the specific immune protecting potential of the mothers' breast milk.

### B. WHO Recommendations and Vaccination Experiences in High-Risk Groups

For public health use, WHO concludes that owing to its low efficacy and short duration of protection, use of the old parenteral vaccine is not recommended. Among the new-generation cholera vaccines, WHO concludes that convincing protection in field situations has been demonstrated only with the BS-WC vaccine. The oral BS-WC cholera vaccine is currently the only cholera vaccine on the WHO list of prequalified vaccines. This means that the vaccine may be used by other organizations, e.g., United Nations agencies. WHO has concluded [9] that the vaccine is safe, lacks any significant adverse reactions, is well tolerated by HIV-positive individuals, and can be given safely to both pregnant and lactating women.

For vaccination of populations at immediate risk of a cholera epidemic, the BS-WC vaccine is recommended by WHO [9]. A special WHO expert group issued specific recommendations on the use of oral cholera vaccines in emergency situations and in very high risk populations as follows: "The oral BS-WC cholera vaccine should be considered among the tools to prevent cholera in populations believed to be at risk of a cholera epidemic within 6 months and not experiencing a current epidemics. Such high-risk populations may include, but are not limited to, refugees and urban slum residents" [74]. The group emphasized that cholera vaccine should be considered only for preemptive use, not reactively as a method of containing an outbreak once it has started. Further, vaccination to prevent cholera outbreaks should be undertaken only in conjunction with other prevention and control measures currently recommended by WHO, and intervention studies should be performed to establish the role cholera vaccination can play in cholera control programs [9,74].

### C. Vaccination Campaigns in High-Risk Groups

The oral killed BS-WC cholera vaccine has been used in a mass-vaccination study in refugee camps in Uganda, which was conducted by Groupe Européen d'Expertise en Épidémiologie Pratique (EPICENTRE), Paris, in cooperation with Médecins Sans Frontières, France [72,73]. The primary objective was to assess the feasibility of a mass cholera vaccination campaign in refugee camps, and it was not designed to determine the protective efficacy of the vaccine. The refugees represented about 55% of the total district population and were spread over 35 different settlements. Approximately 27,000 adults and children above 1 year of age were immunized with the oral BS-WC cholera vaccine.

The general conclusion of the study was that mass vaccination of refugee camps in sub-Saharan Africa is feasible. All vaccinations were carried out within 1 month. One year after vaccination there was an outbreak of cholera in the non-vaccinated settlements. There were 358 cases of cholera in the area, but none occurred in the vaccinated settlements. The data collected are not suitable for valid calculations of protective efficacy of the vaccine, but the organizers of the study conclude that "the results of this study are strongly in favor of a protective effect of the BS-WC cholera vaccine, both against *V. cholerae* and other infectious agents responsible of diarrheal disease."

Following a cholera epidemic in the Comores island, near Madagascar (particularly in the Anjouan island close to Mayotte), the French authorities decided to initiate a vaccination campaign against cholera for the whole population of Mayotte including illegal immigrants. The official decision to carry out a vaccination campaign was made in early October 2000 for implementation on site from November 1 and terminating December 15 before the school holidays, the beginning of Ramadan, and the rainy season. In spite of a very tight time schedule, 64% of the population (93,000 people) was vaccinated. Since this campaign, two cases of cholera have been identified in Mayotte: one in a woman who had not been vaccinated, and the other in a woman who had received only one vaccine dose.

### D. Locally Produced Whole-Cell Vaccine in Viet Nam

By technology transfer, a simplified version of the killed WC vaccine (without the B subunit) has been locally produced, tested, and licensed in Viet Nam. The production cost of this vaccine has been estimated to be US\$0.20 per dose. In a large-scale, open (not placebo-controlled) field trial conducted in more than 22,000 households in the central coastal city of Hue, persons aged over 1 year were allocated in alternate households to receive two doses of vaccine or no vaccine (67,000 persons in each group). During an outbreak of El Tor cholera that occurred 8–10 months after vaccination, significant protection (66%;  $p < 0.01$ ) was noted among the persons who received the two-dose vaccine regimen, and protection was similar for children aged 1–5 years (68%) and for older persons (66%) [75].

Since 1997, in an area of Viet Nam endemic for cholera, a second-generation bivalent WC vaccine, containing serogroup O139 in addition to O1 [76], has been tested in a large-scale, randomized, double-blind, placebo-controlled effectiveness trial. Results from this study have not been analyzed, but in a preceding Phase II trial the vaccine was shown to be safe and to give rise to vibriocidal antibodies against both the O139 and O1 serogroups. The anti-O1 vibriocidal antibody levels achieved were comparable to those elicited by the Swedish-registered BS-WC vaccine (Dukoral) tested side by side with the locally produced vaccine.

These findings give encouragement to the notion that an inexpensive, locally produced effective oral cholera vaccine may be within reach for the limited health care budget of poor countries with endemic cholera.

### VIII. CONCLUSIONS

Many studies in Europe, Asia, Africa, North America, and Latin America have shown that the BS-WC vaccine is safe and immunogenic in both children and adults in cholera-endemic as well as nonendemic countries, stimulating protective gut mucosal immune responses to the CTB and WC vaccine components. A good protective efficacy of the vaccine has been demonstrated, being 85% for the first 6 months after vaccination in both endemic and nonendemic populations, and remaining at or above 60% for at least 2 years in vaccinated adults and children above 5 years of age. In children below age 5, the short-term efficacy is very high (100% for the first 6 months when tested in a field trial in Bangladesh) but of shorter duration than in older children and adults. Based on these data the recommended primary vaccination comprises two doses of vaccine for adults and children over the age of 6 years and three doses of vaccine to children from 1 to 6 years of age. Doses should be administered at intervals of 1–6 weeks. For maintaining a continuous protection, a booster dose after 2 years is recommended for adults and children above the age of 6 years; children below 6 years of age should receive a booster dose after 6 months. The BS-WC cholera vaccine also offers short-term protection against ETEC diarrhea, for which there is currently no other vaccine available, and has been found to substantially reduce overall diarrhea morbidity in areas where cholera and ETEC diarrheas are common.

## Attenuated *Vibrio cholerae* Strains as Live Oral Cholera Vaccines and Vectors

James B. Kaper and Carol O. Tacket

University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.

### I. INTRODUCTION

The first cholera vaccine developed in the 19th century consisted of live whole *Vibrio cholerae* organisms injected parenterally. This vaccine was quickly abandoned. An ideal modern cholera vaccine should possess a number of characteristics regarding safety, efficacy, and practicality. In our view, an ideal cholera vaccine would (1) be well tolerated in all age groups; (2) protect high-risk groups (including young children and persons of blood group O); (3) require only a single dose; (4) be administered orally for practicality and for better stimulation of the intestinal immune system; (5) stimulate both anticolonizing and antitoxic immunity; (6) confer a high level of protection (>80% efficacy) that would endure for at least 5 years; (7) begin protecting within a few days of administering the single oral dose (important for use in explosive outbreak situations); (8) be available in a simple formulation that would retain potency when stored in tropical climates and would facilitate mass vaccination, including vaccination of young children; and (9) be inexpensive.

We think that live, attenuated *V. cholerae* vaccine strains administered orally offer the best possibility for meeting all of the above characteristics. The rationale for the use of attenuated *V. cholerae* strains as live oral cholera vaccines is based on several observations which have been extensively reviewed elsewhere [1–3]:

1. A single clinical infection due to wild-type *V. cholerae* O1 confers significant protection against cholera upon subsequent exposure to wild-type *V. cholerae* O1.
2. Although many virulence properties contribute to the pathogenesis of cholera, the *in vivo* expression of cholera enterotoxin is a prerequisite for the profuse purging of voluminous rice water stools that is a characteristic of cholera gravis.
3. The critical protective immunity to cholera is antibacterial rather than antitoxic in nature, although in

the short term, antitoxic immunity may synergistically enhance antibacterial immunity.

4. The degree of stimulation of serum vibriocidal antibody following ingestion of a live oral cholera vaccine or following infection with wild-type *V. cholerae* O1 constitutes the best correlate of antibacterial immunity in the intestine.
5. The critical antigen or combination of antigens that provide protective immunity in humans has not been definitively identified.

The development of live attenuated vaccines to prevent cholera has been greatly aided by the application of recombinant DNA technology. The major virulence factor of *V. cholerae* is cholera enterotoxin, which is responsible for the large volume of watery diarrhea that is the hallmark of this disease [1]. Before the development of recombinant DNA technology, many attempts were made to attenuate *V. cholerae* O1 using chemical mutagenesis to derive a strain that produced the nontoxic yet immunogenic B subunit of the cholera toxin (CTB) but not the A subunit (CTA), which is the enzymatically active portion of the toxin (reviewed in Ref. 2). This chapter will review recent progress in the development of live oral cholera vaccine strains and *V. cholerae* vector strains. Additional background on the epidemiology, pathogenesis, and immunogenicity of *V. cholerae* can be found in Chapter 43.

### II. EARLY GENERATIONS OF RECOMBINANT ATTENUATED CHOLERA VACCINE CANDIDATES

The basic methods involved in developing live recombinant vaccines against cholera have been to clone and to characterize genes encoding specific virulence factors, to mutate these genes *in vitro* using recombinant techniques, and then to reintroduce the mutated genes into wild-type *V. cholerae*

via homologous recombination. The crucial common mutation in the early and later generations of attenuated cholera vaccines is the deletion of genetic sequences encoding the *ctxA* gene encoding the cholera enterotoxin A subunit which is responsible for the ADP-ribosylating activity of the holotoxin. A number of such vaccines have been constructed by investigators at the Center for Vaccine Development at the University of Maryland and at the Harvard University [1,3–5].

The first generation recombinant cholera vaccines were generated from wild-type El Tor strain N16961 and classical strain 395. These vaccine candidates, strain JBK70 from N16961 and strains CVD 101 and 395N1 from 395, were markedly attenuated compared to the wild parent strain and were highly immunogenic [6,7]. When volunteers who were immunized with a single dose of  $10^6$  JBK70 were challenged with the virulent parent strain, significant protection was observed [6]. Diarrhea occurred in 7 of 8 unimmunized controls but in only 1 of 10 vaccinees, a vaccine efficacy of 89%. This level of efficacy was equivalent to that seen following sequential experimental infections with wild-type El Tor strains. Interestingly, JBK70 produced neither the A nor B subunits of cholera toxin, so this challenge study demonstrated the importance of antibacterial immunity in the absence of antitoxic immunity.

Despite the high levels of immunity engendered by these three vaccine candidates, they were unexpectedly reactogenic. Approximately one-half of the recipients of JBK70, CVD 101, and 395N1 suffered adverse reactions such as mild diarrhea, malaise, nausea, vomiting, abdominal cramps, low-grade fever, and headache [6,7]. These strains never caused severe or even moderate diarrhea but were nonetheless not studied further because of these reactions. These results were surprising since it was previously believed that cholera toxin was the only diarrheagenic factor produced by *V. cholerae*. Two hypotheses were proposed to explain this response [6]. The first hypothesis was that a previously unknown enterotoxin was responsible for the diarrhea in the absence of cholera toxin (CT). The second hypothesis was that avid colonization by the attenuated *V. cholerae* strain in the proximal small bowel, a site where only low numbers of bacteria are found in healthy North Americans, would somehow disturb the normal balance of secretion and absorption resulting in diarrhea and other symptoms.

To investigate the hypothesis that a previously undescribed enterotoxin was responsible for the reactogenicity, reactogenic *V. cholerae* vaccine candidates were tested for enterotoxic activity in rabbit ileal tissue mounted in Ussing chambers. Two candidate toxins, Zot (zonula occludens toxin) and Ace (accessory cholera enterotoxin), were discovered that possessed enterotoxic properties, and the genes for these factors were found to be located immediately upstream of the *ctx* gene in a 4.5-kb region called the “core region” of the Ctx genetic element (reviewed in Ref. 1). This region was subsequently shown to encode a filamentous bacteriophage [8], and at least the *zot* gene is essential for phage morphogenesis, suggesting that Zot and Ace may have dual functions. To address the hypothesis that the putative Zot and Ace toxins were responsible for the reactogenicity of the

attenuated *V. cholerae* O1 strains, a derivative of wild-type El Tor strain E7946 was constructed with the *ace*, *zot*, and *ctxA* genes deleted and the *ctxB* gene was cloned under the control of the *ctx* promoter and inserted into the *hlyA* gene encoding the El Tor hemolysin. Although the resulting strain, CVD 110, provided excellent vibriocidal and antitoxic immune responses in volunteers, it caused mild to moderate diarrhea in 7 of 10 vaccinees (which was accompanied by malaise, nausea, and low-grade fever) and was therefore unacceptably reactogenic [9].

### III. RECOMBINANT ATTENUATED *V. CHOLERAЕ* O1 CLASSICAL STRAIN CVD 103-HgR

The first recombinant *V. cholerae* vaccine strain to be well tolerated yet highly immunogenic and protective was strain CVD 103, derived from the classical Inaba *V. cholerae* O1 strain 569B. This parent strain colonized the intestine at lower levels than other toxigenic *V. cholerae* strains and was reported to lack a Shiga-like toxin activity that was possibly involved in vaccine reactogenicity. CVD 103 was derived from 569B by deletion of the *ctxA* subunit [10], and a further derivative was constructed by inserting genes encoding resistance to mercury (*mer*) into the chromosomal *hlyA* locus. The mercury resistance provides a marker to readily differentiate the vaccine strain from wild-type *V. cholerae*. The resulting strain, CVD 103-HgR, exhibits many of the characteristics of an ideal cholera vaccine and is now licensed and sold in numerous countries under the trade names Orochol® and Mutacol®.

CVD 103-HgR has been extensively studied in a number of randomized, placebo-controlled, double-blind phase I and phase II clinical trials involving more than 7000 subjects in countries in Asia, Latin America, Africa, Europe, and North America (reviewed in Refs. 1, 4, 11, and 12). The safety and immunogenicity of this vaccine have been demonstrated in subjects as young as 3 months and as old as 65 years of age, including subjects infected with the human immunodeficiency virus (HIV) [13,14]. In all studies, neither diarrhea nor any other adverse reaction occurred significantly more often in vaccinees than in placebo recipients. Several efficacy studies have been conducted in which subjects were vaccinated with CVD 103-HgR and then challenged along with unvaccinated controls with virulent toxigenic *V. cholerae* O1 strains. A single dose of CVD 103-HgR provided significant protection against challenge with classical Inaba, classical Ogawa, El Tor Inaba, or El Tor Ogawa strains [3,4,15,16]. In a multicenter, randomized, double-blind, placebo-controlled efficacy trial of a single dose of classical CVD 103-HgR against challenge with virulent El Tor strain N16961, moderate or severe diarrhea ( $>3$  L) was seen in 9 of 23 placebo recipients vs. 1 of 28 vaccinees (91% efficacy). When mild diarrhea was assessed, 21 of 23 placebo recipients and 5 of 28 vaccinees had any diarrhea (mild to severe) (80% efficacy) [15]. Another trial demonstrated that protection is evident as early as 8 days after vaccination and lasts for at least 6 months (the shortest and longest intervals tested) [17]. The single-dose efficacy

and rapid onset of protection are attractive advantages of the live cholera vaccine CVD 103-HgR compared to killed whole cell cholera vaccines.

The efficacy of CVD 103-HgR against natural challenge in a cholera-endemic country was studied in a randomized, double-blind, placebo-controlled field trial involving 67,508 pediatric and adult subjects in Indonesia [18]. A single dose of vaccine did not confer significant long-term protection over the 4-year observation period (13.5% vaccine efficacy overall), but individuals of blood group O, who are at highest risk for severe diarrhea, were modestly protected by the vaccine ( $p = 0.06$ , vaccine efficacy = 45%). Unfortunately, too few cases (5 in controls, 2 in vaccinees) occurred in the first 4 months of follow-up to assess whether CVD 103-HgR provided short-term protection similar to the short-term duration of previous clinical trials involving North American volunteers. The most likely explanation for the poor efficacy in subjects in the developing world is their lower postvaccination vibriocidal titers compared to titers in North American volunteers. Diminished immunogenicity of live oral vaccines given to subjects living in developing countries compared to subjects in industrialized countries has also been observed with both oral polio and rotavirus vaccines. In order to achieve high seroconversion rates of vibriocidal antibody in Indonesian children, it was necessary to give a dose of CVD 103-HgR 10-fold higher ( $5 \times 10^9$  CFU) than the dose ( $5 \times 10^8$  CFU) that is consistently immunogenic in North Americans and Europeans (reviewed in Refs. 4 and 12). Potential explanations for the diminished immunogenicity include small bowel overgrowth [19] and heavy infection with intestinal helminthes [20].

Although the protective efficacy of a single dose of CVD 103-HgR in individuals living in developing countries has not been established, the significant protective immunity demonstrated in challenge studies involving North American volunteers offers strong evidence that this vaccine will protect individuals from noncholera-endemic countries in North America and Europe who travel to cholera-endemic countries. The vaccine is manufactured by Berna Biotech Ltd., Berne, Switzerland, and over 500,000 doses have been distributed worldwide. It is available in a convenient formulation consisting of two aluminum foil sachets, one containing lyophilized vaccine (and aspartame as sweetener) and the other containing buffer (to protect the vaccine strain from gastric acid). The two sachets are mixed in a cup containing 100 ml of water, and the resultant suspension is swallowed. *V. cholerae* CVD 103-HgR is also available in a combination vaccine with attenuated *Salmonella* Typhi vaccine strain Ty21a, and antibody responses resulting from coadministration of the two vaccines were comparable in frequency and magnitude to those levels seen in previous studies using each vaccine alone [21].

#### IV. RECOMBINANT ATTENUATED *V. CHOLERAES* O1 EL TOR VACCINE STRAINS

The current predominant O1 biotype throughout the world is the El Tor biotype, and the attenuated *V. cholerae* CVD 103-HgR vaccine strain belongs to the classical biotype of

*V. cholerae* O1. As discussed above, this classical vaccine provided strong protective immunity against experimental challenge with toxigenic El Tor Inaba or Ogawa strains. Although an El Tor vaccine strain may initially appear to be more desirable than a classical strain given the predominance of the El Tor biotype, there is compelling evidence, both from epidemiological and volunteer studies, that infection with the classical biotype is a more powerful immunizing experience than infection with the El Tor biotype. Clemens et al. [22] studied cholera in Bangladesh during a time in which both classical and El Tor biotypes were causing disease. Over a 42-month observation period, 2214 initial episodes of cholera were recorded in the study population. Seven of these individuals had a second episode of cholera. An initial infection with a classical strain provided 100% protection against a second episode of cholera due to either classical or El Tor strains. In contrast, an initial infection with El Tor provided only 30% protection against a second El Tor episode and no protection whatsoever against subsequent classical biotype disease. (However, a recent examination of cholera in Bangladesh over a 33-year period suggests that classical and El Tor strains protect equally well and that initial infection with an Ogawa strain offers less protection than infection with an Inaba strain [23]). In studying short-term protection in North American volunteers infected with wild-type *V. cholerae* O1 strains, an initial infection with a classical strain led to 100% protection upon subsequent challenge, whereas an initial infection with an El Tor strain led to ca. 90% protection [2]. The reasons for the differences in protection induced by El Tor and classical strains are unknown. The regulation of *ctx* and the *tcp* gene encoding the essential toxin co-regulated pilus (TCP) colonization factor differs between the two biotypes in response to environmental conditions. The TCP from El Tor and classical strains shares only 82% protein sequence homology of the major pilin subunit [24]. Support for the importance of TCP sequence differences in biotype-specific protection comes from animal studies using passive immunization against El Tor or classical TCP preparations. However, in humans, infection with either El Tor or classical strains leads to little or no immune response against either form of TCP, although TCP is clearly essential for intestinal colonization and generation of a protective immune response against other antigens [25]. A mannose-sensitive hemagglutinin (MSHA) expressed by O1 El Tor and the related O139 strains, but not by classical strains, was originally proposed to be important in intestinal colonization and biotype-specific protection. However, in a volunteer trial using an isogenic *V. cholerae* O139 strain in which the gene encoding MSHA was mutated, intestinal colonization was not affected by the deletion of MSHA [26]. Mannose-sensitive hemagglutinin may play a role in environmental survival rather than in disease in the human intestine. Despite the lack of certainty as to the critical differences between El Tor and classical biotypes, a variety of attenuated El Tor vaccine candidates have been prepared using molecular genetic techniques similar to those employed in construction of classical candidates, and these candidates are in various stages of clinical evaluation.

Vaccine candidate CVD 111 was derived from the toxigenic El Tor O1 strain N16117 using methods similar to those used to construct CVD 110 [27]. In previous volunteer studies, this parent strain was not as virulent as other wild-type El Tor challenge strains. The *ctxA*, *ace*, *zot*, and *hlyA* genes were deleted, and the *ctxB* gene expressed from the *ctx* promoter along with the *mer* genes was inserted into the *hlyA* locus to generate CVD 111. When tested in volunteers, CVD 111 caused mild diarrhea in 3 of 25 volunteers (12%) at a dose of  $10^8$  CFU [27]. The seroconversion rate for both vibriocidal and antitoxin responses was 92% after a single dose. When challenged 7 weeks after vaccination, 3 (16.7%) of 18 vaccinees and 7 (87.5%) of 8 controls developed diarrhea, a vaccine efficacy of 80.9%. A bivalent CVD 103-HgR/CVD 111 vaccine has been evaluated in Phase II trials in Peru and Panama and was found to be safe and immunogenic [28,29].

*V. cholerae* IEM101 is an O1 El Tor Ogawa strain that was isolated from a river water sample in China. It naturally lacks *ctxAB*, *ace*, and *zot* genes but contains *tcp* genes encoding the TCP pilus [30]. In volunteer trials in China, this strain colonized well, no diarrhea, fever, or other side effects occurred, and serum vibriocidal antibodies were engendered. This strain has subsequently been modified to express a genetically detoxified derivative of cholerae toxin [31] as well as heterologous antigens such as fragment C of tetanus toxin and tracheal colonization factor from *Bordetella pertussis* [32]. To date, no human efficacy data have been reported for this strain.

*V. cholerae* strain 638 is an attenuated O1 El Tor Ogawa strain developed by investigators in Cuba who deleted the *ctx*, *zot*, and *ace* genes as well as the *hap* gene encoding a hemagglutinin/protease (HAP) possibly involved in the reactogenicity of earlier *V. cholerae* vaccine strains. In an initial phase I study, this vaccine engendered significant vibriocidal antibody titers and mild diarrhea in 4 of 42 vaccinees upon vaccination [33]. No challenge studies of protective efficacy have been reported.

Peru-15 is an El Tor Inaba strain created from a wild-type *V. cholerae* O1 strain (C6709) isolated in Peru in 1991. It was constructed by deleting the 4.5-kb core element containing *ctx*, *ace*, and *zot* as well as the RS I element and attRS sequences flanking the core element. In addition, the *ctxB* gene was cloned under the control of the *htpG* heat-shock promoter and inserted into the chromosomal *recA* gene, thereby inactivating this gene involved in homologous recombination. The attenuated strain resulting from these initial genetic manipulations was called Peru-3. When tested in volunteers at doses of  $4 \times 10^6$  and  $1 \times 10^8$  CFU, Peru-3 stimulated significant vibriocidal antibody responses in 5 of 6 vaccinees and mild diarrhea in 2 of 6 [34]. A spontaneous nonmotile mutant of Peru-3 was isolated and designated Peru-15 [35]; the nonmotile mutant was better tolerated in volunteers than the Peru-3 parent. A recent randomized, placebo-controlled clinical trial enrolled 59 North American volunteers who received  $2 \times 10^8$  CFU of Peru-15 or placebo [36]. Recipients of the vaccine and placebo had similar rates of symptoms, except for headaches, which were more frequently reported by vaccinees on days 0 and 3 ( $p = 0.002$  and 0.05, respectively), and abdominal cramps, which did

not reach statistical significance. Ninety-seven percent of vaccinees mounted significant vibriocidal antibody responses and 28% mounted significant antitoxin responses. After challenge with wild-type El Tor strain N16961, 5 (42%) of the 12 placebo recipients and none of the 24 vaccinees had moderate or severe diarrhea ( $>3$  kg diarrheal stool) (protective efficacy 100%). When mild diarrhea was included, 7 (58%) of 12 placebo recipients and 1 (4%) of 24 vaccinees had any diarrhea (protective efficacy 93%). Further clinical studies of Peru-15 are underway.

## V. LIVE ATTENUATED VACCINE CANDIDATES AGAINST *V. CHOLERAЕ* O139

Before 1992, cholera was exclusively associated with *V. cholerae* of the O1 serogroup. However, in late 1992, epidemic cholera caused by a *V. cholerae* strain of a serogroup other than O1 appeared in India and Bangladesh. The serogroup associated with this new epidemic was designated O139. By late 1993, the O139 serogroup had largely displaced O1 as the principal cause of cholera in Bangladesh and Calcutta, India, although by 1995, O1 had returned as the predominant serogroup in these countries [37]. In contrast to the expected epidemiology of O1 *V. cholerae* in cholera-endemic countries, in which the attack rates are highest in young children and decrease in older age groups, indicating acquisition of immunity in adults after repeated antigenic contact, the attack rate for the initial O139 outbreak was higher in adults than in children, suggesting that antibacterial and antitoxic immunity engendered by *V. cholerae* O1 did not confer cross protection against disease due to *V. cholerae* O139 [38]. Subsequent animal studies supported the lack of cross protection between these two serogroups. Thus vaccination against *V. cholerae* O139 will require new vaccines that contain O139 antigens.

*V. cholerae* O139 strains are very similar to O1 El Tor strains in numerous phenotypic and genetic traits [38]. However, O139 differs from O1 in that a different lipopolysaccharide (LPS) antigen and a capsular polysaccharide not found in O1 strains is expressed by O139 strains. At the molecular level, the O139 clone appears to have arisen by the substitution of ca. 22 kb of DNA encoding the O1 LPS with a unique 35-kb region involved in the expression of the O139 LPS and capsular polysaccharide [39]. The experience gained from construction of attenuated O1 vaccine candidates provided the basis for the rapid development of live attenuated vaccine candidates for the prevention of cholera due to *V. cholerae* O139.

CVD 112 is an O139 vaccine candidate constructed from wild-type O139 strain AI1837 by deleting the core region containing the *ctxAB*, *zot*, and *ace* genes and inserting the *ctxB* and *mer* genes into the *hlyA* locus, analogous to CVD 110 [40]. CVD 112 was fed to volunteers in doses of  $10^6$  and  $10^8$  CFU with buffer. At the lower dose, no adverse reactions such as diarrhea, headache, nausea, fever, or abdominal cramps occurred among 6 recipients. At the higher dose, 3 of 6 volunteers passed a few small volume diarrheal stools without any accompanying symptoms. Five weeks after vaccination, 8 vaccinees and 15 unvaccinated control sub-

jects were challenged with wild-type O139 strain AI1837. Diarrhea occurred in 1 vaccinee and 12 control subjects after challenge. The vaccine efficacy of 84% was remarkably similar to protection conferred by primary wild-type infection with AI1837 against subsequent challenge (80%) [41].

Bengal-3 is another promising attenuated O139 vaccine candidate constructed from the wild-type O139 strain MO10. Like CVD 112, the core element containing *ctxAB*, *ace*, and *zot* genes was deleted along with the flanking RSI and attRSI sequences. The *ctxB* gene was cloned under the control of the *htpG* heat-shock promoter and inserted into the chromosomal *recA* gene [42]. A spontaneous, nonmotile derivative of Bengal-3 was isolated which lacked flagella and was designated Bengal-15 [43]. In initial clinical trials, one of four volunteers who received  $10^7$  CFU of Bengal-3 and none of 10 recipients of  $6 \times 10^6$  or  $10^8$  CFU of Bengal-15 experienced diarrhea upon vaccination [43]. In a challenge study, diarrhea occurred in 1 of 7 Bengal-15 vaccinees and 6 of 7 unimmunized controls, a vaccine efficacy of 83% [43].

A different approach to an attenuated live vaccine against O139 *V. cholerae* was pursued by Favre et al. [44]. Rather than attenuate a wild-type O139 strain, these authors used the O1 vaccine strain CVD 103-HgR as a vector for O139 antigens, specifically the short core-linked O139 polysaccharide (SOPS) and the highly polymerized capsular polysaccharide (CPS). A derivative of CVD 103-HgR was constructed which lacked *rfbAB* genes necessary for expression of the O1 LPS. The cloned genes encoding the O139 polysaccharides were then incorporated into the chromosome of the CVD 103-HgR derivative. The resulting strain, CH25, expressed both O139 SOPS and CPS and stimulated high levels of anti-SOPS and anti-CPS serum antibodies when injected intramuscularly into rabbits. No clinical trials of this vaccine candidate have yet been reported, but if clinical results are promising, the extensive safety record accumulated for CVD 103-HgR and the fact that it has already been licensed by regulatory agencies in several countries should speed the development of such a hybrid vaccine.

## VI. ATTENUATED V. CHOLERAES AS A LIVE VECTOR FOR EXPRESSION OF HETEROLOGOUS ANTIGENS

A variety of foreign antigens have been expressed in attenuated *V. cholerae* vaccine strains including Shiga toxin (Stx) B subunit [45], fragment C of tetanus toxin [32], tracheal colonization factor of *B. pertussis* [32], *Shigella sonnei* O antigen [46], the immunogenic portion of *Clostridium difficile* toxin A [47], the Intimin colonization factor of enterohemorrhagic *Escherichia coli* [48], hepatitis B middle surface antigen [49], gp120 from HIV [50], and the serine-rich *Entamoeba histolytica* protein [51]. No human studies have yet been reported with any of these constructs, but protective immunity has been demonstrated in a rabbit model against challenge with *C. difficile* toxin A [51] and Stx holotoxin [45] and in an intranasal mouse model against challenge with tetanus toxin and *B. pertussis* [32].

To develop optimal *V. cholerae*-vectored vaccines, a number of variables such as choice of promoter, integration

site, and location for heterologous antigen expression within the *V. cholerae* cell have been studied, but extensive comparisons of the relative importance of these variables have not yet been conducted. Most studies have used *E. coli* promoters including *P<sub>tac</sub>* [45,48,52], *P<sub>trc</sub>* [53], *P<sub>sbt</sub>* [53], *P<sub>lpp</sub>* [51], and *P<sub>nirB</sub>* [32], but two *V. cholerae* promoters have also been used, the iron-regulated *P<sub>irgA</sub>* promoter and the heat-shock promoter *P<sub>htpG</sub>* [52,54]. A comparison was made among the constitutively expressed *P<sub>tac</sub>* and the in vivo-induced *P<sub>irgA</sub>* and *P<sub>htpG</sub>* in the attenuated *V. cholerae* strain Peru-2 [52], and it was found that *P<sub>tac</sub>* elicited the most prominent specific antibodies in vivo despite the fact that *P<sub>tac</sub>* and *P<sub>irgA</sub>* expressed equivalent amounts of the antigen in vitro. Regarding integration site of the heterologous antigen gene, most studies have used multicopy plasmids, which usually yield higher antigen expression but are not as stable as chromosomal integration. Ryan et al. [51] have developed a balanced lethal plasmid system for expression of heterologous antigens in *V. cholerae* involving the *glnA* gene in which the chromosomal *glnA* gene copy is deleted and is complemented by a complete *glnA* gene on the plasmid vector. There has been relatively little investigation into the advantages or disadvantages of different cellular locations, i.e., cytoplasmic, periplasmic, or extracellular, of heterologous antigens expressed in *V. cholerae*, nor has there been much investigation of different mechanisms by which noncytoplasmic locations might be achieved. The efficient extracellular secretion of CT via a type II secretion system has led to the construction of CTB fusion proteins with epitopes from hepatitis B middle surface antigen [49], gp120 from HIV [50], and the serine-rich *E. histolytica* protein [51] to allow expression and secretion of these epitopes. However, this system is limited by the small size of the epitope that can be attached while still allowing secretion of the fusion protein. Another approach for extracellular secretion of heterologous antigens from *V. cholerae* utilizes the hemolysin export system of *E. coli*. Ryan et al. [47] used the HlyA export system to export a 720 amino acid portion of *C. difficile* toxin A fused to the HlyA protein and demonstrated that for some but curiously not all strains of *V. cholerae*, the majority (70%) of the fusion protein was found in the supernatant.

## VII. CONCLUSIONS

At the present time, there is no ideal cholera vaccine that can provide long-term protection to individuals from both industrialized and developing countries in a single dose formulation. The live attenuated vaccine that is furthest along in development is CVD 103-HgR, which solidly protected North Americans against experimental challenge but which failed in a field trial in Indonesia. It is not known whether the result of the Indonesian field trial was an aberration, possibly because of the low attack rate for cholera during the surveillance period or other reasons. A second field trial of CVD 103-HgR, possibly comparing a one- and two-dose regimen, is needed. There is precedence for a cholera vaccine providing protection in one field setting but not in another. For example, the killed whole cell B subunit vaccine gave 86% protection in one two-dose field trial in children and

adults in Peru, yet 0% protection in a separate two-dose trial in military recruits in Peru [55,56].

Beyond the unanswered questions specific to CVD 103-HgR, there are additional questions that apply to any live attenuated *V. cholerae* vaccine. For example, can volunteer trials in North Americans reliably predict the success of trials conducted in cholera-endemic countries? Volunteer trials in North Americans are probably most relevant in predicting immunization success for travelers or military personnel from industrialized countries. The higher levels of microbial flora in the proximal small bowels of individuals in developing countries compared to levels in individuals in industrialized countries could present a substantial barrier to replication of a live vaccine in this critical intestinal site. In addition, preexisting antibodies to *V. cholerae* in individuals in cholera-endemic countries could inhibit replication of a live vaccine. Moreover, the mechanism responsible for the mild diarrhea induced in some North American volunteer who received early *ctx*-negative *V. cholerae* vaccine strains is unknown. It is conceivable that these highly immunogenic vaccine strains which were discarded because of their reactogenicity might have been well tolerated and effective among residents of endemic countries.

Another important unanswered question concerns the identity of the antigens required to raise a protective immune response. Clearly, the LPS plays a major role in protective immunity, as demonstrated by the apparent lack of immunity to *V. cholerae* O139 in adults who were presumably immune to *V. cholerae* O1. But additional as-yet-unidentified protein antigens are likely to contribute to protective immunity. Additional questions concern the need for a combined O1 and O139 vaccine. In the early 1990s, some predicted that the emergence of *V. cholerae* O139 was the start of the eighth pandemic of cholera. However, O139 did not spread widely and it is currently present in only a minority of cholera patients in Bangladesh and eastern India. A formulation for worldwide use containing both O1 and O139 would increase production costs of a vaccine that would be marginally profitable in any circumstance. A larger question concerns the fundamental nature of the emergence of the O139 serogroup. How did this novel organism emerge in the early 1990s? Could another novel and lethal serogroup of *V. cholerae* emerge in the future? Such questions continue to challenge us more than a century after the development of the first cholera vaccine.

## Novel Vaccines Against Tuberculosis

Robert J. Wilkinson and Douglas B. Young

Imperial College of Science, Technology and Medicine, London, England

### I. INTRODUCTION

In the 5 years that have elapsed since the second edition of this book, extraordinary and encouraging advances have been made in the field of mycobacteriology. This updated and revised chapter is thus written with the advantage of the whole genome sequence of *Mycobacterium tuberculosis* [1] and the recent completion of the human genome project [2]. Novel analytic techniques now permit comparison of the entire genome, transcriptome, and proteome of bacilli from varying sources grown under differing conditions [3–5]. The difficulties of achieving genetic recombination in *M. tuberculosis* have been overcome. The emphasis now has shifted rapidly from the purely microbiological characterization of recombinant strains to their cellular microbiological characterization in model systems [6–8] and use of such strains as potential vaccines [9]. Tuberculosis was among the first diseases to be shown to be potentially preventable by DNA vaccination [10,11]: subsequent research has also revived interest in the potential for therapeutic vaccination [12]. The analysis of novel rare immunodeficiencies predisposing to mycobacterial infection has greatly clarified human immune resistance to *M. tuberculosis* [13–16]. Lastly, and of greatest clinical significance, the evolution of highly active multidrug regimes to treat HIV infection is potentially of major significance to the 8% of tuberculosis patients co-infected with this virus and to countless millions of other HIV-infected persons who have latent tuberculosis infection.

How well has this explosion in basic knowledge translated into clinical practice? In the United States, the incidence of tuberculosis progressively fell during the 1990s [17]. Nowhere else in the world was this true. No new first line drugs were introduced, and the coexistence of HIV and tuberculosis particularly in Africa has contributed to epidemic tuberculosis [18]. Acquired multiple drug resistance in *M. tuberculosis* has become increasingly prevalent [19], contributing to the fear that the implementation of directly observed chemotherapy (DOTS) alone will be insufficient to control tuberculosis [20]. In 1997, new cases of TB were es-

timated to be 7.96 million and an estimated 1.87 million people died of TB: a case fatality rate of 23% [21]. Never has there been a greater need for an improved or additional vaccine.

### II. BACILLE CALMETTE–GUÉRIN VACCINE

There is a vaccine against tuberculosis that is effective in animals and in humans and which is safe and inexpensive. This vaccine, bacille Calmette–Guérin (BCG), has been evaluated in a series of clinical trials and is currently administered to around 100 million newborn children each year as part of the WHO Expanded Program for Immunization (EPI). What can be learnt from this story and why is it necessary to improve upon BCG?

Calmette and Guérin derived BCG, after 13 years of continuous laboratory passage on deficient media, from an initially virulent isolate of *Mycobacterium bovis*, a member of the pathogenic *M. tuberculosis* complex. The resulting isolate was avirulent in mice, guinea pigs, and humans and was found (and continues to be found) to be effective as an experimental vaccine in animals. By contrast, the efficacy of BCG in humans has been under continuous debate. Bacille Calmette–Guérin has been found to confer a high degree of protection in some trials; for example, in the United Kingdom, the incidence of tuberculosis in the vaccinated group was reduced by 77% when compared to the control group [22]. However, in other trials, the efficacy has been close to zero, most notably in South India (reviewed by Ref. 23). Variations between trials reflect the differences in the ability of BCG to protect adults against pulmonary tuberculosis, as the vaccine has consistently shown significant protective efficacy against the disseminated forms of tuberculosis that are a major cause of childhood mortality [24]. This feature justifies the vaccine's inclusion in the EPI. Bacille Calmette–Guérin also confers protection against leprosy [25]. However, the same trial concluded that revaccination with BCG did not improve its efficacy against tuberculosis. In addition, the limited data

available suggest that the efficacy of BCG vaccination wanes over time.

The reasons for the variations in efficacy have been discussed in extensive detail [23]. There are a number of genetically distinct substrains of BCG, all of which were maintained by further continuous passage until the advent of lyophilization in 1961 [5], raising the possibility that differences in immunogenicity between strains might contribute to the varying efficacy of BCG worldwide. The route of administration and efficacy of immunizing technique have not been rigorously evaluated. A widely favored hypothesis is that saprophytic mycobacteria, which are more common in the environment and water supply in warmer climates, may influence the results of the trials [26]. Thus sensitization by environmental mycobacteria could reverse the immunological benefits conferred by BCG vaccination. Conversely, sensitization by environmental mycobacteria might immunize in the same way as BCG [27], effectively equilibrating responses in control and trial groups.

An alternative hypothesis to account for the variations in trial results is based on recent genomic analysis of BCG strains. Using the genome of the sequenced H37Rv strain of *M. tuberculosis* as a template, it has been possible to identify genetic regions that are missing from various substrains of the original BCG vaccine [5,28]. In addition to regions absent from all *M. bovis* isolates, five regions encompassing 38 open reading frames were found to have been deleted from some or all BCG substrains. By a process of forensic genomics, a chronology for the occurrence of the deletions leading from *M. tuberculosis* to BCG could be drawn up [5]. It is also the case that some genes, contained in regions designated RvD1 and RvD2, are absent from H37Rv but found in *M. bovis* and BCG [29]. Further, in BCG Pasteur, there are two tandemly duplicated regions, DU1 and DU2 [30]. The potential contribution of these genetic differences between BCG and *M. tuberculosis* to the virulence of the latter is not yet clear. However, it is possible that the sequential loss of genes during subculture of BCG substrains has been accompanied by a parallel decline in their protective ability. Calmette [31] was always of the impression that isolates of BCG, which caused regional lymphadenopathy and extensive scar formation, were better vaccines.

Experience with BCG thus holds a number of important lessons for any future TB vaccine program. Firstly, BCG does demonstrate that it is indeed possible to use a vaccine to confer protection against TB. A caveat, however, is that an immunization protocol capable of inducing protection in one population group, whether defined by age or geography, may be ineffective in a different population. A central lesson from the BCG story has been the limitations in understanding protective immunity against tuberculosis. The effect of vaccination has been evaluated solely on the basis of long-term follow-up and monitoring of disease incidence. Unless some short-term measure of potential protective efficacy in humans can be established, future tuberculosis vaccines may follow BCG into decades of controversy and uncertainty.

### III. IMMUNOLOGICAL MECHANISMS AND CORRELATES OF PROTECTION

Tuberculosis is a chronic disease, often difficult to diagnose, which can have a long incubation period of years or decades. Experimental infection of humans, an ethical option when studying some readily curable infectious diseases [32], is difficult to envisage in tuberculosis given that the therapy even of fully drug-sensitive asymptomatic infection involves months of treatment. Thus vaccine trials would benefit enormously if reliable correlates of protective immunity could be established.

#### A. Experimental Models

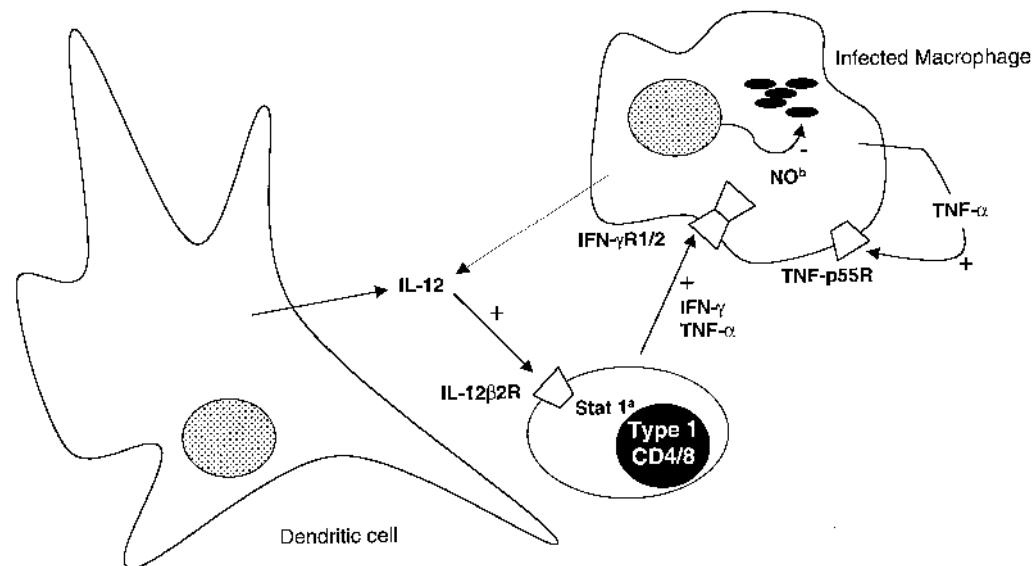

##### 1. Effector Function

In the last decade, experiments in gene knockout mice have delineated some of the crucial host regulatory and effector pathways necessary to contain tuberculosis in this animal. Broadly speaking, two effector pathways necessary to control the replication of *M. tuberculosis* have emerged. Activation of infected mononuclear phagocytes to kill resident intracellular bacilli is the predominant pathway. The second pathway involves the lysis of infected phagocytes, thus facilitating uptake of bacilli by competent phagocytes or the induction of apoptosis of infected phagocytes with concomitant destruction of the bacteria.

The monokine tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is essential for bactericidal granuloma formation [33]. Mice with a disruption of the gene encoding the p55 TNF- $\alpha$  receptor (TNFR1) rapidly develop disseminated infection as do mice which overexpress the soluble TNFR1 [34,35]. Deletion of the gene for interferon- $\gamma$  (IFN- $\gamma$ ) markedly increases susceptibility to tuberculosis via a mechanism involving inducible nitric oxide (NO) [36–38]. Production of IFN- $\gamma$  is, in turn, dependent on the production of interleukin (IL)-12. Deletion of the gene encoding secreted IL-12p40 results in mice that are unable to control mycobacterial growth [39] (Figure 1).

##### 2. T Cell Subsets

T cell responses are accepted to be quantitatively most relevant to protection against mycobacterial infection as the antibody response, with a few interesting exceptions [40,41], is thought to be ineffective. The regulatory T cell subsets required to control murine tuberculosis have been extensively researched. There is an obligate requirement for the CD4 $^{+}$  subset of T cells [42]. In mice, there is also evidence that the phenotypic separation of CD4 $^{+}$  T cells into IFN- $\gamma$  secreting type 1 and IL-4 (IL-10 and IL-13) secreting type 2 cells is of relevance. It is widely assumed that type 2 cells, which downregulate the type 1 response and favor IgG1 and IgE production, are nonprotective. However, mice that are unable to make either IL-4 or IL-10 are no more resistant to tuberculosis [43]. Thus type 1 responses are necessary for protection, but the absence of type 2 responses does not improve resistance. The CD4 $^{+}$  response is thought to be mediated largely by antigen presentation via MHC Class II

**Figure 1** Key protective pathways in murine and human tuberculosis. (a) Only of proven significance in human. (b) Only of proven significance in mice.

molecules, as MHC Class II  $\beta$  chain knockout mice are unable to control growth even of the attenuated BCG vaccine strain [44].

There also appears to be a role for MHC Class I restricted T cells, as mice lacking  $\beta_2$  microglobulin (a component of the MHC Class I molecule) are highly susceptible to intravenous *M. tuberculosis* infection [45]. However, the precise phenotype of MHC Class I restricted T cells involved is more debatable as the degree of susceptibility of the  $\beta_2$  microglobulin knockout animals is not reproduced in mice lacking the gene for CD8 [42] or in those which lack CD1d (which also requires  $\beta_2$  microglobulin to present antigen to CD8 $^+$  T cells) [46]. Mice which lack either perforin, an effector of the granule exocytosis pathway, or CD95 (Fas) ligand, an effector of apoptosis, are also able to control initial infection [47,48]. Some effect of deletion of the genes for CD8, perforin, and CD95L is observed, however, as the infection progresses [42,49]. The inability to attribute a special effector role unique to CD8 $^+$  cells has led some to suggest that CD8 $^+$  T cells contribute to IFN- $\gamma$  production [50,51]. Alternatively, antigen may be available for recognition by Class I restricted cells earlier in infection [52] or on cells which only express the more widely distributed MHC Class I molecule.

## B. Humans

Epidemiological surveys suggest that *M. tuberculosis* latently infects 32% of the world's population, and it is estimated that 7.96 million new cases of active disease occurred in 1997 [21]. From these figures, it can be inferred that around 90% of latently infected people will remain free of disease for life. Thus the immune mechanisms that control *M. tuberculosis* are, in most humans, efficient. In the minority who do

develop disease, however, there is a pronounced role for the immune response in contributing to pathology. It thus follows that the immune response in persons who develop tuberculosis must be qualitatively or quantitatively different from those who remain infected but healthy. Dissecting this paradox between pathology and protection has been at the center of human tuberculosis research.

### 1. Effector Function

When defining the protective response in man, the most informative analyses have been of very small numbers of patients with severe recurrent atypical mycobacterial or *Salmonella* infections. Such individuals have been shown to have mutations in the IL-12- and IFN- $\gamma$ -driven type 1 cytokine pathway (Table 1). Thus in a way that is analogous to the situation in mice with selective gene deletions, there appears to be an obligate requirement for the type 1 pathway in human antimycobacterial defense (Figure 1).

The evidence for a direct role for reactive nitrogen intermediates (RNI) in human defense is less compelling than in the mouse. Induction of the iNOS (*NOSI*) gene has been documented in cells from the lungs of human tuberculosis patients [55], as has the accumulation of nitrite in *M. tuberculosis*-stimulated cultures of alveolar macrophages [56]. However, in the latter study, NO synthase inhibitors inhibited the production of RNI by alveolar macrophages but did not significantly affect the intracellular growth of *M. tuberculosis*. Recently, the 19-kDa antigen-mediated suppression of intracellular *M. tuberculosis* in human cells was shown to be RNI-independent, whereas in mice, clear evidence that this effect was RNI-dependent was shown [57].

Recently, the first convincing evidence for the role of TNF- $\alpha$  in containing latent infection in humans has also been provided by informal reporting of side effects of

**Table 1** Novel Genetic Immunodeficiency Syndromes which Predispose to Mycobacterial Infection

Molecule	Phenotype	Mutation	Reference
IFN- $\gamma$ receptor I	Severe atypical mycobacterial infection	Point mutation at nucleotide 395 that introduces a stop codon	16
IFN- $\gamma$ receptor II	<i>Mycobacterium fortuitum</i> and <i>M. avium</i> infection	Homozygous dinucleotide deletion at nucleotides 278 and 279, resulting in a premature stop codon	53
IL-12p40	BCG and <i>S. enteritidis</i> infection	Large homozygous deletion	54
IL-12 $\beta$ 1 receptor subunit	Severe mycobacterial and salmonella infections	A variety of missense and deletion mutations	15, 54
Stat 1	Disseminated BCG or <i>M. avium</i> infection	Point mutation at nucleotide position 2116	13

infliximab [58]. Infliximab is a humanized antibody against TNF- $\alpha$  that is used in the treatment of Crohn's disease and rheumatoid arthritis. Out of 147,000 patients treated with infliximab, 70 developed tuberculosis within a median of 12 weeks, some after as few as 3 or 4 infusions. Whether this is a true increase over background incidence can be argued, but the trials of infliximab were carried out in countries with a low incidence of tuberculosis, in the order of 10/100,000. The disease pattern was predominantly (57%) postprimary and extrapulmonary, strongly suggesting that TNF- $\alpha$  prevents endogenous reactivation. These data therefore powerfully support a role for TNF- $\alpha$  in containing latent infection.

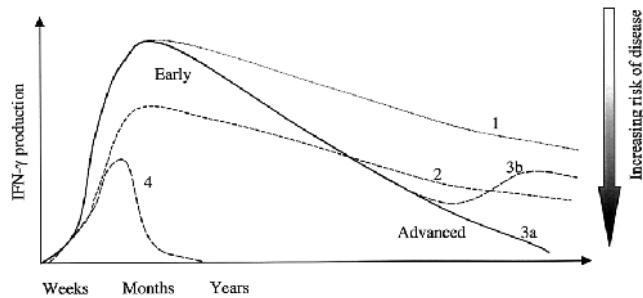

Are humans and mice therefore similar with important roles in the protective response for IFN- $\gamma$ , IL-12, and TNF- $\alpha$  (Figure 1)? Do measurements of the in vitro cytokine response of stimulated cells from larger numbers of patients with tuberculosis and healthy *M. tuberculosis*-infected subjects support this conclusion? Before reviewing such studies, it is important to point out that they rely predominantly on sampling of responses of peripheral blood mononuclear cells (PBMC), and that these may not always accurately reflect events at the site of infection. Lymphocyte IL-2 production is increased in both tuberculous pleural fluid and bronchoalveolar lavage of patients with pulmonary tuberculosis by comparison with PBMC, for example [59,60], and IFN- $\gamma$  mRNA is increased about 60-fold in pleural fluid mononuclear cells of patients with tuberculous pleuritis over that in their PBMC [61]. Sequestration and local activation of lymphocyte replication may contribute to the lower level of IL-2 in *M. tuberculosis* antigen-stimulated PBMC from patients by comparison with control subjects [62–64].

**Responses Favoring Macrophage Activation.** *IFN- $\gamma$* . It seems logical that a deficit of IFN- $\gamma$  production by PBMC may characterize patients with pulmonary tuberculosis, and some reports do indeed document a reduction in IFN- $\gamma$  production in patients when stimulating with PPD or a 30-kDa antigen [65], *M. tuberculosis* [64], or the recombinant 10-, 38-, or 65-kDa antigens [66]. This is not always been observed, however. No reduction in the frequency of IFN- $\gamma$  secreting cells in the blood of patients by comparison with healthy BCG-vaccinated controls was detected when PBMC were stimulated with *M. tuberculosis* soluble extract or the recombinant 19- and 38-kDa antigens [67]. It has more

recently been shown that the frequency of IFN- $\gamma$  secreting cells responding to the antigen early-secreted antigenic target-6 (ESAT-6) is high in untreated patients with tuberculosis and that this frequency tends to fall after effective antituberculous chemotherapy [68]. These apparent discrepancies may be due to the selection of control subjects, the extent of disease of the patients, the choice of antigen, and the potentially confounding effects of chemotherapy.

In an attempt to resolve some of these points, a recent large study placed greater emphasis on the definition of groups with various *M. tuberculosis* sensitization within households of tuberculosis cases and, in particular, on the responses of children with primary infection. In response to culture filtrate antigens of *M. tuberculosis*, IFN- $\gamma$  production was found to be highest in skin test positive children with primary disease and in adults with latent infection [69]. The lowest response was in cases of far-advanced disease. Thus while bulk IFN- $\gamma$  secretion in response to culture filtrate did not discriminate *M. tuberculosis*-infected healthy subjects from those with early disease, progression to advanced disease was associated with a decreased IFN- $\gamma$  response (Figure 2). Therefore differences in the cellular phenotype (e.g., memory vs. short-lived effector cells), antigenic specificity, or rate of loss of IFN- $\gamma$  producing T cells between those who remain healthy and those who progress may be crucial. The dynamics of IFN- $\gamma$  producing cells during infection are also almost certainly more complex than originally suspected.

**IL-12.** Interleukin-12 is a monocyte/macrophage-derived cytokine which favors the differentiation of IFN- $\gamma$  producing T cells [70]. Its active form is a p70 heterodimer formed from inducible p40 and constitutively expressed p35 chains. The p40 chain can also associate with a p19 chain to form IL-23 whose biological spectrum of activity appears similar to IL-12p70 [71]. Interleukin-12 would be expected to favor a protective role in tuberculosis. In humans, small amounts of IL-12 have been demonstrated in tuberculous pleural effusions [72], and an increased frequency of IL-12 producing cells has been demonstrated in patients with tuberculosis [73]. Interleukin-12 production is best stimulated by phagocytosis of intact *M. tuberculosis* organisms [74], but it has also been shown that ligation of the surface-expressed TLR2 toll-like receptor by lipoproteins of *M. tuberculosis* added to cultures of mononuclear phagocytes

**Figure 2** Possible dynamics of CD4 mediated IFN- $\gamma$  production at various stages in the natural history of tuberculosis infection. The curves are idealized representations of induced IFN- $\gamma$  production in various groups over time based on data that are largely cross-sectional in nature. Curve 1 represents natural infection accompanied by lifelong freedom from disease. Curve 2 represents BCG vaccination. This intervention may prime sufficient response to decrease the risk of severe or advanced disease in children, but, over time, its efficacy is known to wane. Curve 3 is the disease curve. Curve 3b shows the effect of chemotherapy, which tends to increase the IFN- $\gamma$  response, although some differences from healthy controls persist even after successful chemotherapy. Curve 4 represents tuberculosis infection in patients already infected by HIV. This is a pernicious combination and the risk of disease is very high.

can induce IL-12p40 [75]. The most potent IL-12p40 inducing lipoprotein, the 19-kDa antigen, has also been shown to trigger the death of intracellular mycobacteria in human cells by a mechanism that is RNI-independent [57]. These findings are, in turn, not easy to reconcile with the observation that expression of the 19-kDa gene in *Mycobacterium smegmatis* inhibits IL-12p40 induction by the recombinant bacteria [76]. In addition, the 19-kDa antigen has recently been reported to deactivate the antigen-presenting function of murine cells by decreasing the expression of MHC Class II by a TLR2-dependent mechanism [77].

Despite these paradoxes, a significant area of consensus in studies on the 19-kDa lipoprotein is that its immunomodulatory activity requires it to be acylated, as recombinant nonacylated 19 kDa does not show these effects. Acylation affects the intracellular trafficking of the 19 kDa directing it to the MHC Class I pathway [78], and it is possible that such differential trafficking may account for some of the diverse effects seen in various systems. One approach to untangling this complex interaction would be the generation of recombinant *M. tuberculosis* that does not express the 19 kDa. In conjunction with complementation of such a recombinant with wild-type and site-directed mutagenized forms of the 19-kDa gene lacking acylation or glycosylation motifs, such an approach would allow dissection of this interaction in the context of the immune response to the whole bacillus.

**Interferon- $\gamma$  Inducing Factor.** Interferon- $\gamma$  inducing factor, or IL-18, is synergistic with IL-12 in IFN- $\gamma$  induction in mice and humans [79,80]. Deletion of the IL-18 gene decreases the granulomatous response to *M. tuberculosis* but has no effect on the survival of mice or the replication of

mycobacteria [81]. The available evidence in humans suggests that IL-18 does have a role in promoting type 1 activation, but that its constitutive production is increased by IFN- $\gamma$  in a positive feedback loop in turn dependent on intact IL-12 function [82–84].

**TNF- $\alpha$ .** Tumor necrosis factor- $\alpha$  is produced by monocytes in response to intact *M. tuberculosis* and to both protein and nonprotein antigens [61,63,85–87]. The observation that orderly (as opposed to necrotic) granuloma formation is accompanied by the highest expression of mRNA for TNF- $\alpha$  supports a protective role [88], as do the findings relating to this cytokine's neutralization in vivo by infliximab [58]. However, TNF- $\alpha$  is also associated with the fever and weight loss characteristic of tuberculosis, leading to the suggestion that this cytokine may be associated with pathology [89–91]. Serum TNF- $\alpha$  levels transiently rise at the onset of antituberculous chemotherapy, and this rise is accompanied by a fall in Karnofsky score [92]. The production of TNF- $\alpha$  is downregulated by both IL-10 and transforming growth factor- $\beta$  (TGF- $\beta$ ) [93] and can also be specifically downregulated by the drug thalidomide, which has been proposed as an immunomodulatory therapy [90].

**Responses Favoring Macrophage Deactivation.** Given that evidence is accruing that a type 1 cytokine response is protective, is there evidence that a type 2 response is deleterious?

**IL-4.** A marked antibody response associated with depression of antigen-specific lymphocyte proliferation occurs in active tuberculosis [94,95]. Interleukin-4 promotes antibody production and antagonizes the effects of IFN- $\gamma$ . Antigen-specific (as opposed to mitogen-induced) IL-4 secretion in tuberculosis has only been demonstrated in T cell clones [96] and in stimulated PBMC by the highly sensitive enzyme-linked immunospot (ELISPOT) assay [67]. In the latter study, the frequency of IL-4 producing cells was increased in tuberculosis patients by comparison with control subjects, although the number of IL-4 secreting cells was very small. It has been demonstrated that very small amounts of IL-4 can markedly bias innate responses to *M. tuberculosis* [97]. However, IL-4 is generally undetectable by conventional ELISA [65,66,98,99] in tuberculosis, which is in marked contrast to other conditions where there is established and significant type 2 activation such as atopic asthma or helminth infection. Using a highly sensitive nested RT-PCR, both IL-4 message and its splice variant IL-4 $\delta$  were detected in PBMC from tuberculosis patients [100]. However, others have found no IL-4 or IL-5 gene expression in bronchoalveolar lavage cells, pleural fluid, or lymph nodes from patients with tuberculosis [59,61,98].

**Transforming Growth Factor- $\beta$  (TGF- $\beta$ ).** Transforming growth factor- $\beta$  mediates a predominantly immunosuppressive and macrophage deactivating response during tuberculosis. Transforming growth factor- $\beta$  downmodulates both T cell responses [101] and macrophage activation [102]; neutralization of TGF- $\beta$  enhances T cell responses to mycobacterial antigens [65]. Macrophages in tuberculous granulomas and monocytes from tuberculous patients (but not healthy subjects) express TGF- $\beta$ 1 [103]. Furthermore, some mycobacterial proteins and lipoarabinomannan induce TGF- $\beta$

secretion by monocytes [87]. Transforming growth factor- $\beta$  also induces IL-1Ra [104] and IL-10 [105]. Naturally occurring inhibitors of TGF- $\beta$ , decorin and latency associated peptide (LAP), reverse depressed T cell functions in peripheral blood mononuclear cells (PBMC) from patients with pulmonary tuberculosis [106]. Recently, an enhanced murine antimycobacterial response to a recombinant BCG expressing LAP has also been reported [107].

*IL-10.* The suppression of proliferation and assistance for antibody production may also be partly accounted for by IL-10, which deactivates macrophages and downregulates type 1 cytokine responses. Expression of MHC Class II molecules on antigen-presenting cells is also suppressed by IL-10 [108,109]. Anti-IL-10 neutralizing antibody is effective in reversing depressed cell proliferation in HIV-infected patients with tuberculosis [110]. In addition, IL-10 downregulates *M. tuberculosis*-induced type 1 responses and CTLA-4 expression [111]. Interleukin-10 is released spontaneously by PBMC from tuberculosis patients (perhaps reflecting macrophage activation), and additional increments due to PPD stimulation are only consistently demonstrable in untreated patients [99]. The above evidence suggests that IL-10 has an important downregulatory role. However, IL-10 did not enhance the growth of *Mycobacterium avium* in human macrophages [112]. Furthermore, levels of IL-10 in supernatants of PBMC stimulated by 30-kDa antigen or PPD were not increased in patients by comparison with controls [65].

Overall, the most available evidence suggests that the classical Th1/Th2 dichotomy as defined by terminally differentiated murine T cell clones [113] is not clearly observed in human tuberculosis. The overwhelming majority of responding T cells are of the type 1 or type 0 and not type 2 phenotype. The suppression of the type 1 response that does occur may be more readily attributable to the overproduction of downregulatory cytokines by monocytes and macrophages.

## 2. T Cell Subsets

The protective function of CD4 $^{+}$  cells in containing latent infection can be indirectly inferred from the high risk of tuberculosis conferred by HIV infection. This risk, although increased at all stages of HIV infection, is highest in persons with the lowest CD4 $^{+}$  counts. It is also worth pointing out, however, that cavitating pulmonary tuberculosis is a less common disease form in advanced HIV infection, implying that a competent CD4 $^{+}$  T cell response is also necessary for the characteristic clinical syndrome to develop. Thus CD4 $^{+}$  T cell responses contribute to pathogenesis as well as to protection.

Numerous studies have identified multiple antigenic targets that induce the proliferation of, and IFN- $\gamma$  production from, CD4 $^{+}$  cells. There is hierarchy in the stimulatory capacity of individual antigens: particularly potent molecules are found among the secreted antigens, with the Antigen 85 complex and ESAT-6 being prominent [95,114]. In addition, certain "somatic" antigens are also highly immunogenic, particularly the heat-shock proteins [115]. At the level of individual peptide epitopes, some

peptides are able to restimulate cells from a high proportion of individuals with varying HLA Class II types. Such "permissive" peptide recognition has been shown in the better-characterized cases to be due to the ability of peptide to bind with high affinity to multiple HLA-DR molecules [94,116]. Interestingly, in another instance, this ability appears to be conferred by peptide presentation in the context of the less polymorphic HLA-DQ molecule [117].

Because of the findings in the murine system, there has also been attention to the possibility that CD8 $^{+}$  T cells may contribute to human defense. Such T cells may contribute because of their unique effector function, timing, or ability to recognize infected cells which are not "seen" by the CD4 $^{+}$  subset. Initial studies confirmed that, in addition to conventional responses restricted by MHC Class I molecules, CD1-restricted and MHC-unrestricted CD8 $^{+}$  responses can be detected [118–121]. Subsequent studies have defined a number of T cell epitopes [122–125]. A general conclusion from these studies is that the frequency of CD8 $^{+}$  cells is low, much lower than the frequency of CD4 $^{+}$  cells. Most studies have used IFN- $\gamma$  production as a measure of the CD8 $^{+}$  cell response. However, in one case, tetramer analysis did reveal a slightly higher frequency of peptide-specific cells and potentially interesting evidence of functional heterogeneity in the CD8 $^{+}$  population [122].

Whether CD8 $^{+}$  cells contribute in a unique way to human defense remains conjectural. An important aspect of the early interaction between infected mononuclear phagocytes and *M. tuberculosis* is that the bacillus manipulates the phagosome that it resides in, preventing the normal maturation of this organelle into an acidic, hydrolytic compartment [126]. In this way, degradation and presentation of peptides via MHC Class II may be crucially delayed allowing the bacillus a "window" to establish intracellular replication before the immune onslaught. The ability of CD8 $^{+}$  cells to recognize infected targets by way of alternative antigen-presenting pathways may provide an important adjunct to the MHC Class II-restricted response. It has been postulated that antigens can traffic out of the phagosome into the cytoplasm [127] and are thus potentially available for presentation via MHC Class I, and intracellular trafficking of glycolipid antigens makes them available for presentation by CD1 molecules [128].

Alternatively CD8 $^{+}$  cells may have some unique effector function. A great deal of interest has been stimulated by the derivation from infected healthy donors of CD1-restricted CD8 $^{+}$  and CD4 $^{-}$ CD8 $^{-}$  double-negative human T cell clones. These clones recognize a variety of hydrophobic mycobacterial lipids in the context of CD1, a relatively nonpolymorphic MHC Class I molecule [129]. Additional evidence of functional dichotomy was presented by the finding that CD8 $^{+}$  clones lysed infected cells via the granule exocytosis pathway and thereby reduced the growth of bacteria. By contrast, the CD4 $^{-}$ CD8 $^{-}$  double negative clones triggered lysis via the ligation of Fas by Fas ligand, but this did not reduce mycobacterial viability [118]. The antimicrobial, and thus unique effector, function of the CD8 $^{+}$  cells was ascribed to granzylisin, a mediator of the granule exocytosis pathway [130]. However, it has subsequently been shown that granzylisin is also associated with CD4 $^{+}$

cells in leprosy lesions [131] and is produced by *M. tuberculosis*-specific MHC Class II restricted CD4<sup>+</sup> T cells [132]. In addition, the latter study showed the CD8<sup>+</sup>-mediated growth restriction of *M. tuberculosis* within infected cells to be uninfluenced by inhibitors of the granule-exocytosis pathway. As CD1-restricted T cells remain to be demonstrated at appreciable frequencies in the peripheral blood of infected subjects, their quantitative significance and unique function therefore remain open to question. The recent successful assembly of human CD1d-glycolipid tetramers should allow this question to be answered definitively [133].

There has also been considerable work on the human γδ TCR T cell response. These cells are known to expand in response to both proteins and nonpeptide ligands of mycobacterial origin [134,135]. γδ cells can be cytolytic and produce IFN-γ and accumulate at disease sites [136,137]. A possibility is that γδ cells play a part in early infection [138].

#### IV. POTENTIAL APPLICATION OF NOVEL TUBERCULOSIS VACCINES

##### A. Replace Neonatal Bacille Calmette–Guérin

The ideal vaccine would be of greater overall efficacy than BCG such that the latter would be replaced. The vaccine should be administered as a single dose at birth and go on to confer lifelong protection against disease. This is an ambitious goal as no single candidate in animal models has yet to clearly surpass the efficacy of BCG, although some combinations are promising. Perhaps it is not realistic to conceive a single “magic bullet,” but rather to consider whether a new vaccine could be given in addition to BCG in order to augment the latter’s partial efficacy.

##### B. Boost Preexisting Immunity in Late Adolescence

The peak incidence of tuberculosis is in young adults, in the 20–30 year age group, with pulmonary disease as the most common presentation. Adult tuberculosis usually results from the reactivation of latent tuberculosis infection (LTBI), although in some circumstances, reinfection contributes [139,140]. Therefore when BCG fails to prevent adult tuberculosis, this could be due to failure to control LTBI or to a gradual decline in the BCG-induced resistance to repeated reinfection episodes. To prevent reinfection, it would be necessary for a new vaccine to be superior to BCG in its ability to protect against initial challenge. The T cell response required to maintain latency in humans is very poorly characterized, and the requirements for a vaccine that would improve the immune control of LTBI are largely unknown. To address this area, there is a need for longitudinal study of healthy *M. tuberculosis*-infected subjects in addition to current patient-centered investigations. One major problem in this respect has been the accurate identification of individuals who are actually infected, as the PPD skin test has important limitations in specificity. Blood-based assays, which rely on antigens of greater species specificity, may offer a route around this problem [116,141]. If the responses maintaining LTBI can be better defined, a boost strategy

could be targeted towards adolescents who would have received neonatal BCG vaccination and subsequently exposed to challenge with *M. tuberculosis*. The available data suggest that revaccination with BCG at this age confers no additional protection [25] and, in contrast to neonatal vaccination, there are no ethical questions related to withholding BCG as part of a vaccine trial. Given the high incidence of disease in early adulthood, this might therefore offer the best opportunity for early vaccination trials in humans.

##### C. Disease-Modifying or Transmission-Blocking Vaccines

The fact that BCG reduces the incidence of miliary and meningeal disease in infants suggests that vaccines may also impact disease severity. If host and bacillary determinants of disease severity (as opposed to correlates of protection) could be ascertained, it might be a basis for designing a third type of vaccine that would lessen clinical symptoms without completely preventing disease. It may be possible to impact transmission of tuberculosis if the immune intervention reduced the number of sputum smear positive patients, for example. The most transmissible form of tuberculosis, cavitating pulmonary disease, is associated with most extensive tissue damage, suggesting that the induction of immunopathology by *M. tuberculosis* may be subject to positive evolutionary selection [142]. The underlying immunopathological mechanisms are poorly understood, but it is conceivable that immune modulation of this event could contribute to decreased transmission. Such a vaccine may be useful for disease control within populations, but might present difficulties in relation to diagnosis of individual patients since the diagnosis of tuberculosis usually relies mainly on detection of bacilli in the sputum.

##### D. Immunotherapeutic Vaccines

Early studies of the chemotherapeutic action of antituberculous drugs established that, while initial bacillary counts fall precipitously, treatment of less than 6 months duration is associated with an unacceptably high relapse rate. This phenomenon is attributed to “persisting” organisms, which, by virtue of not dividing, are insensitive to drug action. In humans with active tuberculosis, quantitative and qualitative changes in the immune response occur during treatment, encouraging the view that immunomodulation should be possible [99]. Such modulation would undoubtedly be beneficial if the duration of treatment could be shortened and also of potential impact when there is drug resistance. There is experimental evidence of therapeutic vaccine efficacy in mice [12]. In leprosy, addition of immunotherapy with *Mycobacterium w* vaccine to multidrug therapy benefits multibacillary leprosy patients by increasing the rate of bacillary clearance [143]. However, this is at the cost of an increased risk of upgrading reactions. In leprosy, these immunopathological reactions are of considerable clinical significance. Less well recognized, but known since the adverse experience of Robert Koch with tuberculin, is the upgrading reaction which can occur in tuberculosis [144].

The risk of inducing immunopathology therefore has to be carefully weighed against likely therapeutic advantage. More knowledge of the correlates of pathology, as distinct from protection, in human tuberculosis is also required.

## V. THE FRAMEWORK FOR VACCINE EVALUATION AND DEVELOPMENT

Vaccines are, in general, produced and marketed by large pharmaceutical companies. There are anxieties within the private sector regarding the likely financial yield of developing a new tuberculosis vaccine since such a product would be predominantly used in resource-poor environments. While the massive health benefits that would accrue from a successful vaccine do not preclude justifying a relatively high unit vaccine cost, at present, tuberculosis vaccine development is not a major priority for big pharmaceutical companies. There is commendable work from smaller biotech companies [145–147], but it is likely that the major impetus for vaccine development will have to come from the public sector.

Development of new vaccines will require effort not only from research scientists, but also from epidemiologists and clinicians. Considerable momentum towards developing and testing novel vaccines in humans has built up in the last few years. Following wide consultation which included the WHO, the International Union Against Tuberculosis and Lung Disease (IUALTD), and the Food and Drugs Administration, the NIH has issued a “blueprint” for tuberculosis vaccine development [148]. A specific commitment to evaluation of novel vaccines in aerosol-infected mice and guinea pigs was made and over a hundred candidates and combinations have been tested [149]. The European Community has also recognized the need for a wide-ranging approach to preclinical research with the establishment of a TB Vaccine Cluster [150] which includes a primate model for testing of novel vaccines [151]. Human tuberculosis vaccine research units have also been created which will facilitate the Phase I/II clinical testing of promising candidates. Identification of appropriate high-incidence areas for future efficacy trials and establishment of suitable long-term clinical and epidemiological support for such ventures are a priority. Importantly, ethical approval for studies should be obtained both in the country in which the trial will take place (likely resource-poor) and also from the country in which the vaccine originated (likely resource-rich). It is important to appreciate that, even in high-incidence areas, Phase III trials will need to include many tens of thousands of participants and, because the efficacy of BCG is known to vary by geographical region, parallel trials may need to be established in different parts of the world. The need for longstanding international collaboration and expense is therefore clear.

## VI. VACCINE CANDIDATES

It has already been noted that many new candidate vaccines have already been produced. This section cannot therefore be comprehensive: we have used candidates to illustrate principles (Table 2). There is no clear rationale at this stage

**Table 2** Novel Vaccine Candidates with Protective Efficacy in Small Animal Models

Vaccine	Model	Reference
Live vaccines		
BCG overexpressing Ag85B	Guinea pig	9
<i>M. tuberculosis</i> leuD auxotroph	Mouse	156
<i>M. tuberculosis</i> trpD auxotroph	Mouse	157
Protein subunit vaccines		
<i>M. tuberculosis</i> culture filtrate	Mouse	163, 165
<i>M. tuberculosis</i> culture filtrate	Guinea pig	185
Ag85B (Rv1886c)	Mouse	186
Guinea pig	164	
ESAT-6 (Rv3875)	Mouse	186
Ag85B/ESAT-6 fusion	Mouse	171
38-kDa antigen (PstS1; Rv0934)	Mouse	187
Mtb8.4 (Rv1174c)	Mouse	146
DNA vaccines		
Ag85A (Rv3804c)	Mouse	11
Guinea pig	188	
Ag85B (Rv1886c) <sup>a</sup>	Mouse	179
<i>M. leprae</i> Hsp60 <sup>b</sup>	Mouse	10
ESAT-6 (Rv3875)	Mouse	179
38-kDa antigen (PstS1; Rv0934) <sup>c</sup>	Mouse	175
PstS3 (Rv0928)	Mouse	189
MPT64 (Rv1980c)	Mouse	179
Mtb39A (Rv1196)	Mouse	145
MPT63 (Rv1926c)	Mouse	190
MPT83 (Rv2873)	Mouse	190
MTB41 (Rv0915c)	Mouse	191
Mtb8.4 (Rv1174c)	Mouse	146
Combination vaccines		
MPT63/ESAT-6 DNA + vaccinia boost	Mouse	182
Ag85A DNA + protein boost	Mouse	178
Ag85B DNA + BCG boost	Mouse	184

<sup>a</sup> Other investigators found Ag85B to be ineffective as a DNA vaccine [11,178].

<sup>b</sup> DNA vaccination with the corresponding *M. tuberculosis* gene (Rv0440) induced immunopathology [180].

<sup>c</sup> Other investigators found no protection with PstS1 DNA [189].

for the design of the optimal tuberculosis vaccine. Bacille Calmette–Guérin provides a precedent to indicate that vaccination with a live mycobacterium can confer protection, but considerations related to safety, manufacture, and distribution favor a nonliving subunit formulation. This approach requires identification of relevant antigens and

selection of appropriate delivery systems. It is not clear whether priority should be given to formulations designed to induce a prolonged memory response per se or whether the aim should be to set up a strong initial response that would be boosted by natural exposure to infection and environmental organisms.

### A. Live Vaccines

Experience with BCG provides a precedent for tuberculosis vaccines based on live attenuated mycobacteria, and the improvement of the existing BCG vaccine represents one general approach to the generation of new vaccine candidates. New tools for genetic manipulation of mycobacteria provide an opportunity to refine the live vaccine strategy of Calmette and Guérin by addition of genes to BCG or by targeted removal of genes from initially virulent *M. tuberculosis* [152].

#### 1. Modified Strains of Bacille Calmette–Guérin

Bacille Calmette–Guérin has been engineered to express recombinant mammalian cytokines designed to augment immunogenicity or decrease immunopathology, for example [107,153]. The addition of the listeriolysin gene has been shown to enhance the ability of BCG antigens to traffic into the cytoplasm and thereby to induce a CD8<sup>+</sup> T cell response [154]. Particularly promising results have been generated by the overexpression of antigen 85B carried on a multicopy episomal plasmid in recombinant BCG [9]. However, the in vivo stability of such plasmid-bearing strains was not assessed: for bacteria, the possession of plasmid often reduces fitness, especially under immune pressure.

One possible reason for the incomplete efficacy of BCG is that it lacks “protective” antigens present in *M. tuberculosis*. Comparison of the genomes of *M. tuberculosis* and BCG identified a 9.5-kb region, designated RD1, that has been deleted from all strains of BCG [5,28]. RD1 encodes two antigens (ESAT-6 and CFP-10) that are highly immunogenic and prominent immune targets in *M. tuberculosis*-infected humans [141,155]. Further, there is some evidence that ESAT-6-specific CD8<sup>+</sup> T cells may contribute to the immune maintenance of latency in humans [119,124]. Selective reintroduction of the genes for ESAT-6 and CFP-10 into BCG is an attractive concept. In pursuing this as a vaccine strategy, it would be important to ensure that adding back RD1 products does not increase virulence. A second caveat is that the specific diagnostic advantage conferred by the use of these antigens would be lost.

#### 2. Attenuation of *M. tuberculosis*

Several laboratories have generated novel attenuated strains by deletion of genes from *M. tuberculosis*. Three strategies have been pursued. The first involves the introduction of auxotrophic mutations that render the bacteria dependent on exogenous growth factors that are in limited supply. Successful examples include the derivation of attenuated strains dependent on leucine [156] and tryptophan [157]. A second approach is to inactivate *M. tuberculosis* genes analogous to those involved in virulence in other bacterial

pathogens. An interesting recent example is the construction of a *phoP* attenuated mutant, based on the knowledge of the key role of this regulator in pathogenic *Salmonella* [158]. The third strategy for identification of attenuated strains exploits the technique of signature-tagged transposon mutagenesis (STM). This involves screening of a library of transposon mutants to identify clones selectively lost during murine infection. The STM approach has identified attenuated mutants with defects in biosynthesis of cell-wall lipids [159,160]. Decreased persistence within tissues and altered patterns of tissue dissemination has been described for several attenuated variants of *M. tuberculosis* or *Mycobacterium marinum* [6–8,161], further indicating that the technology of mycobacterial attenuation is now well established.

Whether any of these mutants could function as vaccine candidates still requires empirical analysis. Aside from the overriding need for safety, the properties required for an improved live vaccine strain are unknown; interactions with antigen-presenting cells, the precise mode of death, and duration of persistence within the host are all likely to influence vaccine efficacy. Information from the current round of trial and error screening of novel attenuated strains, together with progress in understanding of the cellular microbiology of mycobacterial infection, may ultimately allow the design of rational selection procedures for improved live vaccines.

### B. Protein Subunit Vaccines

Two criteria have been used to identify *M. tuberculosis* antigens for incorporation into programs for subunit vaccine development. The first is the ability to elicit a strong recall response in man or experimental animals exposed to *M. tuberculosis* infection. The response is assessed primarily in terms of the release of IFN-γ from antigen-specific CD4<sup>+</sup> T cells. While this represents a realistic strategy to identify antigens available for T cell recognition, it will (like BCG) tend to reproduce rather than augment the natural immune response. Amplification of naturally subdominant responses represents a potentially interesting alternative approach [162], particularly in the context of postexposure vaccination.

A second common criterion for antigen selection is their identification in the supernatant of in vitro cultures. The presence of proteins secreted by actively dividing bacilli may be one factor in determining the superior protective efficacy of live as compared to killed mycobacteria. This idea is supported by experiments from several laboratories demonstrating successful vaccination with culture filtrate preparations [163–165]. However, live mycobacteria also require immunogenic proteins that are not secreted such as the small heat-shock protein Acr or 16-kDa antigen [166]. Given this protein’s putative role in stabilizing cellular structures during conditions of stress such as those found in the “immune” granuloma, it may be an important target of T cells maintaining immunity during persistent infection [94].

Several purified protein antigens have been shown to induce protective immunity following immunization in appropriate adjuvant (Table 2). The most extensively studied are antigen 85B (Ag85B) and ESAT-6. Ag85B is a member of

the antigen [85] complex, a set of three closely related proteins which function as mycolyl transferases and are the most abundant protein components in culture filtrate preparations [167]. Early secreted antigenic target-6 is a low molecular weight protein antigen, present in culture filtrates of *M. tuberculosis* but absent from BCG [168]. Early secreted antigenic target-6 is a member of a *M. tuberculosis* gene family comprising several prominent immunogens [169], including CFP-10 which is encoded by the adjacent gene and is also deleted from BCG [170]. Since any single protein may be insufficiently immunogenic, the use of fusion proteins could be important for future subunit vaccine development [171].

Subunit vaccination with purified proteins requires delivery of the protein in adjuvant in order to generate a strong immune response. Unfortunately, the adjuvants currently licensed for use in humans generally optimize the antibody rather than the T cell responses, although novel preparations such as the SBAS2 adjuvant or microspheres [172,173] may be useful in moving mycobacterial protein subunit candidates into clinical trials.

### C. DNA Vaccines

DNA-based vaccines are considered to be potentially revolutionary due to their ease of production, low cost, long shelf life, lack of requirement for a cold chain, and ability to induce good T cell responses. However, there are concerns about the potential for mutagenesis and the induction of autoimmunity. Despite this, a number of phase 1 trials in humans are underway and, in the case of falciparum malaria, completed phase 1 studies with exciting early evidence of efficacy are available [32,174].

DNA vaccination against tuberculosis has proved effective in small animal models using some [10,11,175], but not all, antigens [176,177]. Two examples from DNA vaccine studies highlight the potential importance of fine antigenic specificity in the protective response. Firstly, Ag85A, but not Ag85B, is effective when administered as a DNA vaccine [11,178]. Interestingly, when antigen 85B is delivered to guinea pigs either as a subunit or overexpressed in a recombinant BCG, it is an effective vaccine [9,164] and protection has also been reported using an alternative Ag85B DNA formulation [179]. Thus the form of vaccination and host species are also crucial for any given antigen. The second instance indicating a potential contribution of fine specificity to the immune response in tuberculosis concerns the very closely related Hsp60 molecules of *Mycobacterium leprae* and *M. tuberculosis*. DNA vaccination using Hsp60 of *M. leprae* is effective in mice both as a prophylactic and an immunotherapeutic vaccine [10,12]. The vaccine efficacy could not, however, be reproduced using a DNA construct encoding the closely related Hsp60 gene of *M. tuberculosis* [180]. Further, rather than clearing persistent infection when administered as a therapeutic vaccine, as had been shown for the *M. leprae* Hsp60 [12], the *M. tuberculosis* homologue was found to induce necrotizing bronchointerstitial pneumonia. It is intriguing to consider the heterologous protection apparently associated with the *M. leprae* antigen in light of the protective efficacy of BCG vaccination against leprosy [25]. Might the immune response to an *M. leprae* gene

protect against tuberculosis, and the minor sequence differences between the Hsp60 molecules be immunologically crucial, contributing to the protection/pathology paradox in this instance?

### D. Combination Vaccines

*Vaccinia* virus has also been used as a delivery system for mycobacterial antigens [181,182]. This live vector has the advantage of proven safety and efficacy in the context of the smallpox eradication program. The combination of three vaccinations of plasmid DNA containing MPT63 and ESAT-6 plus one "boost" with a recombinant *Vaccinia* construct expressing the same antigens induced protection against intraperitoneal infection of mice close to that conferred by BCG [182]. Protection was attributed to increased antigen-specific CD4<sup>+</sup> IFN- $\gamma$  producing T cells induced by this vaccination protocol. Similarly, injection of Ag85A DNA-primed mice with purified Ag85A protein in adjuvant increased the protective efficacy of the DNA vaccine against an intravenous *M. tuberculosis* challenge: again, the response was CD4<sup>+</sup>-mediated [178]. However, there is at least one report of a theoretically elegant prime-boost strategy using ESAT-6 in which there was no enhancement above the protection provided by individual subunits [183]. Perhaps of greatest interest is that sequential immunization with antigen Ag85B-expressing DNA followed by BCG was more effective than BCG immunization alone. In this case, depletion of the CD8<sup>+</sup> T cells in the immunized mice impaired protection in their spleens, indicating that this improved efficacy was partially mediated by CD8<sup>+</sup> T cells [184]. This last study suggests a clear and ethical way ahead for trials of novel vaccines in humans. It would seem entirely reasonable to propose a comparative trial of BCG against BCG plus another vaccine.

## VII. STRATEGIES FOR VACCINE EVALUATION

### A. Testing in Animal Models

While success or failure of any given vaccine candidate in a traditional animal model for tuberculosis will not necessarily predict similar behavior in humans, scientists and public health officials agree that evidence of effectiveness in experimental animal models is a crucial factor in selecting vaccine candidates for entry into clinical trials. Mice and guinea pigs have been used extensively for evaluation of new tuberculosis vaccines. More expensive models in rabbits, cattle, and nonhuman primates are available for further characterization of promising candidates.

#### 1. Mice

The mouse, apart from being least costly, is an invaluable model for investigation of the genetics and the immunology of the host response to tuberculosis [192]. Mice are, however, relatively resistant to tuberculosis; they have a low degree of skin test reactivity to tuberculin and show an almost complete absence of caseation and fibrosis, histopathological hallmarks of human tuberculosis.

## 2. Guinea Pigs

Guinea pigs are innately susceptible to low-dose infection with virulent *M. tuberculosis* and display at least some of the necrotic pathology found in immunocompetent humans. Their exquisite sensitivity to tuberculosis infection provides an experimental window of sufficient width to allow ranking different vaccines according to their individual protective efficacies [149].

## 3. Rabbits

Rabbits are relatively resistant to *M. tuberculosis* but display an intermediate type of susceptibility to *M. bovis*, similar to human susceptibility to *M. tuberculosis*. In an additional parallel with human disease, infection of rabbits with virulent *M. bovis* frequently produces pulmonary cavities as a result of the liquefaction of caseous foci and subsequent extracellular multiplication of tubercle bacilli [193]. This feature renders the rabbit model particularly interesting, presenting the opportunity to study the pathology largely responsible for flooding the lungs of infected humans and thereby via sputum of the immediate environment, with massive numbers of bacteria.

## 4. Cattle

Tuberculosis in cattle and in farmed deer is of considerable economic significance [194], and efforts to develop a new vaccine against human tuberculosis are paralleled by attempts to develop diagnostic agents and vaccine control strategies for bovine tuberculosis [195–197]. Given the relationship between the respective infectious agents, *M. tuberculosis* and *M. bovis*, it may be that the prevention of human and bovine tuberculosis can be achieved using similar vaccines. Therefore vaccine trials in cattle can be considered a relevant animal model for human tuberculosis, given the fact that the endpoint of this model will be the reduction of transmission in a naturally susceptible host system.

## 5. Nonhuman Primates

Establishment of experimental tuberculosis in nonhuman primates provides an opportunity to study protective and pathological mechanisms with close resemblance to those in humans [198]. Bacille Calmette–Guérin vaccination has been characterized in rhesus and cynomolgous monkeys, and studies have been initiated with new candidates [151]. It should be borne in mind that nonhuman primate models are relatively poorly standardized, however, and ethical and financial aspects of such research dictate that it should be reserved for the end stages of preclinical evaluation.

In each of these model systems, challenge with virulent mycobacteria can be by parenteral injection or, in an attempt to mimic the natural route of infection, by aerosol. Measuring the reduction of bacterial load in target tissues, particularly in the lung and spleen, at a specified time after challenge is the most widely accepted readout system to assess protection in the above animal models, although there is increasing recognition that the effect of vaccination on longer-term pathological changes is important in the comprehensive analysis of a new candidate. Typically, BCG vac-

cination results in a reduction of approximately 10-fold in bacterial numbers in mice and up to 5-log reduction in guinea pigs. The slow growth rate of mycobacteria makes the standard determination of colony forming units both labor-intensive and time-consuming and thus unsuitable for high throughput screening of the large numbers of vaccine candidates discussed above. Recently, reporter gene technology has been applied to mycobacteria with luciferase-expressing mycobacteria allowing the measurement of luminescence in organ homogenates as a rapid endpoint for vaccine evaluation [199]. Extension of the use of such bacteria into simple whole blood-based assays in humans also has considerable potential as a surrogate of protective immunity that makes no assumptions of the detailed nature of this response [200]. An alternative surrogate for colony forming units (CFU) is the use of precisely quantitated PCR: both the RNA for some genes and DNA content are closely related to CFU [91,201,202].

## B. Clinical Trials in Humans

There are general logistic and ethical issues related to tuberculosis vaccine trials that will determine the type of vaccine that can be tested and may therefore have an important influence on more immediate research strategies. It is important that these issues begin to be addressed now, rather than waiting till vaccine candidates have already reached the stage of field evaluation. Clinical evaluation of any new tuberculosis vaccine will follow the general path of vaccine testing, starting off with phase I safety trials in a small group of healthy volunteers. This will be followed by phase II trials in a larger population to establish a preliminary estimate of protection and parameters such as induction of appropriate immune responses, dose response, and possible interaction with preexisting tuberculous infection. Phase III trials, finally, will establish the overall efficacy and the incidence of adverse effects in a large study group.

### 1. Preinfection Trials

In testing a vaccine designed to replace BCG, an important ethical problem would arise in relation to any side-by-side comparison. In light of the proven efficacy of BCG in prevention of childhood forms of tuberculosis, it is difficult to envisage the withdrawal of BCG as part of a trial design. A comparative trial may therefore be impossible in children from developing countries, the most important group of future users for a new tuberculosis vaccine. Comparative trials may be possible by focusing on high-risk groups in countries such as the United States, where BCG is not used. A prerequisite for such trials would be the further development and field applicability of specific tests to distinguish vaccination from infection in order to avoid compromise of existing control strategies. Even in high-incidence areas, TB case rates rarely exceed 250/100,000 of the population, imposing a requirement for large study populations and long follow-up periods for vaccine trials. The key readout period for a new vaccine would be when the neonatal target group reaches adulthood, representing a minimum 20-year trial period.

## 2. Postinfection Trials

An antireactivation vaccine might be simpler to evaluate. By administration to a high-risk young adult cohort, a trial period in the region of several years could be envisaged. Evaluation of a transmission-blocking vaccine, measured by a reduction in the number of smear-positive cases, would require the development of improved diagnostic tools for smear-negative tuberculosis. For any live vaccine formulation, safety concerns related to use in HIV-positive individuals would require detailed consideration.

The point has already been made that, in the absence of an understanding of the factors responsible for variable results with BCG, a series of trials in different populations of BCG will be necessary. There is a moderate genetic influence on susceptibility to tuberculosis [203], and the tuberculin reaction following BCG vaccination is under stronger influence [204,205]. Therefore individuals may also vary in their response to vaccination. Identification of genes involved in determining susceptibility to mycobacterial infection has been an area of revived interest that might provide new insight relevant to vaccine design and testing [206].

## 3. Immunotherapeutic Vaccination

Control of TB by immunomodulation has been a long-standing scientific goal. After the discovery of the tubercle bacillus in 1882, Robert Koch devoted his efforts to the development of an immunotherapeutic vaccine. In some patients, the results were disastrous, with the induction of pathogenic responses leading to death, dramatically illustrating that the immune response also mediates the pathology of tuberculosis. However, one new tuberculosis vaccine has already undergone clinical trials. *Mycobacterium vaccae* is an environmental mycobacterium, which in some trials showed dramatic effects, including prolonged survival of HIV-positive tuberculosis patients [207–210]. However, the initial promise of *M. vaccae* as an immunotherapeutic vaccine has not been upheld by more recent randomized clinical trials [211,212].

## VIII. CONCLUDING COMMENTS

The goal of tuberculosis vaccine development has frustrated several generations of enthusiastic research. Nevertheless, there has been considerable progress and Phase I/II trials in humans can be anticipated in the near future. Whether this optimism can be translated into improved efficacy will take much longer to ascertain. In the meantime, the availability of genetic tools for mycobacteria and the development of novel immunization strategies remain to be important objectives. The magnitude of the public health problem requires international coordination of translational effort and is a problem that cannot be put to one side.

### I. INTRODUCTION

#### A. Significance and Magnitude of Influenza

Influenza epidemics are regularly associated with excess rates of pneumonia- and influenza-associated hospitalizations [1,2]. Both influenza A (H3N2 and H1N1) and B can cause severe illness [3], although the highest mortality rates in recent years have generally been seen during years with significant H3 virus activity [4]. Complications and deaths from influenza are of particular concern in those with certain high-risk medical conditions, including adults and children with cardiovascular and pulmonary conditions, or those requiring regular medical care because of chronic metabolic, renal, blood, or immune diseases [5]. Influenza may cause more severe disease and increased hospitalization rates in individuals with human immunodeficiency virus infection [6,7] or iatrogenic immunosuppression [8], and women in the second or third trimesters of pregnancy [9]. Influenza is increasingly recognized as an important health problem in young children. Rates of influenza-related hospitalizations are particularly high in healthy children under 2 years of age, in whom rates approach those of older children with high-risk conditions [10,11]. In addition, a high rate of secondary complications, particularly otitis media and pneumonia, occur in children with influenza infection [12].

Although the impact of influenza has been extensively documented in terms of death and hospitalization, it is important to recognize the impact of influenza illness even in young, healthy individuals. A typical case of influenza, on average, is associated with 5–6 days of restricted activity, 3–4 days of bed disability, and about 3 days lost from work or school [13,14]. The average number of medical visits for

cases in which medical attention was sought is between 1.1 and 3.6 visits, depending on year of the outbreak and age of the patient. Influenza is also associated with significant lost workplace productivity [15]. Therefore development and implementation of more effective control measures for influenza represents an important research and health policy priority.

#### B. Immune Responses Involved in Protection

##### 1. Serum Antibody

Infection with influenza virus stimulates antibody to the viral envelope glycoproteins hemagglutinin (HA) and neuraminidase (NA), as well as to the structural matrix (M) and nucleoprotein (NP) proteins. Some individuals may develop antibody to the matrix-2 (M2) protein as well [16]. Serum IgM, IgA, and IgG antibody to HA appear within 2 weeks of inoculation of virus [17], and anti-NA antibodies parallel anti-HA antibodies [18]. Peak antibody responses are seen 4–7 weeks after infection and slowly decline thereafter; titers can still be detected years after infection even without re-exposure.

Antibody to HA can be measured by hemagglutination-inhibition (HAI) tests, enzyme-linked immunosorbent assay (ELISA), and neutralization of virus infectivity [19]. Anti-hemagglutinin antibody protects against both disease and infection with the homologous virus [20]. Serum HAI titers of 1:40 or greater, or serum neutralizing titers of 1:8 or greater, are associated with protection against infection [21]; HAI titers of 1:20 or 1:10 are associated with lesser degrees of protection [22]. Among the elderly, a serum HAI antibody titer above 1:80 may be required for protection [23,24]. Pro-

tection in clinical studies is primarily strain specific but some protection is present against strains showing antigenic drift within a subtype, depending on the degree of drift [25,26]. Antibody which is present in low quantity, or which is primarily directed against a heterologous strain of influenza, may not prevent infection but may modify the severity of illness.

Antibody to NA can be measured by NA inhibition (NI) or ELISA. In contrast to anti-HA, anti-NA antibody does not neutralize virus infectivity but instead reduces efficient release of virus from infected cells, resulting in decreased plaque size in vitro [27] and reductions in virus shedding in vivo [28,29]. Observations on the relative protection of those with anti-N2 antibody during the A/Hong Kong/68 (H3N2) pandemic [18,30], as well as experimental challenge studies in humans [31], show that anti-NA antibody does not prevent infection but does protect against disease, diminishes severity of illness and decreases virus shedding [32]. Passive transfer studies in mice suggest that antibody to the M2 protein of influenza A viruses may have a similar effect to that of anti-NA antibody [33,34].

## 2. Local Immunity

Because the replication of influenza virus in humans is restricted to epithelial cells of the respiratory tract, it is reasonable to expect that immune responses with a mucosal site of action would be highly effective at preventing infection. Studies in a variety of systems confirm the importance of mucosal immunity in protection against influenza. Studies in mice and ferrets have emphasized the importance of local IgA antibody in resistance to infection, particularly in protection of the upper respiratory tract. Polymeric IgA is specifically transported into the nasal secretions of mice and protects against nasal challenge. Protection could be abrogated by intranasal administration of antiserum against IgA but not IgM or IgG [35]. Limited studies have demonstrated significant mucosal responses to influenza virus infection in humans, with development of both HA-specific IgA and IgG in nasal secretions. Nasal HA-specific IgG is predominantly IgG<sub>1</sub>, and correlates well with serum levels, suggesting that nasal IgG originates by passive diffusion from the systemic compartment [36]. Nasal HA-specific IgA is predominantly polymeric and mostly IgA<sub>1</sub>, suggesting local synthesis. Studies in humans suggest that protective immunity induced by influenza virus infection is predominantly mediated by local HA-specific IgA [31,37]. Thus methods to induce mucosal immunity are being pursued.

## 3. Cellular Immunity

Influenza-virus-infected cells can be lysed by antibody in the presence of complement, by antibody-dependent cellular cytotoxicity [38], or by the action of cytotoxic T (Tc) lymphocytes. Generally, Tc lymphocytes express CD8 and are restricted by class I. Such cells may recognize either HA, or internal proteins such as M, NP, or PB2 [39]. Therefore Tc lymphocytes may be subtype specific, or in the case of those that recognize internal proteins, may be broadly cross-reactive, e.g., lysing cells infected with influenza A but not influenza B virus [40–42]. Class II restricted cells

may exhibit cytotoxic activity similar to class I restricted cells [41].

Adoptive transfer experiments show that virus-specific Tc lymphocytes mediate recovery from influenza virus infection in animal models [43–48], including both HA-specific and cross-reactive Tc. Virus-specific prechallenge class I restricted Tc lymphocytes correlate with reductions in the duration and level of virus replication in adults with low levels of serum HA and NA antibody following experimental challenge with influenza A virus [49]. The significance of Tc directed against internal viral proteins in protection against severe disease in humans is unclear, as the internal virus proteins were shared between viruses causing the pandemics of 1957 and 1968 and the viruses in circulation immediately prior to these pandemics [50,51]. However, memory Tc lymphocyte responses may play a role in ameliorating the severity of disease and speeding recovery following infection, as suggested by the finding of more severe influenza in individuals with severe defects in cell mediated immunity [8]. For these reasons, there is interest to improve the ability of influenza vaccines to induce Tc, in addition to antibody.

## C. Inactivated Influenza Vaccine

The most effective measure available for the control of influenza is the annual administration of inactivated influenza vaccines. Chemically inactivated influenza virus vaccines first licensed in the United States in 1943, consisting of formalin-inactivated whole virions grown in embryonated chicken eggs, showed a protective efficacy of 70% in healthy adults [52]. Although there have been advances in the techniques for producing vaccine, the basic vaccine strategy remains the same. The zonal gradient centrifuge, which can remove reactogenic contaminants, allows more efficient production of more highly purified vaccines [53]. Treatment of whole virus with solvents to create “split” vaccines, or detergents to create “subunit” vaccines, results in vaccines that cause fewer adverse reactions, particularly fever, compared to whole-cell vaccine [54]. Efficiency of vaccine production has also been improved through techniques that create high-yield reassortant strains that contain HA and NA genes from currently circulating influenza viruses and remaining genes from a master strain adapted for high yield from hens’ eggs [55]. The current vaccine is generally formulated as a trivalent preparation, containing influenza A (H1N1, H3N2) and influenza B viruses thought most likely to cause disease in the upcoming season based on epidemiological and antigenic analysis of currently circulating strains. Since the late 1970s, vaccine has been standardized to contain at least 15 g of each hemagglutinin (HA) antigen as assessed by single radial immunodiffusion (SRID) [56].

Influenza vaccine is generally very well tolerated in adults. A randomized, double-blind, prospective study in over 800 healthy working adults [57] documented rates of arm soreness of 64% in vaccine recipients compared to 24% in placebo recipients. Only 3% rated arm soreness as severe. Rates of mild local soreness following inactivated influenza vaccine in the range of 60–80% have been documented in other, similar studies [58–60]. Local side effects are slightly more common in women than in men [57].

Systemic reactions, including malaise, flu-like illnesses, and fever, are relatively uncommon. For example, in the large randomized study of influenza vaccine in working adults, systemic complaints, such as fever (6% in both placebo and vaccine recipients) and malaise (17.5% in placebo and 16.0% in vaccine), were seen at equal rates in vaccine and placebo recipients. In other studies, rates of transient, low-grade fever have varied from 2% to 10% of recipients [58–61]. In these studies, rates of systemic effects immediately following vaccination are only marginally increased above baseline [61]. Whole virus and split product vaccines are similarly reactogenic in adults [62], but whole virus vaccines are associated with fever in children [63], and should not be used in those under 12 years of age. Fever occurs in approximately 8–50% of vaccinated children and may be associated with other systemic symptoms such as myalgia, arthralgia, headache, and malaise, but not respiratory symptoms [64]. Severe, life-threatening, immediate hypersensitivity reactions to parenteral inactivated vaccine have been rare. Although the vaccine is grown in eggs, most individuals with “egg allergy” can be safely immunized [65].

During the 1976 National Immunization Program against swine influenza, 45 million persons received influenza vaccine. In the first 4–6 weeks after vaccination, an excess rate of Guillain–Barré syndrome (GBS) occurred among vaccinees as compared with persons who did not receive the vaccine [66]. The estimated risk of acquiring GBS during that vaccination program was 1 in 100,000 vaccinations; the mortality for those with GBS was 5% (i.e., 1 in 2,000,000 vaccinations), and another 5–10% had some residual neurologic abnormality [66]. The relationship between inactivated influenza vaccines other than the Swine/New Jersey/76 vaccine and GBS is less clear cut. National surveillance conducted since 1976 has generally not identified increased rates of this syndrome following vaccination [67]. However, slight increases in the risk of GBS were seen following the 1992–1993 and 1993–1994 vaccines, representing an excess of approximately 1 case per million persons vaccinated [68].

Increases in HAI antibody are seen in about 90% of recipients of vaccine [62,69,70]. A single dose of vaccine elicits seroconversion in individuals who have been previously vaccinated or who have experienced prior infection with a related subtype, but a two-dose schedule is required in unprimed individuals [63,71]. Primed individuals generally respond with antibody that recognizes a broader range of antigenic variants than do unprimed individuals [72]. Serum antibodies peak between 2 and 4 months after vaccination but quickly fall to near baseline before the next influenza season [73]. Mucosal anti-influenza antibodies are not efficiently generated by parenteral inactivated influenza parenteral vaccine [74,75]. Cytotoxic T lymphocyte or cellular immune responses have been reported after administration of parenteral inactivated influenza vaccine [76].

Adults who generally mount decreased responses to inactivated influenza vaccine include the elderly [77–79], those with renal disease [80], and transplant recipients [81–83]. The responsiveness to influenza vaccination in human immunodeficiency virus (HIV)-infected individuals is related to the degree of immunosuppression [84,85]. The immune activation associated with influenza immunization may transiently

stimulate HIV replication [86], but the clinical significance of these observations is unclear. Most patients with chronic lung disease respond reasonably well to vaccination, and steroids at doses commonly used to treat reactive airways disease do not appear to preclude vaccine responses [87,88].

Inactivated influenza vaccine is effective in the prevention of influenza A in controlled studies conducted in young adults, with levels of protection of 70–90% when there is a good antigenic match between vaccine and epidemic viruses [26,89,90]. In the most recent randomized controlled trial [91], the efficacy of TIV for preventing culture proven influenza A illness in adults was 76% (95% C.I. 58–87%) for H1N1 and 74% (95% C.I. 52–86%) for H3N2. A subanalysis of efficacy in children in this trial demonstrated efficacy of 91% and 77% in preventing symptomatic, culture-positive influenza A H1N1 and A H3N2 illness respectively compared to placebo [92]. Vaccination of young adults is also associated with decreased absenteeism from work or school [93]. Two studies have demonstrated a reduction in otitis media in children who received TIV. In Finland, children less than 3 years of age who received TIV had an 83% reduction in influenza-associated otitis media and 36% reduction of all otitis media during the subsequent influenza season [94]. In North Carolina, a 41% reduction in acute otitis media was demonstrated in 6–30-month old children attending day care after receiving parenteral TIV [95].

Few prospective trials of protective efficacy have been conducted in high-risk populations. In one placebo-controlled prospective trial in an elderly population, inactivated vaccine was approximately 58% effective in preventing laboratory-documented influenza [96]. In addition, numerous retrospective case control studies are available, which have documented the effectiveness of inactivated influenza vaccines in the elderly [5,97–103]. Vaccine is protective against influenza- and pneumonia-related hospitalization in the elderly, and is accompanied by a decrease in all-cause mortality [104]. However, the protective efficacy of vaccination appears to be lower in individuals over age 65 than in younger adults. Vaccine has also been shown to be protective in limited studies in other high-risk groups, including those with HIV infection [105].

## D. Economics of Influenza Vaccination in Adults and Children

The potential economic benefits of influenza vaccination are often underappreciated among clinicians and policy makers. This is due in part to confusion over the economic terms used in such studies, the specific methodologies used to assess economic impact, and the context of cost analyses. The economic impact of a vaccination program can be presented as the cost per outcome of interest such as episodes of pneumonia prevented or life saved (cost-effectiveness), general net cost savings or loss per person vaccinated (cost-benefit analysis), or cost per quality-adjusted life year (QALYs, cost-utility analysis). Economic analyses may include direct costs (which include expenses associated with disease, care for the ill, or prevention) and/or indirect costs (which include unpaid goods or services such as lost wages or extra care-giving). They must also be understood in the context of the

“perspective” (from the view of the individual, the health-care payer, e.g., direct costs only) or from society as a whole (direct and indirect costs) and with the target population and morbidities in mind (adult vs. pediatric groups; low-risk vs. high-risk for influenza). Most studies of children and healthy adults have included indirect and direct costs, whereas those of the elderly usually have only included direct costs. Some studies have included information over several influenza seasons, which allows for stratified results for those seasons in which the vaccine strain may or may not match the circulating strain. The magnitude of the economic impact depends on several factors including the assumed level of vaccine efficacy, coverage, and cost, disease incidence, herd immunity, age of the vaccine recipient, and inclusion of future medical costs with years of life gained [106–108]. Ultimately, use of such analyses is tailored to local or national needs and prevailing societal value systems for prioritization of available resources.

### 1. Adults

In general, influenza vaccination appears to be most cost-effective among the elderly (i.e., those  $\geq 65$  years of age) and those at high risk of complications of infection, regardless of age. In elderly populations, vaccination has consistently

been shown to be cost-effective or cost saving, due in large part to the higher risk of incurring substantial health care costs related to influenza complications in this age group. The cost savings per vaccine in studies in the elderly varied from as little as \$1 to nearly \$250 [109–111], and often resulted in savings of millions of dollars [110–113]. Details of selected studies are noted in Table 1.

Stratified analyses of the elderly, based on the presence of underlying medical conditions, are conflicting: One study reported cost savings, over a 6-year period, for the elderly regardless of whether concomitant comorbid conditions were present [109] and the other reported, over a 9-year period, that vaccination of the low-risk elderly group would incur net costs to the health maintenance organization (HMO), although vaccination of all the elderly (regardless of risk) would be cost saving [111]. In addition, one study from Hong Kong found that vaccination of the elderly would not be cost saving, due likely to exclusion of the prevention of influenza-related hospitalizations because of congestive heart failure (CHF) and other respiratory conditions and the relatively small amount of saved productivity earnings through vaccination since wages are substantially lower in Hong Kong compared to the United States [114]. A comprehensive analysis of clinical preventive services recommended by the U.S. Public Health Service noted that vac-

**Table 1** Selected Economic Analyses of Influenza Vaccination in Adults

Study	Main effectiveness result	Main economic result	Comments
<i>Healthy adults &lt;65 years of age</i>			
Nichol, 2001 [118]	12% less workdays missed, 6% less ILI	Average \$14 savings/vaccinee (95% C.I.: \$33 savings–\$2 cost)	Direct and indirect costs, simulation model
Muennig, 2001 [117]	Not reported	\$13 savings/vaccinee	Direct costs only, decision analysis model
Bridges, 2000 [116]	34%, 42%, 32% less ILI, MD visits, lost workdays, respectively (when vaccine strain matched community strain)	\$66 cost/vaccinee (poor strain match); \$11 cost/vaccinee (good strain match)	Direct and indirect costs, randomized trial over two seasons
Nichol, 1995 [93]	35%, 52%, 24% less URI, days of URI-associated missed work, MD visits, respectively	\$47 savings/vaccinee	Direct and indirect costs, randomized trial over one season
Riddiough, 1983 [113]	Not reported	\$64 and \$23 cost/year healthy life gained for 25–44 and 45–64 years, respectively	Direct costs only, simulation model
<i>Seniors <math>\geq 65</math> years of age</i>			
Nichol, 1998 [109]	39%, 27% less hospitalized pneumonia or CHF, respectively; 50% less all-cause mortality	\$73 savings/vaccinee	Direct costs only, staff model HMO over six influenza seasons
Nichol, 1994 [110]	48–57% less hospitalization for pneumonia and influenza; 39–54% less all-cause mortality	\$21–235 savings/vaccinee according to year	Direct medical hospitalization costs in staff model HMO over three seasons
Mullooly, 1994 [111]	Effectiveness for prevention of influenza and pneumonia: 30% and 40%, high-risk and all elderly, respectively	\$6.1 savings/high-risk vaccinee; \$1.1 savings/any vaccine	Direct costs in one HMO over nine seasons
Riddiough, 1983 [113]	Not reported	Cost savings/year healthy life gained	Direct costs only, simulation model

cination of the elderly against influenza is more cost-effective than many other interventions including screening for high cholesterol and breast cancer [115].

Among healthy working adult populations less than 65 years of age, economic data generally support routine vaccination, if the vaccine strain matches the strain circulating in the community. All studies that include direct and indirect costs, except for one [116], report net savings to society [93,106,113,117]. The range of cost savings to society was approximately \$14–47 per vaccinee. A recent study reported that vaccination of working adults was cost saving (average nearly \$14 per vaccinee over a 6-year period) and was predicted to be so 95% of the time using up to 10,000 Monte Carlo simulations—a multivariate technique that allows for simultaneous variance of several variables to estimate the probability distribution of the cost–benefit [118]. The most important cost driver in these studies is the indirect costs avoided through prevention of missed work by vaccination. Selected data are summarized in Table 1.

However, one study using data from a randomized trial over two seasons, reported net societal cost of \$11 per vaccinee in a year in which the vaccine strain matches the community strain [116]; this value was \$66 per vaccinee in the unmatched year. Another study from Hong Kong also concluded that routine vaccination of adults was not cost saving, but the wages in that country are somewhat low compared to the United States (depressing indirect costs benefits of vaccination) and illnesses expected to be worsened following influenza infection (CHF, respiratory disease) were not included in the direct costs assessments [114]. In 1983, the U.S. Congress Office of Technology Assessment determined that routine influenza vaccination of persons 15–24, 25–44, and 45–64 years of age was cost-effective at \$181, \$64, and \$23 per year of healthy life gained, respectively. If productivity gains were included in the analysis for adults 15–44 years, then 25–50% of the costs associated with vaccination would be offset [113]. A meta analysis of influenza vaccination of healthy adults performed by the Cochrane Center group did not reveal it to be cost-effective, but the authors did not include loss of productivity because of illness [119].

The generally favorable economic impact of vaccination of healthy adults results in large part because of prevention of work absenteeism and increased productivity, unlike the elderly among whom reduced utilization of healthcare resources by vaccination is the important cost driver. The economic data, coupled with the significant impact of adult influenza vaccination on health, make a compelling case for annual vaccination of all adults against influenza.

## 2. Children

The cost implications of influenza vaccination in children have been analyzed using pediatric influenza morbidity data. Two reports evaluated this issue in preschool and school-aged children, respectively [120,121]. These cost–benefit studies included direct and indirect costs, and considered two different vaccine delivery scenarios: (1) a health provider's office during normal work hours, and (2) a more flexible setting that does not require parents to miss work to vaccinate their child (e.g., community-based settings such as day-care centers, schools, or supermarkets). Vaccination was cost saving for each age group, in either scenario. The net savings ranged from \$1–21 per vaccine recipient for the preschool age group and \$4–35 for the older children (Table 2). In both studies, the largest proportion of savings was attributed to prevention (by vaccination) of indirect costs incurred with disease. However, the cost savings for each study were likely underestimated because (1) the school-aged group study did not include savings associated with prevention of influenza-associated otitis media and hospitalization and (2) the preschool study did not include prevention of day-care transmission.

Another study reported a cost-effectiveness analysis using prospective data collected during a 2-year, randomized trial of a live, intranasal influenza vaccine among children 15–71 months of age [122]. This study found that routine vaccination was cost-effective assuming a vaccine price of \$20, resulting in \$19–30 per febrile influenza-like illness day prevented, and was cost saving to society when vaccination is performed in the flexible setting defined above (Table 2). When given in the health provider's office, the societal cost-

**Table 2** Economic Evaluations of Routine Influenza Vaccination of U.S. Children

Study	Vaccine cost <sup>a</sup>	Vaccination in physician offices		Vaccination in community-based setting	
		Societal perspective <sup>b</sup>	Health Payer perspective <sup>c</sup>	Societal perspective	Health Payer perspective
Luce, 2001 [122]	\$20	\$30 cost/febrile ILI day avoided	\$19 cost/febrile ILI day avoided	Cost saving	\$19 cost/febrile ILI day avoided
White, 1999 [121]	\$10, \$4 <sup>d</sup>	\$4 savings/vaccinee	\$6 cost/vaccinee	\$35 savings/vaccinee	Not cost savings
Cohen, 2000 [120]	\$10	\$1 savings/vaccinee	\$15 cost/vaccine	\$21 savings/vaccinee	\$15 cost/vaccine
Riddiough, 1983 [113]	\$11	\$258, \$196 cost/year healthy life gained for 1–3 and 3–14 years, respectively			
Dayan, 2001 [123]	\$10	For children 0–15 years (direct and indirect costs): savings of \$10/vaccinee and \$57 savings/influenza episode averted (study performed in Argentina)			

<sup>a</sup> Cost is sum of estimated vaccine price and costs associated with its administration.

<sup>b</sup> Direct and lost productivity costs included.

<sup>c</sup> Direct medical costs only.

<sup>d</sup> In this study, the vaccine cost was \$10 in the “physician offices” setting and \$4 in the “community-based” setting.

effectiveness was \$30 per influenza-like illness prevented with greater cost-effectiveness noted from the health payer perspective. Another analysis from Argentina concluded that immunization of high-risk children 6 months to 15 years of age with the inactivated vaccine would be cost saving to society at approximately \$10 per vaccinated child, a societal savings of \$57 per influenza case averted [123]. This study also showed, using Monte Carlo simulation, that vaccination was cost saving 64% of the time over 1000 trials, with the following variables subjected to variation: vaccine efficacy, vaccine price, incidence of infection, and number of days lost by a parent. These economic benefits favorably compare to immunization against pediatric disease of high incidence and relatively low morbidity, such as varicella and rotavirus diarrhea [124,125].

### E. Indications and Usage

The main goal of the current strategy for use of influenza vaccine is to reduce complications by targeting individuals at highest risk of influenza-related hospitalizations or death. Table 3 lists those groups for whom annual influenza vaccination is currently recommended [126], including the elderly and adults and children with chronic conditions known to increase the risk of influenza complications. The age at which annual vaccination is recommended has been lowered from 65 to 50. The rationale for this recommendation is to achieve higher vaccination rates in nonelderly individuals with high-risk conditions, a large proportion of whom are between 50 and 65 years old.

The Advisory Committee on Immunization Practices (ACIP) has recommended that practitioners consider annual influenza vaccine for all children 6–23 months of age [127], mostly to prevent medically attended illnesses and complications such as otitis media. An additional benefit of widespread vaccination of young children could be reductions in rates of influenza in other groups, because children play an important role in the propagation of influenza epidemics in a community [22]. There is relatively little direct evidence supporting the use of influenza vaccine to prevent transmission, but in one study mass vaccination of school-age children resulted in reduced rates of influenza in teachers and parents compared to a control community where children were not vaccinated [128]. In addition, it has been observed that influenza-related mortality rates among the elderly have increased in Japan, coincident with discontinuation of that country's policy of universal vaccination of school children [129]. Targeting of children for annual influenza immunization could reduce the impact of influenza in the whole community.

## II. OPPORTUNITIES TO IMPROVE CURRENT VACCINES

The performance of inactivated influenza vaccines could be improved by enhancing the level and duration of systemic immune responses (particularly in elderly and high-risk subjects), augmenting mucosal responses, and stimulating cellular immune responses. Two features of the current in-

activated vaccines are important to keep in mind while considering the development of new or improved vaccines. First, although the current vaccine is very well tolerated, concern about side effects is one factor that is frequently cited as a reason why individuals choose not to receive influenza vaccine. In addition, successful implementation of vaccine strategies will necessarily expose large numbers of recipients to potential side effects. Therefore any new influenza vaccine must be very safe, and significant increases in local or systemic reactogenicity over that seen with current vaccine would probably be unacceptable. Second, the current vaccine is relatively inexpensive, and is cost-effective and possibly cost saving. These types of considerations will become increasingly important as large health care providers make decisions about covered benefits.

## III. IMPROVED PARENTERAL INFLUENZA VACCINES

### A. High-Dose Vaccine

Within the relatively narrow dose range feasible using standard technology inactivated vaccines, there is a fairly flat dose-response curve [62,71,130,131], but improved purification techniques have allowed exploration of much higher doses. In young adults, highly purified hemagglutinins have been administered at doses as high as 405 µg without significant adverse events. Administration of 405 µg of monovalent H1 antigen, or trivalent vaccine containing 135 µg of each antigen was well tolerated and associated with twofold to fourfold higher geometric mean HAI and neutralizing antibody titers 4 weeks after vaccination, compared to standard doses [132]. Improved nasal secretion antibody responses with high-dose vaccines were also seen [132]. Elderly subjects have manifested a more flattened dose response curve than young adults [133,134], but the efficacy of very high doses of HA in this population remains to be evaluated.

### B. Neuraminidase Vaccines

The infection-permissive nature of anti-NA immunity has stimulated interest in NA-based vaccines that could provide clinical protection yet allow subclinical infection that would elicit other immune responses to the virus. Purified NA antigens induce NA antibody and prevent death in lethal mouse models of influenza [32,135–137]. Because the neuraminidase appears to undergo antigenic drift at a slower rate than hemagglutinin, a neuraminidase or neuraminidase-supplemented inactivated vaccine may induce better protection against drifted viruses than does standard inactivated vaccine [138]. Preliminary results in the human challenge model suggest that neuraminidase-supplemented vaccines may be more efficacious than standard vaccine in protection against an antigenic variant [139].

### C. Vaccines Produced in Alternative Substrates

Production of inactivated influenza vaccines in embryonated hen's eggs has practical drawbacks, including: (1) the expense and difficulty in ensuring the availability of sufficient

numbers of hens in the compressed time frame in which influenza vaccine is prepared, and (2) the potential for antigenically variant influenza A viruses to be selected during the process of developing strains for vaccine production, which grow well in eggs. Direct polymerase chain reaction (PCR) amplification of viruses in nasal secretions has documented that the HA of the major population of virus shed from the nasopharynx of infected humans is identical to that isolated in MDCK cells, and significantly different from that isolated in eggs. Antigenic differences of this type have been documented for H3N2, H1N1, and influenza B viruses [140–147]. Alterations in CTL epitopes have also been described [148]. Although these differences may amount to only a few amino acids, the MDCK-cell-grown virus appears to be more effective than egg-grown virus as an inactivated vaccine for protection of experimental animals [149,150]. Thus current inactivated influenza vaccines grown in eggs may not exhibit optimal antigenic representation of the viruses that are infecting humans.

For these reasons, mammalian cell culture for growth of influenza viruses for vaccine production is being explored [151]. The main technical challenges have been to develop mammalian cell lines suitable for use as vaccine production substrates [152], and to optimize culture techniques to obtain maximal yields. Vaccine generated in Vero cells induces serum antibody responses to the same extent as standard vaccine in mice [153]. Recently, human studies showed that at similar doses a candidate MDCK cell grown vaccine generated antibody titers similar to those generated by egg-grown vaccines [154].

Recombinant DNA techniques to generate vaccine antigen expressed in cells also allow control over the sequence of the HA used. Hemagglutinin antigens generated in insect cells by recombinant baculoviruses have been evaluated in young adults and elderly community dwelling adults over the age of 65 years [155–157]. Administration of recombinant HA vaccine stimulated HA-specific serum antibody in both young and older adults. Antibody responses to higher doses of 90 or 135 µg of H3 vaccine antigen occurred with greater frequency and resulted in higher titers of antibody than did subvirion vaccine. Antibody responses to both the H1 and H3 antigens when a bivalent vaccine containing 45 µg of each antigen was administered were similar to those when the monovalent vaccines were separately administered at doses of 45 µg each. Similar results were seen for neutralizing and HA-specific IgG ELISA antibody. In one trial of A/Beijing/89 (H3) vaccine in healthy adults, subjects were followed during the subsequent influenza season for ascertainment of influenza-like illnesses [155], and although not designed as an efficacy trial, preliminary evidence of protection was reported. These results suggest that the known differences in glycosylation in insect as compared to mammalian cells [158] do not affect the generation of a functional antibody response in primed individuals; however, confirmation awaits studies in children.

#### D. Adjuvants and Alternative Formulations

Generally, adjuvants used with influenza vaccine have consisted of agents that directly modify the immune response,

such as the squalene derivative MF59, monophosphoryl lipid A (MPL), the purified soap-bark derivatives Quil A or QS-21, dihydroepiandrosterone (DHEA) [159], or cytokines such as IL-2 or thymosin [160]; or consist of attempts to physically modify the vaccine to improve antigen presentation, such as formulation in liposomes [161,162], or multimeric complexes such as ISCOMs (immunostimulating complexes) [163,164]. Combinations of both approaches are frequently applied.

In healthy adults, MF-59-adjuvanted vaccine is well tolerated and results in slightly higher GMT rises than standard subunit vaccine [165,166]. This vaccine has also been well tolerated and induced somewhat higher titered serum antibody responses in the elderly than does standard split-product vaccine [167,168]. Formulation of hemagglutinin into ISCOMs with the adjuvant Quil A improved antibody and CTL responses in Phase I studies in humans [169,170]. Formulation of HA into liposomes with the *Escherichia coli* heat labile toxin (HLT) has been evaluated for intranasal immunization, but such virosomes are also effective adjuvants for parenteral immunization [171].

#### E. Transcutaneous and Dermal Immunization

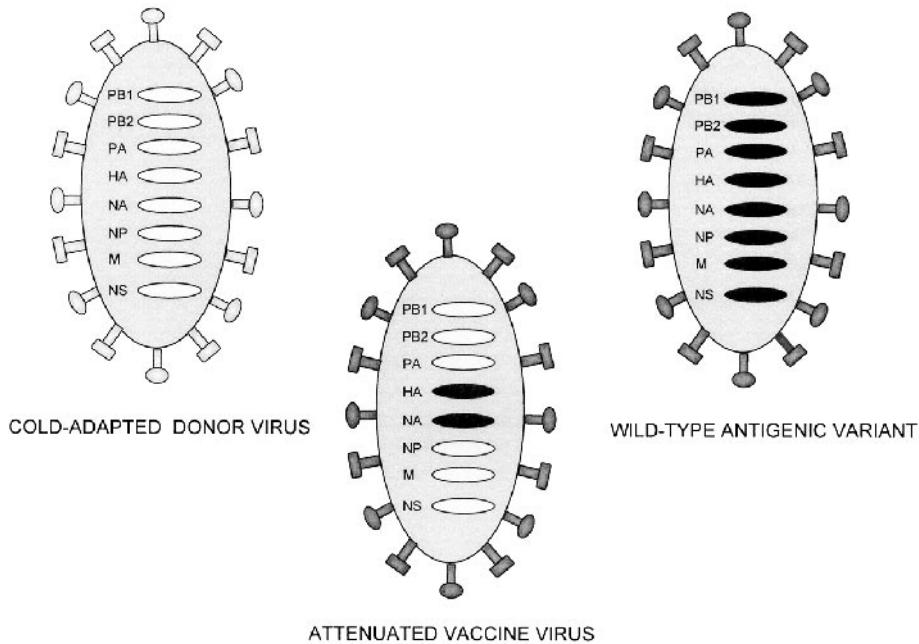

Two transcutaneous immunization approaches have recently been described for influenza. When influenza antigen is directly applied to hydrated skin in the form of a patch for several hours, antigen penetrates the stratum corneum to reach antigen-presenting cells [172]. In a second approach, antigen is applied to the skin using a powder vehicle such as trehalose delivered via gene gun device [173]. Both approaches require the use of powerful adjuvants for optimal responses to elicit systemic antibody, cytotoxic T-lymphocytes, and mucosal antibodies.

### IV. INTRANASAL APPROACHES TO VACCINATION

#### A. Cold-Adapted Influenza Vaccines (CAIV)

Live virus vaccines for influenza, which have been intensively evaluated in humans, offer several potential advantages over parenteral inactivated vaccines, including induction of a mucosal immune response that closely mimics that induced by natural influenza virus infection [174]. In addition, the potential superiority of such vaccines in protection of the upper respiratory tract [175] might be useful in immunization strategies to limit transmission of influenza. In practical terms, the nasal, rather than parenteral, route of administration might be more acceptable to patients, particularly in certain age groups.

A key requirement for the development of attenuated influenza vaccines is the ability to rapidly attenuate new antigenic variants. The most widely used approach takes advantage of the segmented nature of the influenza virus genome to generate reassortant viruses in which the gene segments encoding attenuation are derived from a well-characterized master donor vaccine virus, and the gene segments encoding the HA and NA are derived from the new antigenic variant [176,177] (Figure 1). In the past,

**Figure 1** New influenza antigenic variants can be rapidly attenuated by genetic reassortment with a well-characterized master attenuated vaccine virus. The attenuated vaccine master virus donates the gene segments encoding attenuation, while the epidemic virus donates the genes encoding the antigenically variant HA and NA in the construction of a live attenuated reassortant vaccine virus.

extensive studies were performed to evaluate the use of temperature-sensitive [178] or avian [179] influenza viruses as donors of attenuating genes. However, these approaches were not successful, either because of genetic instability [180] or unreliable attenuation [181,182]. Importantly, such deficiencies in the safety profile of these approaches to live attenuated influenza vaccine were only detected when studies were performed in young children, who are generally most susceptible to infection by the vaccine viruses.

The most promising master donor viruses are cold-adapted influenza A/Ann Arbor/6/60 (H2N2) and B/Ann Arbor 1/66 strains [183]. The process of cold adaptation refers to the repetitive passage of a virus at gradually decreasing temperature until a virus is isolated that efficiently replicates at a low temperature at which the replication of the original wild-type virus is significantly restricted [184]. During this process, additional mutant phenotypes are frequently acquired. The cold-adapted influenza viruses demonstrate three such phenotypes: (1) the cold-adapted (*ca*) phenotype, defined as the ability to replicate efficiently at 25°C, a restrictive temperature for wild-type influenza viruses; (2) the temperature-sensitive (*ts*) phenotype, defined as significant ( $>2 \log_{10}$ ) restriction of virus replication at 38–39°C; and the attenuation (*att*) phenotype, defined as restricted replication in the lower respiratory tract of experimental animals.

Genetic analysis of the cold-adapted A/Ann Arbor/6/60 virus has demonstrated multiple mutations in all six of the so-called “internal” or non-HA or NA gene segments, and analysis of single gene reassortants has shown that at least

three of these gene segments (PB1, PB2, and PA) participate in the attenuation of the virus in animals and humans (Table 4) [185,186]. The basis of attenuation of the B/Ann Arbor/6/66 virus has been less completely worked out. Mutations in five of the six internal gene segments have been described [187], and analysis of laboratory-derived revertant viruses has implicated the PA gene segment as playing an important role in attenuation [188,189].

### 1. Safety

A large number of monovalent *ca* A/AA/6/60 and B/AA/6/66 reassortant influenza viruses have been evaluated in young adults, children, and elderly subjects, and found to be reliably attenuated and immunogenic (reviewed in Ref. 190). Bivalent or trivalent CAIV has also been well tolerated in adults [91,191–195]. Adults who receive bivalent or trivalent CAIV have had the following statistically significant excess symptoms compared to placebo recipients in the immediate period following vaccination: runny nose or coryza, sore throat, lethargy, headache, and muscle ache (Table 5) [91,191–195]. However, when considering these studies in aggregate, nasal symptoms (runny nose, nasal congestion or coryza) and sore throat were the most frequently identified adverse symptoms in these studies. No severe reactions have been consistently attributed to CAIV.

Bivalent and trivalent CAIV have been safe and well tolerated in children [92,196–206]. As seen in Table 5, the following symptoms have occasionally been found to be significantly more common within 7–11 days after vaccina-

**Table 3** Target Groups to Receive Annual Trivalent, Inactivated Influenza Vaccine

Individuals at high risk for influenza-related complications
<ul style="list-style-type: none"> <li>Age 50 years or older.</li> <li>Adults and children who have chronic disorders of the pulmonary or cardiovascular systems, including asthma.</li> <li>Residents of chronic-care facilities that house persons of any age who have chronic medical conditions</li> <li>Adults and children who have required medical follow-up or hospitalization during the preceding year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression by medication or by HIV virus).</li> <li>Children and teenagers (6 months to 18 years) who are receiving long-term aspirin therapy and therefore might be at risk for developing Reye syndrome after influenza.</li> <li>Women who will be in the second or third trimester of pregnancy during the influenza season. (Please note that some experts prefer to administer influenza vaccine beyond the first trimester to avoid coincidental association with spontaneous abortion, which is common during this trimester, and because vaccines have traditionally been avoided during this trimester.)</li> </ul>
Individuals who can transmit influenza to those at high risk
<ul style="list-style-type: none"> <li>Physicians, nurses, and other health care personnel in both hospital and outpatient-care settings, including emergency responses workers.</li> <li>Employees of nursing homes and chronic-care facilities who have contact with patients or residents.</li> <li>Employees of assisted living and other residences for persons in groups at high risk.</li> <li>Individuals who provide home care to persons in high-risk groups.</li> <li>Household members (including children) of person in high-risk groups.</li> </ul>

tion in young children (under 8 years of age) who received multivalent CAIV compared to placebo: low-grade fever, runny nose or coryza, cough, headache, chills, vomiting, and abdominal pain. All symptoms resolved without sequelae. However, when considering all the pediatric studies in aggregate, no consistent symptom was seen significantly

more commonly in CAIV compared to placebo recipients. Nasal symptoms (runny nose, nasal congestion, or coryza) were more frequently observed in CAIV recipients in only 3 of 12 pediatric studies cited in Table 3. In older children, 11 to <16 years of age, sore throat was observed slightly more frequently in CAIV recipients than in inactivated influenza

The percentages below each adverse event column represent statistically significant increases in events compared to placebo groups. Negative (—) signs represent no statistical difference between CAIV and placebo recipients and NA signifies not assessed in that report. The parentheses under the trial column is the reference number.

<sup>a</sup> Eighty five of the subjects were >16 years of age.

<sup>b</sup> There were 4120 doses of intranasal CAIV and 8380 doses of nasal placebo given to the study participants. The 1733 intranasal CAIV recipients received intramuscular saline in year 1 and intramuscular monovalent influenza B vaccine in years 2–5. Of the 3477 nasal placebo recipients, 1738 received saline intramuscularly in year 1 and intramuscular monovalent inactivated influenza B vaccine in years 2–5 and 1739 received TIV for years 1–5. The latter two groups comprise the placebo group to compare to CAIV recipients.

<sup>c</sup> Doses of vaccine. In this subanalysis of Ref. 91, 791 total children under 16 years of age participated. See footnote <sup>b</sup> for dosing assignments.

vaccines [92]. CAIV has been demonstrated to be safe in infants 2 to 6 months of age [207].

Safety has also been demonstrated in high-risk individuals who would not be able to tolerate even minor lower respiratory tract inflammation. No significant vaccine-related adverse events have been seen in studies of children with cystic fibrosis [208,209] or asthma [210,211], and vaccinated children with asthma have not experienced significant changes in FEV1, use of beta adrenergic rescue medications or asthma symptom scores compared to placebo recipients [211]. CAIV has been well tolerated in adults with or chronic obstructive airway disease [212–214]. Vaccine is well tolerated in the elderly, although in one study vaccine recipients had a 13% excess of sore throats compared to those who received placebo [191].

Young children with advanced HIV infection have difficulty clearing influenza virus from the respiratory tract,

and there have been several reports of very prolonged virus shedding in highly immunosuppressed individuals [215], including children with AIDS. Although CAIV is not intended for use in individuals with HIV, such persons could be inadvertently vaccinated. Small numbers of adults with relatively asymptomatic HIV infection have received CAIV [192]. There was a 30% excess reporting of runny nose/congestion compared to placebo recipients but no lower respiratory tract illnesses were observed in this group. No excess or prolonged CAIV virus shedding was detected in HIV-infected compared to non-HIV-infected CAIV recipients. No significant changes in blood CD4 counts or quantitative HIV RNA levels after vaccination with CAIV were detected in HIV-infected adults who received CAIV compared to those who received placebo. This was followed by a study in which 23 children, 1–8 years of age, with relatively asymptomatic human immunodeficiency infection, received triva-

lent CAIV [200]. In that study, CAIV was safe and well tolerated compared to placebo in these children. Importantly, no increased frequency, excess quantity, or prolonged shedding of the trivalent CAIV vaccine viruses were detected in HIV-infected compared to non-HIV-infected children of similar age, nor were significant differences observed in peripheral blood quantitative HIV RNA levels or CD4 counts.

Although vaccinated adults and children shed CAIV, transmission to susceptible contacts is rare. No transmission of CAIV from vaccine recipients to susceptible contacts was detected in studies of young children in day-care-like settings where CAIV and placebo recipients played together for up to 8 hr a day for 7–10 days after vaccination [177,216]. In the largest study [217], 197 children between 8 and 36 months of age were randomized to intranasally receive trivalent CAIV or placebo, and vaccine virus shedding was assessed for 21 days after vaccination. Although 80% of CAIV recipients shed at least one vaccine strain, for a mean of 7.6 days, trans-

mission was detected in only one placebo recipient, for an estimated transmission rate of 1.75% (95% upper bound of 8%). Vaccine virus recovered from vaccinated volunteer subjects have all retained the attenuated phenotype and genotype [217,218].

## 2. Immunogenicity

The immunogenicity of cold-adapted reassortant vaccines in children, adults, and the elderly correlates with replication of cold-adapted vaccines in the upper respiratory tract, and hence their immunogenicity is influenced by the susceptibility of the host at the time of vaccination. Therefore the frequency and magnitude of immune responses to vaccination is highest in young children, intermediate in adults, and lowest in elderly subjects who have been repeatedly infected with influenza viruses throughout their lifetimes. Mucosally administered *ca* vaccine is generally more effective than

parenterally administered inactivated influenza vaccine at inducing nasal HA-specific IgA, while inactivated vaccine usually induces higher titered serum HAI and HA-specific IgG antibody [219].

The serum and mucosal HA-specific antibody responses in children in several studies are shown in Table 6 [198,199, 201,202,204,206,209,220]. Most susceptible children demonstrate measurable serum and mucosal antibody responses. For example, nasal vaccine strain-specific IgA responses were detected in 50% of susceptible children who received A/H3N2 CAIV [221]. Post-CAIV-vaccination secretory antibody persists for up to or beyond a year in children. A study of trivalent CAIV administered to children 15–71 months of age demonstrated mucosal IgA strain specific responses of 62–85% [222]. In contrast, vaccination with bivalent or trivalent CAIV in unscreened adults generally results in a low proportion of more than fourfold rises in serum strain specific influenza antibody [91,194,195] and relatively lower rates of mucosal responses [223]. Even in those prescreened to have low prevaccination vaccine-specific influenza antibody, the rates of serum antibody responses to intranasal CAIV in adults and the elderly are low [195,224].

Cytotoxic T lymphocyte responses to live CAIV have been measured in adults who intranasally received CAIV [76,225]. Although not extensively studied, limited data suggest that cold-adapted influenza vaccines may induce antibody and cytotoxic T cells (Tc) with more broadened recognition within a subtype than seen after inactivated vaccine as well [226,227]. However, these responses have been more difficult to measure in young children [228].

There may be interference between components of multivalent cold-adapted vaccines [192,196,199,201,204,220]. However, interference can be overcome by administering a second dose of multivalent CAIV within 1–2 months after the first dose [196,201]. This may reflect development of immunity to the dominant virus with the first dose of a multivalent vaccine, allowing the weaker component to replicate upon a second dose. A similar situation has been well described for multivalent live poliovirus vaccine [229].

### 3. Efficacy and Effectiveness

CAIV was efficacious in the prevention of influenza in a 2-year, randomized placebo-controlled trial conducted in 1314 children aged 15–74 months in the United States [196]. Efficacy against culture confirmed influenza illness in the first year of this trial was 95% (95% C.I., 88%–97%) against influenza A/H3N2 and 91% (95% C.I., 79%–96%) for influenza B. In the second year of the trial, the H3 component of the vaccine (A/Wuhan/93) was not a close match with the predominant H3 virus that season, A/Sydney/95. Nevertheless, the efficacy of CAIV against this variant was 86% (95% C.I., 75%–92%) [197], suggesting that CAIV can induce protective immunity against drift variants. Overall, the efficacy of intranasal trivalent CAIV to prevent any influenza illness during the 2-year period of surveillance in this field study was 92% (95% C.I. 88%–94%). Although some CAIV recipients developed culture-documented influenza infection, the spectrum of influenza illnesses were milder compared to influenza illnesses in placebo recipients. There were

fewer febrile illnesses, fewer days of fever, and fewer cases of influenza associated otitis media in CAIV recipients who did contract influenza illness compared to placebo recipients.

The efficacy in children determined in this trial is consistent with the results of earlier trials using monovalent or bivalent vaccines. In a subset analysis of a large field trial of bivalent CAIV [92], efficacy against culture positive A/H1N1 influenza illness was 96% (95% C.I., 67%–99%) and was 68% (95% C.I., 1%–90%) against A/H3N2 illness in 791 children less than 16 years of age. This favorably compared to parenteral trivalent inactivated vaccine where the efficacy against A/H1N1 was 91% and A/H3N2 was 77%. In another, smaller study in children 6–18 months old, efficacy against H3N2 culture positive illness was 65% for children 6–18 months of age who received monovalent H3N2 CAIV or bivalent (H3N2 + H1N1) CAIV compared to those that intranasally received placebo or monovalent A/H1N1 CAIV [204].

Efficacy of trivalent cold-adapted influenza vaccine against naturally acquired influenza in adults has not been directly demonstrated. However, efficacy of trivalent CAIV was demonstrated in an experimental infection study in which adults were given either trivalent live intranasal CAIV, parenteral trivalent inactivated influenza vaccine, or placebo and then experimentally infected with wild-type influenza A/H1N1, A/H3N2, or B viruses [195]. The combined efficacy in preventing laboratory-documented influenza illness because of the three wild-type influenza strains was 85% for the CAIV and 71% for the inactivated vaccine. These data are consistent with observations from other experimental infection studies conducted with monovalent CAIV in which protection against challenge with wild-type virus was at least equal to and sometimes better than that provided by inactivated vaccine [37,175,230,231]. In addition, in a large, 5-year field trial in Nashville [91], the efficacy of bivalent CAIV was 85% (95% C.I., 70%–92%) against A/H1N1 illness and 58% (95% C.I., 29%–75%) against A/H3N2 illness. This efficacy against influenza illness was similar to that induced by parenteral trivalent inactivated vaccine which was 76% against H1N1 illness and 74% against H3N2 illness.

The potential utility of trivalent CAIV in adults has been demonstrated in an effectiveness trial where the endpoints were not influenza virus specific. In this study, performed in 4561 healthy working adults [193], effectiveness in preventing severe febrile respiratory illness of any cause during the influenza season was 29%. Of note, this trial was conducted in a year when the antigenic match between the vaccine virus (A/Wuhan) and the predominant epidemic virus (A/Sydney) was not close.

No studies of the protective efficacy of *ca* vaccine alone have been conducted in the elderly, an age group in which immunogenicity may be reduced. However, the combination of local live attenuated influenza vaccine and parenteral inactivated vaccine administered together resulted in an approximately 60% decrease in cases of laboratory confirmed influenza in an elderly nursing home population, compared to inactivated vaccine alone [232].

The mechanism of protection induced by cold-adapted vaccine has mostly been evaluated in experimental infection

**Table 6** Serologic Responses to Multivalent CAIV (trivalent A/H1N1, A/H3N2, and B=T-CAIV, bivalent A=B-CAIV)

All serologic responses represent more than fourfold rises pre- to postvaccination measured by hemagglutination inhibition assay except where indicated.

<sup>a</sup> Subjects were selected who had “low” prevaccination titers to at least one of the three vaccine strains.<sup>b</sup> Serology performed = neutralizing antibody.<sup>c</sup> Four separate lots of T-CAIV assessed.

studies. Cold-adapted vaccine is protective in these experiments in the absence of significant serum HAI responses, suggesting that the main protective effect is via induction of mucosal antibodies. However, protection can be demonstrated in some circumstances in the absence of detectable mucosal responses [233], and the specific levels of mucosal antibody required for protection are unknown. In addition, the role that induction of cellular immune responses plays in the protective effect has not been elucidated.

### B. Other Live Viral Vaccines

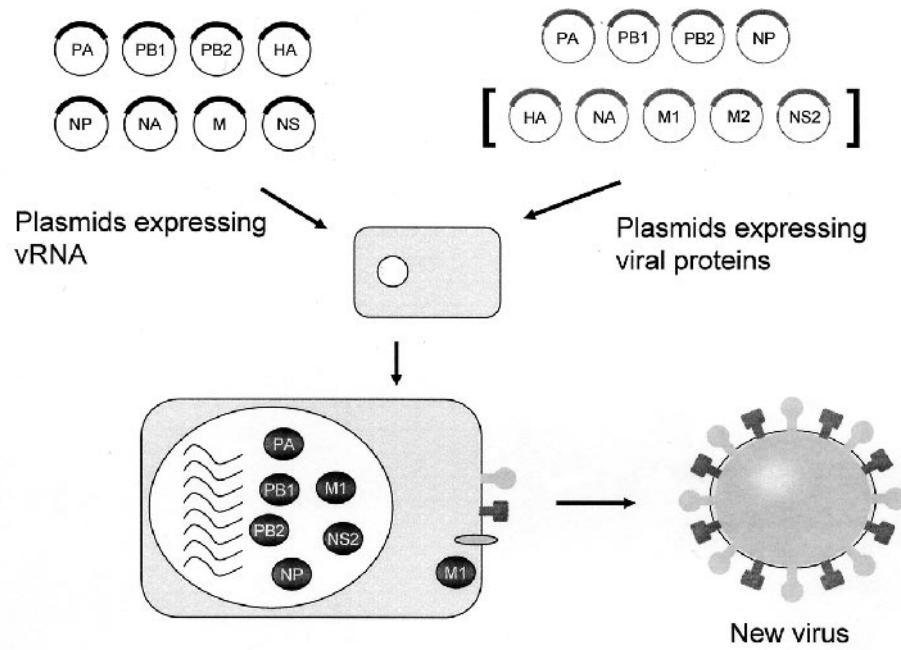

The development of techniques for direct genetic engineering of specific mutations in the genome of influenza A and B viruses [234–236] has provided a tool to generate live influenza vaccine candidates. Because these viruses can now be entirely constructed from plasmid DNA [237,238], any non-lethal mutation in any gene can be incorporated (Figure 2). Directly introduced mutations at several sites have been shown to result in attenuation. These include replacement of the 3' and 5' ends of a gene segment of influenza A virus by the corresponding regions of an influenza B virus [239], manipulation of the stalk of the NA [240,241], and placement of avian-like sequences into the PB2 gene [242,243]. One intriguing approach has been complete or partial deletion of the NS1 protein [244]. These viruses manifest significantly reduced replication in systems in which the type I interferon system is intact, implicating the NS1 protein as an interferon

antagonist. Complete or partial NS1-deleted viruses provide excellent protection against homologous wild-type influenza virus in mice [245], and are being developed as possible second-generation vaccines.

### C. Intranasal Inactivated Influenza Vaccines

Studies in humans conducted over many years have shown that nasopharyngeal administration of inactivated vaccines by nose drops or aerosol can stimulate production of local antibody in primed individuals [246–250]. However, the simple administration of soluble antigen to this mucosal surface is inefficient, requiring relatively large amounts of antigen to induce mucosal immune responses. Therefore attenuation has focused on ways to enhance the immunogenicity of mucosal inactivated vaccine, basically by increasing uptake by mucosal antigen-presenting cells. Strategies used have included mucosal adjuvants, incorporation of HA and other antigens into particulate formulations, or both.

Bacterial enterotoxins, such as cholera toxin (CT), have been extensively evaluated as mucosal adjuvants for influenza and other vaccines. However, these toxins are far too reactogenic in man for routine use, as even a few microgram quantities can induce cholera diarrhea if they reach the intestine. Initial studies showing a potential adjuvant effect of purified B subunit [251,252] were complicated by the presence of residual amounts of holotoxin [253], and it became more clear that the holotoxin was responsible for the major-

*Neumann et al PNAS 96:9345, 1999*

**Figure 2** Generation of new attenuated viruses by direct manipulation of the viral genome. Cells are simultaneously transfected with plasmids expressing each of the eight virion RNAs and with plasmids expressing, at a minimum, the viral polymerase (PA, PB1, and PB2) and nucleoproteins. Transfection of the plasmids shown in brackets is not required but increases the efficiency of recovery of transfectants. (From Ref. 238.)

ity of the adjuvant effect [254]. Further development has focused on engineering mutations designed to reduce or eliminate toxicity while retaining adjuvanticity into CT or the highly-related heat-labile toxin (LT) of *E. coli*. Two types of mutations have been described: mutations that block the enzymatically active (ADP-ribosylating) site (e.g., LTK63 or LTR172) and mutations that block the protease activation site (e.g., LTG192) [255].

In animal models, LT-adjuvanted intranasal vaccine has provided protection against infection with antigenically distinct strains of virus [256,257]. The mechanism of protection is B-cell dependent and appears to be the result of the induction of nonneutralizing HA-specific mucosal antibody after nasal but not parenteral administration [258]. Similar observations have been made with transcutaneous vaccination (see below).

The largest experience in humans with intranasal inactivated influenza vaccine has been with HA formulated in phosphatidylcholine liposomes coadministered with mutant LT. In prelicensure studies, this vaccine was well tolerated in adults, children, and the elderly, and induced strong nasal anti-HA IgA responses in adults [259]. Responses were less strong in the elderly, but the vaccine exceeded European licensing guidelines for serum antibody in all age groups [260]. In addition, the vaccine protected adults and children and reduced the frequency of otitis media in otitis-prone children [261,262]. However, this vaccine was later withdrawn from the market after multiple reports suggesting an association between administration of vaccine and subsequent development of Bell's palsy. These observations were consistent with studies in rodents showing that the strong avidity of enterotoxins for GM1 gangliosides present on neuronal cells of the olfactory bulb can result in colocalization of toxin and antigen in neural tissue [263]. Thus intranasal administration of enterotoxins could potentially result in low level neural toxicity.

Additional adjuvants or alternative formulations that do not include enterotoxins are currently being evaluated in humans with inactivated influenza vaccine for intranasal immunization. These include liposomes [264], proteosomes (mixtures of influenza HA and outer membrane proteins of group B *N. meningitidis*) [265] (see the chapter on Proteosomes) and the use of the MF59 oil-in-water adjuvant intranasally [266] (see the chapter on MF59 adjuvant). Each of these studies has shown induction of serum HAI responses in a minority of recipients, with detectable nasal IgA responses in 50–70% of subjects.

## V. POLYNUCLEOTIDE VACCINES

Immunization of mice with DNA encoding HA, as well as the internal M and NP proteins of influenza A, induces long-lived humoral and cellular immune responses [267,268] that are protective against viral infection and disease. Immunization of African Green monkeys with DNA encoding a combination of three HAs and other influenza virus genes induced serum antibody against all three HAs [269]. However, studies in humans of influenza DNA vaccines have not yielded impressive responses.

## VI. VACCINES FOR PANDEMIC INFLUENZA

Pandemics, a defining characteristic of the epidemiology of influenza, occurred in 1918 (550,000 U.S. deaths), 1957 (70,000 U.S. deaths), and 1968 (38,000 U.S. deaths). The mechanisms of pandemic influenza have been extensively considered and reviewed [270]. It is considered inevitable that a new pandemic will occur in the future. This concern was heightened with the recent epidemic of A/Hong Kong/157/97 (H5N1) influenza on the island of Hong Kong that killed six people [271,272]. This epidemic represented the first documented natural infection of humans with H5 influenza viruses, and represents direct transmission of the avian virus from birds to humans in live poultry markets. Subsequently, two cases of human infection with avian H9N1 viruses in Hong Kong have also been recognized [273].

The first strategy for control of a pandemic would be the use of a traditional egg-grown inactivated influenza vaccine. However, use of highly pathogenic viruses for vaccine production would require stringent infection control procedures to prevent contamination of vaccine workers or release of the virus into the environment. In addition, some avian influenza viruses are highly lethal to eggs. To circumvent these problems, one approach to generate vaccines for H5N1 utilizes the nonpathogenic, but antigenically related A/Duck/Singapore/57 (H5N2) virus. This virus is antigenically similar to the A/Hong Kong/157/97 virus but does not have the highly cleavable HA and would not pose an agricultural risk or risk to humans. However, conventional inactivated vaccine generated from this virus was poorly immunogenic in humans, and induced antibody to the Duck/Singapore virus that did not cross react well with the Hong Kong virus [274]. Subsequent studies have suggested that the immunogenicity of the Duck Singapore vaccine can be significantly enhanced with the MF59 adjuvant.

Baculovirus-expressed HA of the A/HK was also evaluated. Because generation of this vaccine did not require handling live influenza virus, special containment facilities were not needed, and a candidate vaccine representing the authentic A/HK HA could be quite rapidly generated. This vaccine was also poorly immunogenic, requiring doses of 90 µg to generate significant neutralizing titers in most recipients [275]. Other approaches to vaccination against H5 that were tested in animal models but not in humans included attenuation of the pathogenicity of the virus by genetically deleting the HA cleavage site, and the use of a cold-adapted H5 reassortant virus as either a nonpathogenic seed for generation of an inactivated vaccine, or as a live vaccine [276], and DNA vaccination [277].

The experience in confronting the H5 outbreak underscores some of the difficulties that will be encountered in dealing with vaccine development for the next pandemic. No vaccine was available for testing, the optimal dose and timing of vaccination was not known, and it was not clear which tests of immune response should be used to assess immunogenicity. To be better prepared, there is interest in developing and testing pilot vaccine representing likely candidates for the next pandemic virus. Several such viruses can be identified based on current surveillance. These include avian viruses of the H5 and H7 subtype, possibly the H9 viruses,

and H2 influenza viruses, and Phase I studies of pilot lots of vaccine for some of these viruses are in progress. The logistics of vaccine delivery are also generating much discussion. One economic analysis suggested that in a pandemic setting, the economic impact to society would range from \$71 to 167 billion, but that a vaccine delivery policy that strives to prevent the largest number of deaths (>65 years of age) would not be as economically advantageous as targeting those 0–64 years of age as a group, regardless of risk [278]. The continued threat of pandemics and the re-emergence of new influenza viruses ensure that the topic of influenza vaccine will continue to be of great interest in the years to come.

## Chimeric Vaccines Against Japanese Encephalitis, Dengue, and West Nile

Konstantin V. Pugachev, Thomas P. Monath, and Farshad Guirakhoo

Acambis, Inc., Cambridge, Massachusetts, U.S.A.

Japanese encephalitis (JE) and dengue (DEN) viruses are two of the most important human pathogens within the *Flavivirus* genus of the *Flaviviridae* family. This group of small RNA viruses includes approximately 70 members, 38 of which have been associated with human illnesses. The West Nile (WN) virus is an important emerging pathogen recently introduced into the Western Hemisphere. In addition to the *Flavivirus* genus, the *Flaviviridae* family also includes the *Pestivirus* genus, which encompasses several veterinary pathogens of worldwide economic impact, such as bovine viral diarrhea virus (BVDV) and classical swine fever virus (CSFV), and the *Hepacivirus* genus, represented by only one member, hepatitis C virus (HCV), which is yet another extremely important human pathogen. Although currently grouped together, recent studies have shown that pestiviruses and HCV differ significantly from representatives of the *Flavivirus* genus in terms of their life cycle, genome organization, processing of viral proteins, etc. (reviewed in Refs. [1a,1b,3]). Therefore, the approaches to vaccine development discussed below may not be easily applied to these viruses. In the following pages, we will refer to members of the *Flavivirus* genus only as flaviviruses.

With a few exceptions, flaviviruses are mostly arboviruses, transmitted by mosquitoes and ticks (reviewed in Ref. [1]). Based on immunological cross-reactivity and genome sequence similarity, different flaviviruses are grouped into four distinct complexes (Table 1): the YF complex (contains only YF virus); the JE complex [JE, WN, St. Louis encephalitis (SLE), Kunjin (KUN), and Murray Valley encephalitis (MVE) viruses]; the dengue complex that includes the four serotypes of DEN (types 1–4), and the TBE complex [TBE, Langat (LGT), Powassan, and Louping ill viruses] [1]. Because of the lack of effective antiviral drugs and obstacles in vector control programs, prevention through vaccination of people living in or traveling to endemic and epidemic areas is the most effective weapon in fighting these devastating illnesses. No licensed vaccines against dengue fever and WN encephalitis exist. The vaccines, currently available against

JE can be improved in terms of their efficacy, manufacturing cost, and use of acceptable cell substrates by applying the tools of molecular biology. Several molecular approaches, as well as the classic approaches currently being explored to create new DEN and JE vaccines have recently been reviewed [2]. This chapter will focus on the construction of live attenuated vaccines generated by one new approach, ChimeriVax™ technology.

### I. FLAVIVIRUS ORGANIZATION AND REPLICATION

Flavivirions are spherical particles of roughly 50 nm in diameter (Figure 1A). The genome, which is a single-stranded RNA molecule of positive polarity of about 11,000 nucleotides (nt) in length, encompasses a long open reading frame (ORF) flanked by 5' and 3' untranslated terminal regions (UTRs), ~120 and 500 nt in length, respectively. The ORF encodes a polyprotein precursor which is cleaved co- and posttranslationally to generate individual viral proteins. The proteins are encoded in the order: C-prM/M-E-NS1-NS2A/2B-NS3-NS4A/4B-NS5, where C (core), prM/M (premembrane/membrane), and E (envelope) are the structural proteins, i.e., the components of viral particles, and NS are the nonstructural proteins necessary for intracellular virus replication (reviewed in Ref. [3]) (Figure 1B).

Upon infection of cells and translation of genomic RNA, the processing of the polyprotein starts with translocation of the prM portion into the lumen of endoplasmic reticulum (ER) of infected cells, followed by translocation of E and NS1 portions as directed by the hydrophobic anchor-signal tails of C, M, and E proteins, respectively. The amino-termini of prM, E, and NS1 are generated after cleavages by cellular signalase located on the luminal side of the ER membrane, and the resulting individual proteins remain carboxy-terminally anchored in the membrane. It is still unclear which protease is responsible for the NS1/NS2A

**Table 1** Major Serocomplexes of Flavivirus Human Pathogens<sup>a</sup>

Serocomplex (by name of prototype virus)	Viruses	Principal vector
Yellow fever (YF) Japanese Encephalitis (JE)	YF virus JE, St. Louis encephalitis (SLE), West Nile (WN), Murray Valley encephalitis (MVE), Kunjin (KUN) viruses, etc.	Mosquito Mosquito
Dengue (DEN) Tick-borne encephalitis (TBE)	DEN types 1–4 viruses TBE (Russian spring–summer encephalitis and Central European encephalitis), Omsk hemorrhagic fever, Langat (LGT) viruses, etc.	Mosquito Tick

<sup>a</sup> Based on phylogenetic analysis of E protein sequences, the serocomplexes generally share 40–44% of amino acid sequence (46–53% between the JE and DEN serocomplexes), while the homologies between species within serocomplexes are higher, 62–96%.

Source: Ref. 1.

cleavage. Most of the remaining cleavages in the nonstructural region are carried out by the viral NS2B/NS3 serine protease, with the exception of the N-terminus of NS4B formed by the signalase. The viral protease is also responsible for generating the C-terminus of the mature C protein found in progeny virions ( $C_{vir}$ ). Newly synthesized genomic RNA molecules and the C protein form a dense spherical nucleocapsid, which becomes surrounded by cellular membrane in which are embedded the E and prM proteins (Figure 1A). The mature M protein is produced by cleavage of prM shortly prior to virus release by cellular furin or a similar protease [4]. In addition to M, small amounts of residual uncleaved prM can often be found on the virion surface [5]. Among the NS proteins, NS1 remains an enigma. It appears to be essential for viral RNA amplification [6,7], but it is also secreted from cells and could be involved in virus spread and pathogenesis in the host. The prM (but not M), E, and NS1 of most flaviviruses are glycosylated.

E, the major protein of the envelope, is the principal target for neutralizing antibodies. The crystal structure of the ectodomain of E has been resolved [8]. This milestone significantly advanced our understanding of the function of the E protein, such as putative receptor recognition and fusion of viral and cell membranes during infection, and also elucidated the locations of antibody-binding epitopes. The virus-specific cytotoxic T-lymphocyte (CTL) response is the other key attribute of immunity. Multiple CD8<sup>+</sup> and CD4<sup>+</sup> CTL clones have been characterized in both humans and mice that recognize specific epitopes in many flavivirus structural and NS proteins (reviewed in Refs. [1] and [9]; [10,11]). The CTL responses are primarily directed against E and NS3 of DEN [12–15], NS3, NS4A, and NS4B of WN, KUN, and MVE viruses [1], as well as E of the JE virus (but not NS1) expressed in poxvirus vectors [16].

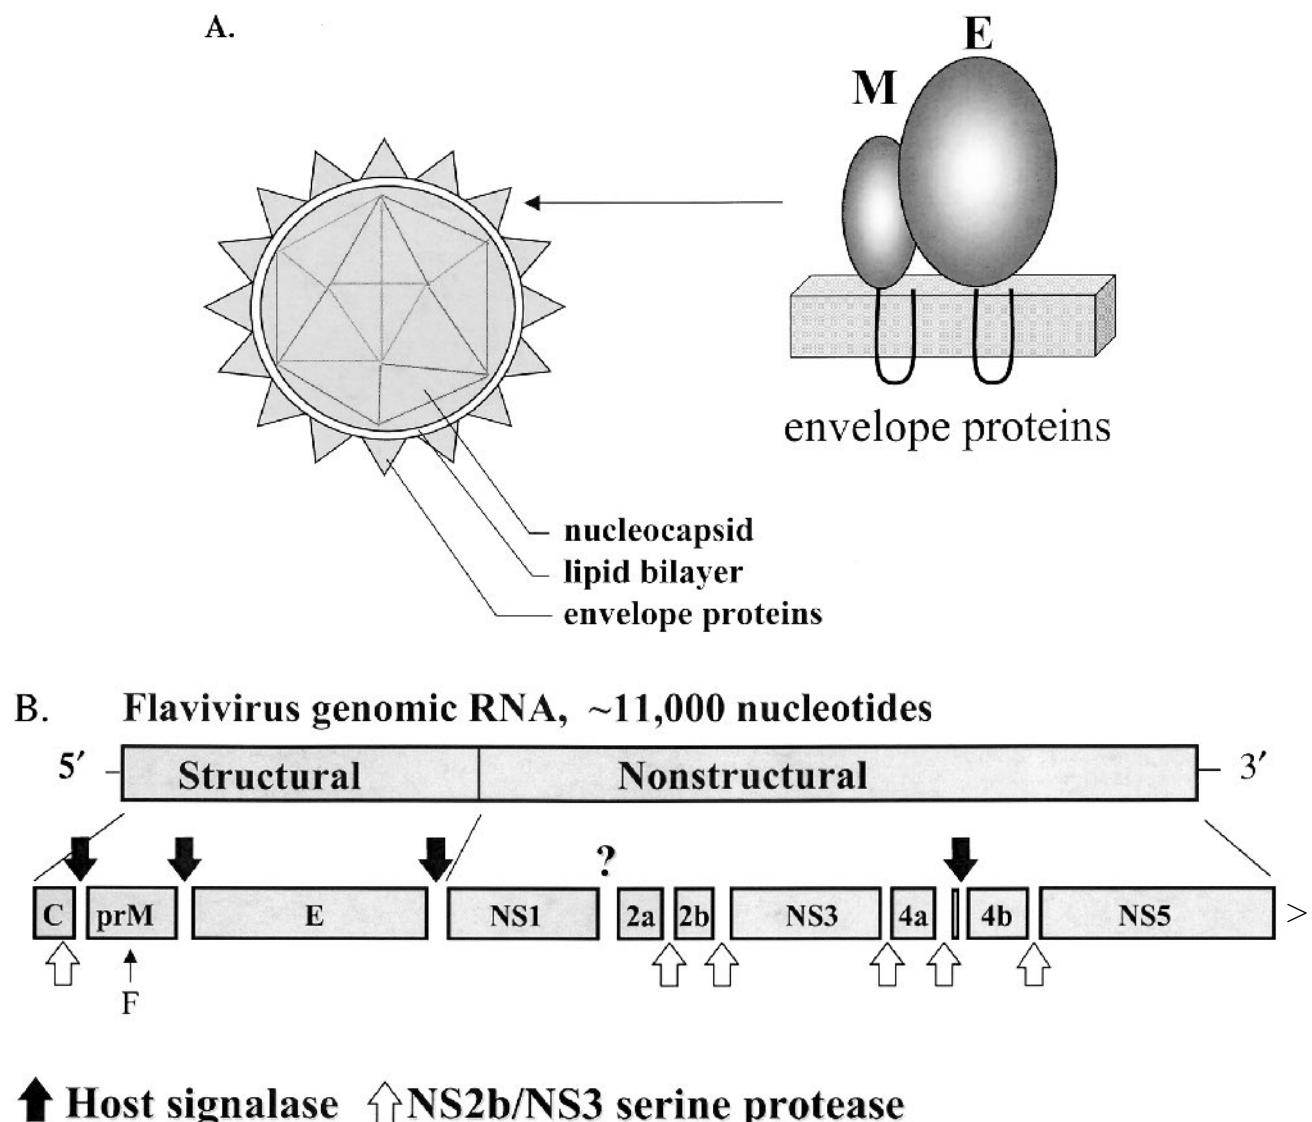

## II. ENEMIES AND A FRIEND

### A. Japanese Encephalitis Virus

In Asia, JE is a grave neurological disease of children with a case-fatality rate ranging from 5% to 40%. Three billion people are estimated to live in endemic regions. In the last 25 years, the incidence has intensified in certain countries, and the disease has extended its geographical range to previously unaffected areas of Asia and northern Australia [17,18]. More than 35,000 JE cases are reported officially each year, of which 5000–10,000 are fatal. A high proportion of survivors suffer from neurological and psychological sequelae. The virus is transmitted from infected animals, mainly domestic pigs, to humans by *Culex* mosquitoes. A mouse brain-derived, formalin-inactivated vaccine (Biken, Japan) is available internationally, and has significantly reduced disease rates in Japan, Republic of Korea, Taiwan, Sri Lanka, and parts of Thailand and Vietnam. The vaccine is 91% effective [19] and is administered in two primary doses, one booster at 1 year and subsequent boosters every 3 years. It has been associated with 0.6% rate of allergic reactions in adults, sometimes severe [17], and it is costly to manufacture. A live, cell culture-derived vaccine (attenuated SA14-14-2 strain produced in primary hamster kidney cells) is used in China. Although inexpensive and quite effective, it requires two doses for full protection [20] and has not been licensed for use outside China [17].

### B. Dengue

Dengue is a global public health problem occurring mostly in tropical regions of the world. Over 2 billion people in tropical Asia, Africa, Australia, and the Americas are at risk of infection. Annually, up to 100 million cases of dengue

**Figure 1** Flavivirus structure. A. Organization of the virion. Each viral particle contains a nucleocapsid composed of one genomic RNA molecule and the capsid protein C. Nucleocapsid is surrounded by a lipid membrane with embedded membrane M and envelope E proteins. B. Organization of the genome. The positive-sense RNA molecule encodes a long open reading frame, which is translated into a polyprotein precursor. Most of the individual viral proteins are produced by cleavages of the polyprotein by the cellular signalase (black arrows) and the viral NS2B/NS3 protease (open arrows). The prM protein (precursor for M) is cleaved by furin-like protease shortly prior to virus release (F). The C protein generated by the signalase cleavage ( $C_{\text{intracellular}}$ ) can only be found inside infected cells. Virions contain a carboxy-terminally truncated form of C ( $C_{\text{vir}}$ ) that is generated by the viral protease and lacks the signal peptide for prM.

fever and 450,000 cases of the more severe form of the disease, dengue hemorrhagic fever (DHF)/dengue shock syndrome (DSS), occur [1,21]. The majority of DHF/DSS cases occur in young children living in Asia, who suffer a case-fatality rate of 1–10%, depending on the quality of supportive medical care. The virus is transmitted to humans by *Aedes aegypti* mosquitoes. Dengue strains constitute a separate antigenic complex among flaviviruses. Four antigenically related, but distinct serotypes of DEN (types 1–4)

are recognized by cross-neutralization tests. The amino acid homology between the four serotypes is 63–68% (and up to 77% in the E protein), compared with 44–51% between DEN and other flaviviruses [1,22–24]. Infected individuals become protected against homotypic infection, probably for life, but cross-protection between serotypes is short, lasting for less than 12 weeks [25]. Therefore, repetitive infections with different serotypes occur. Epidemiological data indicate that the majority of cases of DHF/DSS occur in patients who

have previously encountered one of the serotypes, and became superinfected with a different serotype. This led to the emergence of the theory of immune enhancement of heterologous serotype infection because of the antibody-dependent enhancement of virus replication [26,27] and exacerbation of symptoms by preexisting cellular immunity [9,28]. Both virus-specified and host-related factors may influence the severity of the disease, because only a small subset of persons with secondary infections develops DHF (~3%). Alternatively, DHF may be caused by particularly virulent strains [29,30], and it has been suggested that anti-NS1 antibodies may cross-react with fibrinogen, thrombocytes, and endothelial cells triggering hemorrhage [31]. It is generally accepted that a dengue vaccine must be tetravalent, capable of inducing a robust protective immunity against all four serotypes simultaneously.

### C. West Nile Virus

The virus is widespread and prevalent in Africa, Middle East, some European and former USSR countries, India, and Indonesia, and has caused sporadic outbreaks of encephalitis in humans and horses (reviewed in Ref. [1]). In humans, the infection is typically self-limited, accompanied by mild flu-like symptoms that usually go unnoticed. Infection of the central nervous system (CNS) happens infrequently (roughly in 1 out of 300 infections), principally in the elderly. The transmission cycle of WN virus includes *Culex* mosquitoes and primarily birds, while humans and horses develop low viremias, insufficient for further transmission to mosquitoes.

Recent WN encephalitis outbreaks have been documented in traditionally endemic regions, such as in Romania, Democratic Republic of the Congo, southern Russia, and Israel, with 200–800 reported human cases and a 15% case-fatality rate in patients with encephalitis. But in 1999, the WN virus unexpectedly emerged for the first time in the Western Hemisphere, in North America. It debuted in the United States, in Queens, NY (and surrounding areas), resulting in 62 confirmed cases, including 7 deaths. The disease then reemerged in New York City in 2000, with 18 cases and 2 deaths. During 2000 and 2001, the virus successfully invaded nearly the entire eastern one-third of the country, causing deaths as far south as the state of Georgia. Based on nucleotide sequence data, the U.S. virus appears to have come from Israel, but the means is unknown. An intriguing feature of the virus in the United States is its high mortality in wild birds (e.g., crows and blue jays), which is conspicuously absent in the Old World, ironically facilitating its epidemiological surveillance in the United States (reviewed in Ref. [32]).

As with other flaviviruses, there is no specific antiviral drug treatment. Currently, there is no licensed WN vaccine for humans. All WN strains belong to a single serotype and are similar at the nucleotide sequence level, which should simplify the development of a vaccine with broad protection. There were hopes that the inactivated Biken JE vaccine (marketed in the United States as JE-VAX®, Aventis-Pasteur) could provide cross-protection from WN. However, recent studies have suggested that no detectable cross-reac-

tivity could be elicited in human volunteers vaccinated with JE-VAX® [33]. Besides the necessity of a new human WN vaccine, there is a need for a veterinary horse vaccine. Recently, Fort Dodge received a Department of Agriculture (USDA) approval to market their formalin inactivated vaccine for horses, and is developing a DNA vaccine using technology developed at the Centers for Disease Control (Ft. Collins, CO).

### D. Yellow Fever 17D—A Friend

The YF virus is the prototype member of the *Flavivirus* genus. Yellow fever was first clinically recognized in the seventeenth century and remained one of the most dreaded diseases in tropical areas of the world until the twentieth century, when an effective vaccine was finally developed. The symptoms of this highly lethal hemorrhagic fever transmitted to humans by *Aedes* mosquitoes include fever, hepatic, renal, and myocardial injury, hemorrhage, prostration, and shock. Today, due to the incomplete vaccination coverage, YF still affects approximately 200,000 persons a year, mainly in tropical South America and Africa, and continues to be a threat to people traveling to these regions [1,34]. Wild-type YF virus, strain Asibi, was first isolated in 1927 by inoculation of a rhesus monkey with blood of a patient in Ghana. In 1937, Theiler and Smith [35] reported the successful attenuation of this virus by multiple passages in mouse and chick embryo tissues that yielded the 17D vaccine strain. Since its development more than 60 years ago, the 17D vaccine has been administered to over 400 million people, with a remarkable history of safety and efficacy [36]. Yellow fever vaccines are currently manufactured in several countries (United Kingdom, Germany, France, United States, Russia, Brazil, Senegal, and Colombia) in embryonated chicken eggs under standards established by the World Health Organization (WHO) (Brazil uses a substrain of 17D called 17DD). The vaccine is well tolerated, with very few, usually mild, side effects (injection site pain, redness, headache, etc.) After vaccination, a low viremia is detectable during the first few days, not exceeding  $2 \log_{10}$  plaque-forming units (PFU) per milliliter. Because of a low viremia in vaccinated individuals and the fact that, in contrast to wild-type virus, the 17D virus does not replicate well in mosquitoes, vaccination cannot lead to dissemination of 17D in nature. Serious postvaccination complications (such as encephalitis or classical YF symptoms) are extremely rare. Vaccination is contraindicated in persons with immune deficiency disorders or taking immunosuppressive medications [34]. Because of the vulnerability of infants, the vaccine is not recommended in children under 9 months of age. Pregnancy is another contraindication. Congenital infection has been shown to occur (albeit at low rate, 1–2%), although not clearly associated with any harm to the fetus [34]. The period of onset of immunity is short. Ninety percent of vaccinees develop protective levels of YF neutralizing antibodies by day 10, and 99% by day 30 after vaccination. The immunity appears to be lifelong after a single dose. All the above features of the 17D vaccine are surrogate characteristics of an ideal vaccine, and validate the use of YF 17D virus in the construction of novel genetically engineered vaccines against other flavivirus diseases.

### III. INFECTIOUS CLONES OF FLAVIVIRUSES: THE TOOL

Since it was first successfully implemented some 20 years ago for bacteriophage Q $\beta$  [37] and poliovirus [38], infectious cDNA clones of RNA-containing viruses have become an invaluable tool for studying the mechanisms of viral replication and pathogenesis, as well as for developing modern, genetically engineered vaccines. An infectious cDNA clone is a DNA copy of a viral RNA genome, which is stably cloned (most frequently in bacteria), and can be easily manipulated in vitro. Various mutations can be introduced, and parts of genomes from different viruses can be swapped. To initiate virus replication, the cDNA template is converted to RNA via in vitro transcription, and appropriate substrate cells are transfected with the RNA transcripts. Alternatively, the infectious clone can be engineered in such a way that cells can be directly transfected with plasmid DNA. The DNA is then transcribed in the nucleus, and the resulting RNA exits into the cytoplasm to start normal virus replication cycle. The construction of a first flavivirus infectious clone was reported in 1989 for YF virus, strain 17D [39], followed by several strains of DEN types 1, 2, and 4 [40–45], JE [46], TBE [47], LGT [48], MVE [49], KUN [50], and WN [51] viruses. Construction of infectious clones is a very complicated task accompanied by many technical hurdles. Because of the toxicity of some flavivirus cDNA regions for *Escherichia coli*, it is sometimes difficult to assemble a stable full-length clone in one bacterial plasmid. Therefore researchers have to resort to splitting viral sequence into two [39,46] or three [52] pieces cloned in separate plasmids, which have to be ligated prior to in vitro transcription.

### IV. PREHISTORY OF ChimeriVax™

#### A. Dengue Intertypic Chimeras

The construction of the very first live flavivirus chimera was reported in 1991 by Bray and Lai of the National Institutes of Health (NIH; Bethesda, MD). They were able to replace the entire structural region, the C-prM-E genes, in the infectious clone of DEN4 (wild-type strain 814669) with the corresponding C-prM-E cassettes from DEN1 [Western Pacific strain (WP)] and DEN2 [New Guinea C (NGC), a laboratory strain neurovirulent for mice] [53]. Upon transfection of simian LLC-MK<sub>2</sub> cells with in vitro RNA transcripts, the DEN4/DEN1 and DEN4/DEN2 chimeras were readily recovered and grew to peak titers of  $5 \times 10^6$  and  $10^5$  PFU/mL, respectively. The DEN4/DEN2 virus grew slower and produced smaller plaques compared to its parent NGC virus. Suckling (3-day-old) mice inoculated intracerebrally (i.c.) with both the neuroadapted DEN2 NGC and the chimeric DEN4/DEN2 viruses developed encephalitis and died. There was, however, a 3- to 5-day delay in death caused by the chimera, while both the DEN1 WP and DEN4/DEN1 viruses were not neurovirulent. Later, other chimeras between DEN4 and DEN2 were successfully generated, containing the prM-E cassette (without C) or only NS1 gene from DEN2 in place of the corresponding genes in the DEN4 backbone [54]. Both the prM-E and NS1 chimeras grew

efficiently in mosquito C6/36 cells ( $10^6$  and  $2 \times 10^7$  PFU/mL, respectively). However, it is intriguing that attempts to produce a chimera containing all four DEN2 C-prM-E-NS1 genes failed [54]. A DEN4/DEN3 chimera containing the C-prM-E genes from a wild-type DEN3 strain CH53489 was also obtained and shown to replicate to a high titer in mosquito C6/36 cells ( $10^6$  PFU/mL) [55].

These studies indicated that the engineering of live intertypic dengue chimeras by replacement of the structural proteins (as well as NS1) is possible. Further genetic analysis of these and other similar chimeras based on the DEN4 background yielded valuable information on genetic determinants of neurovirulence of DEN viruses in mice [54–56]. Next, the ability of these viruses to replicate efficiently in nonhuman primates and to induce a protective immunity (precluding replication of corresponding wild-type DEN viruses upon challenge) was addressed [57]. Both the DEN4/DEN1<sub>C-prM-E</sub> and DEN4/DEN2<sub>prM-E</sub> chimeras inoculated subcutaneously (s.c.) into rhesus monkeys (4 animals per virus;  $3 \times 10^5$  PFU per dose) induced detectable short-lived viremias in half and all inoculated monkeys, respectively, as well as respective homologous type-specific neutralizing antibodies. Antibody titers ranged from 1:640 to 1:1,280 in most animals, which was similar to titers observed in control animals inoculated with the wild-type parents. After challenge at 66 days postimmunization with corresponding wild-type DEN viruses (DEN1 or DEN2), no viremia could be detected in the majority of immunized monkeys, while it was pronounced in all unimmunized animals. Similarly, monkeys immunized with a mixture of the two chimeras (DEN4/DEN1<sub>C-prM-E</sub> and DEN4/DEN2<sub>prM-E</sub>) developed high titers of both DEN1- and DEN2-specific neutralizing antibodies (generally ranging between 1:320 and 1:640). Animals were solidly protected from challenge with both wild-type DEN1 and DEN2, even despite the fact that the DEN4/DEN2 chimera clearly outgrew the DEN4/DEN1 chimera in the doubly immunized animals as evidenced by the analysis of postimmunization viremias [57]. These data confirmed the theoretical possibility of constructing a tetravalent dengue vaccine composed of chimeric viruses based on the genetic background of one flavivirus. In this particular case, the DEN4 genetic background was used, which may sensitize vaccinees to DEN4-primed DHF. On the other hand, the backbone of these viruses was a pathogenic virus. Thus some of the created chimeras might be pathogenic for humans per se. In addition, they may be efficiently transmitted in nature by mosquitoes. The latter two issues were recently addressed by the introduction of various nonlethal deletions into the 5' and 3' UTRs of the DEN4 infectious clone. This resulted in an array of variants with altered characteristics in terms of plaque morphology and reduced growth rates in simian and/or mosquito cell cultures, or in *Aedes* mosquitoes [58,59]. Some of the 3'-UTR deletions, such as the deletions of nt 303–183 and 172–113 (numbering from the 3' end of the genome), resulted in a marked reduction of viremia in rhesus monkeys compared to wild-type DEN4. Nevertheless, those variants were able to induce high DEN4 neutralizing antibody titers (geometric mean titers of 1:334 and 1:115, respectively, compared to 1:337 for wild-type virus) [59].

Another possibility to create a safer backbone could be the introduction of attenuating point mutations affecting functions of the nonstructural genes [60]. However, the theoretical disadvantage of this approach is that the mutations could back-mutate more easily than defined deletions, returning the virus to its original virulent phenotype. In any case, the vector virus, DEN4 containing 3'-UTR deletions has recently been tested in humans, and appeared to be both safe and immunogenic (Durbin, A., presentation at Annual Meeting, Am. Soc. Trop. Med. Hyg., Atlanta GA, Nov. 13, 2001).

Recently, scientists from the CDC (Fort Collins, CO) and Mahidol University (Bangkok, Thailand) have adopted the above strategy to design a different set of intertypic DEN chimeras [61]. They chose the PDK-53 strain of DEN2 as a backbone, which offers several principal advantages over the wild-type DEN4 backbone. This virus is one of the four attenuated DEN vaccine candidates (DEN1 PDK13, DEN2 PDK-53, DEN3 PGMK-30/FRhL-3, and DEN4 PDK-48) that were originally obtained at Mahidol University [62] by multiple passages of wild-type isolates in primary dog kidney cells or PGMK/FRhL cells for DEN3. These empirically derived vaccines are currently being tested in a tetravalent formulation by Aventis-Pasteur (Lyon, France). The DEN2 PDK-53 candidate vaccine has the lowest infectious dose in humans (only 5 vs. 10,000 PFU for DEN1 PDK-13 virus, for example), is highly immunogenic, and appears to have a satisfactory safety profile. In contrast to its wild-type parent DEN2 strain 16681, its replication is restricted in *Aedes albopictus* C6/36 cells [42] and *A. aegypti* mosquitoes [63]. Thus this attenuated DEN2 backbone appears to be superior to the DEN4 backbone described above in terms of safety. In addition, attenuation determinants of the PDK-53 virus have been identified that are responsible for its small-plaque phenotype, temperature-sensitivity, reduced replication in C6/36 cells, and low neurovirulence in newborn mice [64]. The three major attenuation markers (C to T change at nt 57 in the 5' UTR, Gly to Asp amino acid change at NS1-53, and Glu to Val change at NS3-250) were mapped outside the structural protein region. Because all the attenuating mutations in the DEN2 PDK53 vector reside outside the structural region, it should be possible to construct chimeras containing the C-prM-E region from any heterologous donor dengue serotype or strain, and expect that the non-structural genes of the vector would confer acceptable properties of safety and immunogenicity. Chimeras with the donor genes, for example, of either the DEN1 attenuated strain PDK-13 or its wild-type parent, DEN1 strain 16007 [61] would have a good potential as safe vaccine candidates. Three variants of the chimera containing the structural genes from the wild-type DEN1 were immunogenic in 3-week-old outbred ICR mice ( $10^4$  PFU/dose; mean titers of anti-DEN1 neutralizing antibodies ranging between 1:40 and 1:160 after primary immunization and 1:2560–1:10,240 after secondary boost). Interestingly, however, the other variants with the structural genes from the attenuated DEN1 strain appeared to be significantly less immunogenic. Chimeras based on this backbone for the other three serotypes are being constructed. Some concerns about whether this genetic background will potentiate DHF in vaccinees encountering DEN

viruses in nature still remain. It is also impossible to examine the potential of these viruses to lead to DHF in any models other than humans. Therefore clinical field trials will be the ultimate test.

## B. Chimeras Between Unrelated Flaviviruses

The construction of the intertypic DEN chimeras described above was a major breakthrough and stimulated experimentation with other flaviviruses. However, it did not guarantee that viable chimeras between unrelated flaviviruses from different serocomplexes could be made. The first report on the construction of a viable chimera between two distinct flaviviruses, a mosquito-borne DEN4 and a tick-borne TBE virus, was published by Pletnev and coworkers in 1992 [65]. The same DEN4 genetic background described above was used (DEN4 wild-type strain 814669). A construct containing the prM-E genes from a highly virulent Russian isolate of TBE (Far Eastern subtype, strain Sofjin) readily yielded viable virus following transfection of LLC-MK<sub>2</sub> cells. The DEN4/TBE<sub>prME</sub> chimera grew to a titer of  $10^8$  PFU/mL in these cells, which was ~1000 times greater than the parental DEN4 virus, but replicated ~100 times less efficiently than DEN4 in mosquito C6/36 cells (a peak titer of roughly  $10^4$  PFU/mL). A chimera containing the TBE C-prM-E genes was also viable, but crippled in terms of its replication compared to the prM-E chimera. The latter fact could be attributed to a number of possible reasons, including the inefficient encapsidation of the hybrid genomic RNA by the TBE-specific C protein, the disruption of viral RNA cyclization essential for viral RNA synthesis [66], and the inefficient cleavage at the C-terminus of the TBE-specific C protein by the DEN4-specific viral protease that generates the mature form of C (C<sub>vir</sub>; see Figure 1B) [67,68]. Attempts to generate other chimeras containing TBE-specific prM-E-NS1 or E-NS1 cassettes, or singly C, E, or NS1 genes, also did not result in viable viruses [65]. As discussed above, the DEN4/DEN2<sub>NS1</sub> chimera was viable [54]. Therefore in contrast to closely related DEN types, it appears that NS1 is not easily interchangeable between distant flaviviruses. This is not surprising if NS1 is a component of a very delicate RNA replication complex that could be highly restrained in terms of structural compatibility of all participating proteins. Recent data from trans-complementation studies in vitro seem to support this point of view. Specifically, the YF virus with an engineered in-frame deletion of the entire NS1 gene could not replicate in cells expressing DEN2-specific NS1 protein. However, replication of the deletion mutant in these cells was restored in selected variants, each containing a specific mutation in NS4A protein, one of the components of the viral replicase [7].

The DEN4/TBE<sub>prM-E</sub> chimera remained highly neurovirulent for both suckling and adult BALB/c mice, causing 100% mortality at the doses tested ( $10^2$  and  $10^3$  PFU, respectively) [65]. Surprisingly, the chimera completely lost its neuroinvasiveness (the ability to invade the brain upon peripheral inoculation). It induced protective immunity in mice [65,69].

In hopes to obtain a better, less neurovirulent TBE vaccine candidate, viable DEN4-based chimeras containing

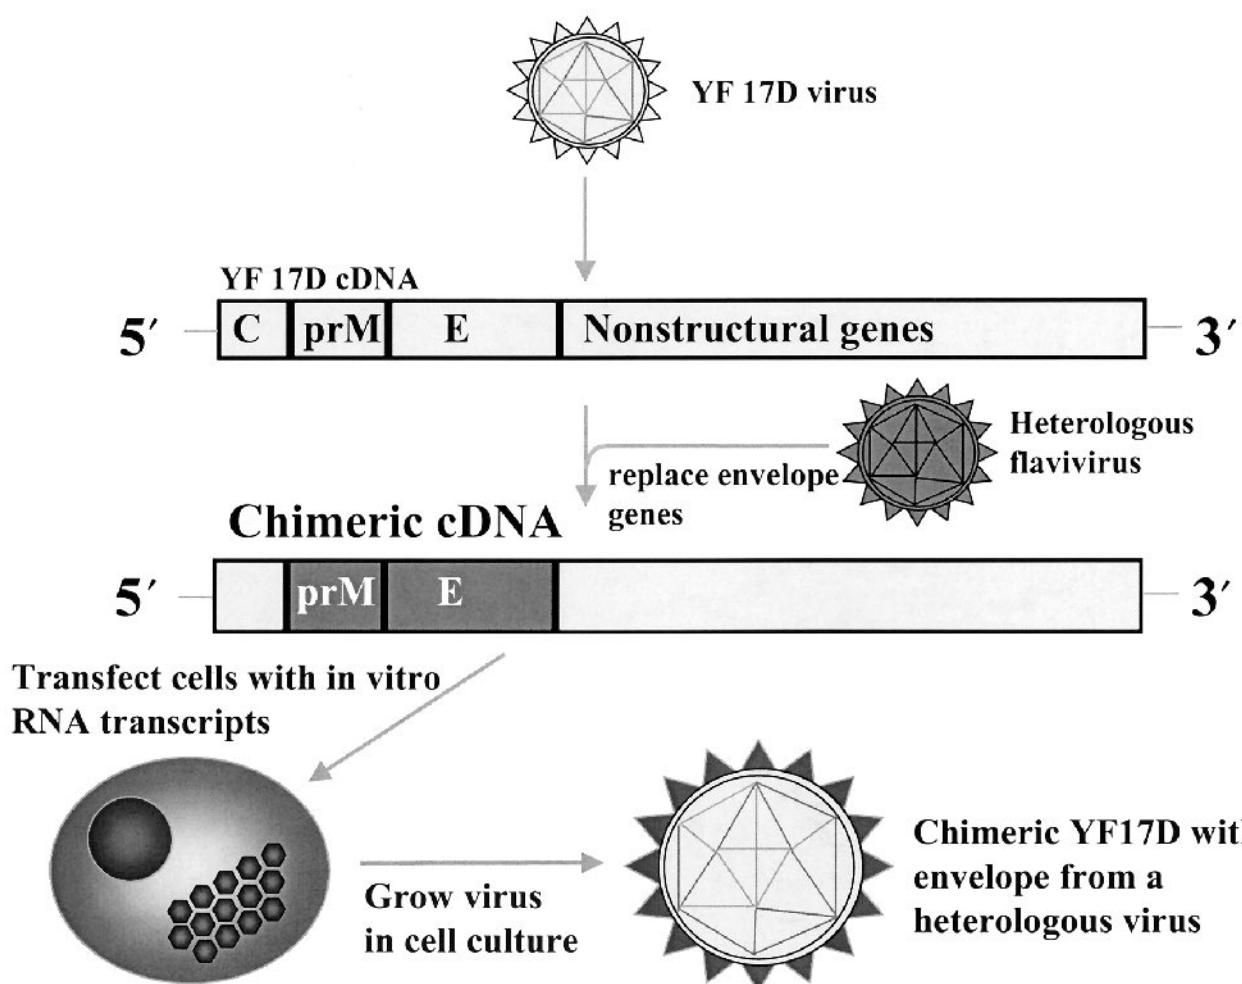

the prM–E genes from LGT virus (wild-type TP21 and its attenuated E5 derivative strains) were constructed. LGT is a member of the TBE serocomplex and provides strong cross-protection against TBE, but has been associated with very rare cases of human illness [70]. Attempts to generate other chimeric variants containing the LGT-specific C-prM-E, NS1-NS2A, NS1-NS2A-NS2B-part of NS3, and NS2B-NS3 cassettes failed, again suggesting that the prM-E genes are easily interchangeable while the others are not. Interesting peculiarities were observed with these DEN4/LGT<sub>prM-E</sub> chimeras compared to the DEN4/TBE<sub>prM-E</sub> virus. They could only be produced by transfection of mosquito C6/36 cells, but not of simian LLC-MK<sub>2</sub> cells, and initially they grew well only in these mosquito cells (peak titer of up to 10<sup>6</sup> PFU/mL). In contrast, the DEN4, LGT E5, and LGT TP21 parents replicated efficiently in both LLC-MK<sub>2</sub> and Vero cells (titers of 6–9 log<sub>10</sub> PFU/mL). The chimerization resulted in approximately 6000-fold reduction of neurovirulence of both TP21 and E5. Both chimeras were completely

nonneuroinvasive in outbred Swiss mice as well as in more susceptible immunodeficient SCID mice [70,71]. It was recently shown that the DEN4/TP21 chimera induced barely detectable viremia in inoculated rhesus monkeys but, nevertheless, was highly immunogenic in this model at all tested doses (10<sup>3</sup>, 10<sup>5</sup>, or 10<sup>7</sup> PFU). It did not replicate in nonhematophagous mosquitoes *Toxorhynchites splendens*, which are highly permissive for DEN viruses [72].

## V. CHIMERIVAX™ VACCINES

### A. ChimeriVax™ -JE

Early reports on the construction of intertypic dengue chimeras and DEN4/TBE were a prelude to the ChimeriVax™ technology (illustrated in Figure 2), the essence of which is the use of the best characterized and safest flavivirus backbone available, that of the YF 17D vaccine. It started with the work of Chambers and coworkers, who

**Figure 2** The ChimeriVax™ technology. The prM–E genes of the YF 17D virus are replaced with their analogs from a heterologous flavivirus. The C/prM junction is at the signalase cleavage site (see Figure 1B). Chimeric virus is produced following transfection of appropriate culture cells. Its new envelope induces a robust protective immunity in inoculated animals against the heterologous virus infection/pathology.

succeeded in the construction of first YF 17D chimeras containing the prM-E genes (but not C-prM-E) from either a virulent strain of JE virus, Nakayama, or the attenuated JE vaccine strain SA14-14-2 [73]. The chimeric viruses were obtained by transfection of simian Vero cells and had the antigenic specificity of JE virus (i.e., were neutralized by anti-JE specific antibodies but not by anti-YF antibodies). They efficiently replicated in several simian, human, mouse, and mosquito cell cultures. Similar to the YF17D parent, the YF/JE-Nakayama chimera remained neurovirulent for 3-week-old ICR mice. In contrast to its parent Nakayama, it was not neuroinvasive in ICR mice and was only partially neuroinvasive in C57/BL6 mice, indicating that a significant degree of attenuation had been attained by chimerization. Most importantly, the YF/JE-SA14-14-2 chimera (as well as the SA14-14-2 donor strain) was completely avirulent in mice by both i.c. and i.p. routes, even at the highest tested i.c. dose of  $6 \log_{10}$  PFU. This indicated that the use of the SA14-14-2-specific envelope provided an additional degree of attenuation. Later, we investigated relative contribution of each of the 10 amino acid differences between the SA14-14-2-specific and Nakayama-specific E protein to the attenuation. The results showed that E to K mutation at E138 had a dominant attenuating effect, but multiple simultaneous reversions in at least three distinct clusters were required to restore the high neurovirulence of YF/JE-Nakayama virus [74]. The YF/JE-SA14-14-2 virus was subsequently chosen as a primary candidate chimeric JE vaccine designated ChimeriVax™-JE and was further evaluated in cell culture and mouse model [75] (Table 2).

The ChimeriVax™-JE virus grew to titers in excess of  $7 \log_{10}$  PFU/mL in Vero cells, a cell line acceptable for human vaccine production. C57/BL6 mice immunized s.c. with  $10^3$  PFU (or more) of the chimera were solidly protected from subsequent i.p. challenge with 158 LD<sub>50</sub> doses of the virulent JE strain IC-37. The virus was completely avirulent in adult ICR mice by the i.c. route, despite efficient replication in mouse brains reaching a peak titer of  $6 \log_{10}$  PFU/g of brain tissue on day 6 postinoculation, which then declined to undetectable levels by day 12. The neurovirulence test in infant mice was found to be a sensitive marker of the attenuated phenotype of ChimeriVax™-JE. Infant mice (3–5 days old) were sensitive to i.c. inoculation, but became

resistant to the virus around 7 days of age, at which point the mortality rate was 40% (at a dose of  $10^4 \log_{10}$  PFU). For comparison, 66% of 8-day-old mice were killed by only  $1.4 \log_{10}$  PFU of YF 17D, and thus, ChimeriVax™-JE was significantly less neurovirulent in this model than the commercial YF vaccine. The chimera was also found to be highly genetically stable, which is an important feature of a candidate vaccine. All putative attenuating SA14-14-2-specific mutations were preserved after 18 passages in cell culture or six brain-to-brain passages in mice, and there was no increase in neurovirulence [75].

The ChimeriVax™-JE virus was then extensively tested in a nonhuman primate model for its safety and immunogenicity [76,77] (Tables 2 and 3). Undiluted ChimeriVax™-JE as well as YF 17D virus were inoculated i.c. into rhesus macaques, followed by observation of clinical signs, viremia measurements, clinical laboratory tests, as well as pathological examination of the brain, spinal cord, and extraneuronal organs. Low, similar viremias were observed in all monkeys inoculated with YF 17D or ChimeriVax™-JE. ChimeriVax™-JE caused no clinical signs, while some monkeys inoculated with YF 17D developed transient mild encephalitis. Neither hematological or biochemical serum abnormalities, nor histopathologic changes in liver, spleen, kidney, heart, or adrenal glands were detected, demonstrating the lack of ChimeriVax™-JE-induced pathology. Lesion scores in all animals that received ChimeriVax™-JE were statistically significantly lower compared to YF 17D. Upon peripheral (s.c.) inoculation, all monkeys also developed low, self-limited viremias, similar to those induced by the YF 17D vaccine (Table 2). The low level of viremia suggested that the likelihood of neuroinvasion as well as the capacity of the host to serve as a source of infection for blood-feeding mosquitoes is low.

To demonstrate protective properties of ChimeriVax™-JE in nonhuman primates, an efficient challenge model had to be first developed that relied on the i.c. inoculation of rhesus monkeys with a large dose of a wild-type JE virus ( $\sim 5 \log_{10}$  PFU of IC37 strain) [76], because these animals do not develop illness after parenteral inoculation. Because natural infection occurs by intradermal injection of small doses of virus, this challenge model is a very severe test of vaccine efficacy.

**Table 2** Attenuation/Safety Phenotype of ChimeriVax™/JE in Animal Models as Compared to YF 17D [32,75–78]

<sup>a</sup> i.c. LD<sub>50</sub> in  $\log_{10}$  pfu.

<sup>b</sup> Mean values after i.c. inoculation; scoring methods described in Refs. [76,77].

<sup>c</sup> Mean values after s.c. inoculation ( $\log_{10}$  pfu/mL for viremia).

<sup>d</sup> Titers in mosquitoes in  $\log_{10}$  pfu/mosquito; IT, intrathoracic inoculation; OF, infection by oral feeding; in comparison, JE virus strains (both wild-type and vaccine SA14-14-2) grew to titers of  $\sim 6 \log_{10}$  pfu/mosquito in both species by either route [78].

All animals immunized s.c. with graded doses of ChimeriVax™-JE (varying from 2 to 5.3 log<sub>10</sub> PFU) developed high titers of neutralizing antibodies (Table 3) [76,77]. They were solidly protected from i.c. challenge with wild-type JE virus, judged by the absence of viremia and clinical encephalitis (except for one monkey which turned out to be pregnant; whether pregnancy played a role is unknown, but it is a contraindication for YF 17D vaccination). These results provided strong evidence that ChimeriVax™-JE had a very good potential as a safe and robust human vaccine.

Three Phase I/II clinical trials of ChimeriVax™-JE vaccine have been carried out in healthy adult volunteers. It was demonstrated that the vaccine is well tolerated and fully immunogenic after a single inoculation of 4 or 5 log<sub>10</sub> PFU of the virus. In one trial, subjects with or without prior immunization against YF were vaccinated with ChimeriVax™-JE. All 24 subjects (100%) developed JE virus-specific neutralizing antibodies. Interestingly, the mean neutralizing antibody titers were higher in the YF-immune subjects, indicating that anti-YF vector immunity (e.g., T-cell-mediated immunity to the YF-specific nonstructural proteins) did not preclude, and indeed may have enhanced, immune responses to the envelope proteins of this YF-based chimeric vaccine. In another trial, 10 subjects vaccinated with ChimeriVax™-JE 9 months earlier, and 10 control subjects were challenged with one standard dose of formalin-inactivated JE vaccine (noninfectious JE antigen representing a surrogate for exposure to live virus). The vaccinated subjects responded with a significant rise in JE-specific neutralizing antibody titers (mean titers were 20- and 100-fold higher on days 7 and 14 postchallenge, respectively, compared to prechallenge titers), while none of the control subjects developed antibodies by day 7, and only 2 out of 10 had any detectable antibody response within the 30-day observation period [differences in titers between the treatment groups were statistically significant on all study days ( $P < 0.001$ )]. Thus a strong anamnestic immune response, which is an important prerequisite of vaccine effectiveness, was observed in the vaccinated subjects.

Finally, the concern about whether ChimeriVax™-JE can infect insects feeding on the blood of vaccinees was

addressed. The YF 17D vaccine lost its ability to infect mosquitoes in the process of its attenuation. In contrast to the JE SA14-14-2 parent virus, ChimeriVax™-JE was unable to infect *Aedes* and *Culex* mosquitoes by oral feeding and replicated poorly following direct intrathoracic inoculation (Table 2), suggesting that the restricted mode of replication is specified by the YF 17D nonstructural proteins [78]. Together with the fact of low viremias in vaccinees, these data make the possibility of uncontrolled spread of chimeras in nature very unlikely.

### B. ChimeriVax-DEN Tetravalent Vaccine

The first viable YF 17D/DEN chimera was constructed by Chambers and coworkers using the prM-E genes from PUO-218 strain of DEN2 virus isolated from a case of dengue fever in Thailand [79]; this construct became ChimeriVax™-DEN2. Interestingly, initial attempts to produce a similar chimera by a group from Brazil failed [80]. Close examination of the cloning strategies used by the two groups revealed that the latter initially followed the approach of Pletnev and coworkers for the DEN4/TBE chimera. They attempted to fuse the 5' end of the DEN2 prM gene with the 3' end of the YF C gene at the C<sub>virion</sub>/C<sub>intracellular</sub> cleavage site and thus, the signal peptide for prM was DEN2-specific, whereas Chambers et al. retained the YF-specific signal sequence (Figure 1B). Our working hypothesis to explain this phenomenon is that the length of the signal peptide makes a principal difference. While the YF and TBE parental viruses both contain a 20-amino acid-long signal, the DEN2 and DEN4 parents contain a shorter, 14-amino acid signal. Thus it appears that when the DEN4-backbone is used to create a chimera, the short DEN4-specific signal can be replaced with the long TBE-specific signal, resulting in a viable chimera (DEN4/TBE). However, when the long YF-specific signal is replaced with the short one of DEN2 (Brazilian group), no viable recombinant virus can be recovered. It is possible that the replacement of a long signal with a short one renders the C<sub>vir</sub>/C<sub>int</sub> cleavage site inaccessible for the viral NS2B-NS3 protease, possibly because it becomes buried inside the ER mem-

**Table 3** Immunogenicity of ChimeriVax™/JE in Rhesus Monkeys: Animals Were Immunized with Different Graded Doses of the Chimera and Later Challenged I.C. with Wild-Type JE Virus [76,77]

brane. Cleavage at this site was shown to be critical for virus replication [67,68]. When the YF-specific signal is preserved in YF/DEN2 chimera (Chambers' approach), the virus is viable. Consistent with this view, when we experimentally replaced the YF-specific signal with the short DEN2-specific signal in the ChimeriVax™-DEN2 virus, viability was lost (C. Miller and J. Arroyo, Acambis Inc., unpublished data). The Brazilian group eventually succeeded when the Chambers' approach was implemented [80]. A third group engineered another YF 17D/DEN2 chimera and demonstrated that it induced robust CD8<sup>+</sup> T-cell response directed against the DEN2-specific prM-E envelope proteins in immunized mice [81].

Recently, we reported the construction of the three additional YF 17D/DEN chimeras, ChimeriVax™-DEN1, 3, and 4 containing the prM-E cassettes from wild-type DEN1 PUO 359 (isolated in 1980 in Thailand), DEN3 PaH881/88 (Thailand-1988), and DEN4 1228 (Indonesia-1978) strains [52]. These viruses were recovered after the transfection of Vero cells, and efficiently replicated in this vaccine substrate cell line to similar titers of  $\sim 7.5 \log_{10}$  PFU/mL (except for DEN3 chimera which produced 10-fold lower titers). They demonstrated the same low neurovirulence profile described above for ChimeriVax™-JE in that they were completely avirulent in adult outbred ICR mice (inoculated i.c. at doses of up to  $6 \log_{10}$  PFU) and significantly less neurovirulent in suckling mice, compared to the YF 17D parent (which is lethal for mice of all ages inoculated by the i.c. route) [52,79]. No increase in mouse neurovirulence was observed after the DEN2 chimera was passaged 18 times in Vero cells, suggesting its genetic stability and safety profile [79].

The four DEN chimeras were then evaluated in rhesus monkeys for their safety, as judged by the levels of induced viremia, and protective efficacy, judged by the levels of

corresponding DEN-specific neutralizing antibodies and protection against challenge [52,79]. Monkeys inoculated s.c. with one dose of these chimeric viruses as monovalent ( $\sim 4 \log_{10}$  PFU) or tetravalent ( $5.3 \log_{10}$  PFU total) formulations developed brief viremia with magnitudes similar to that of YF 17D (mean peak titers of  $0.7\text{--}1.65 \log_{10}$  PFU/mL), but significantly lower than those of their parent wild-type viruses ( $2.2\text{--}4.9 \log_{10}$  PFU/mL). They produced neutralizing antibodies of expected type-specificities. Interestingly, in one experiment in which graded doses of ChimeriVax™-DEN2 were administered (2, 3, 4, and  $5 \log_{10}$  PFU/dose), animals from the lowest-dose group had viremia similar in magnitude and duration (although slightly delayed) to the other groups (mean peak titer of  $\sim 1.5 \log_{10}$  PFU/mL and mean duration of  $\sim 4$  days). Similar levels of neutralizing antibodies were produced (mean titer of  $\sim 1:320$  across all groups on day 30), indicating that the vaccine may be effective even at a dose as low as  $2 \log_{10}$  PFU [79]. Sixty-two days postimmunization, these animals were challenged by the s.c. route with  $5.0 \log_{10}$  PFU of a wild-type DEN2 virus. No viremia was detected in any of the vaccinated groups, demonstrating the effectiveness of immunization, whereas all animals in the placebo control group developed high viremia of the challenging virus. Importantly, a strong anamnestic response was observed after challenge of ChimeriVax™-DEN2-vaccinated animals, with an increase in mean neutralizing antibody titers of about 10-fold.

Because the final dengue vaccine will contain all four chimeras, the behavior of these viruses after being administered as a tetravalent mixture is of critical importance. Ideally, all four components should replicate equally well and induce uniform immune response to all four dengue serotypes. This is not an easy goal because rates of replication in vivo can be different for these viruses, and because they presumably target the same cells and tissues of the body,

**Table 4** Properties of Tetravalent ChimeriVax™-DEN Vaccine in YF-Immune or Nonimmune Rhesus Monkeys [52]<sup>a</sup>

they may interfere with each other. In this regard, in our first published experiment with the tetravalent ChimeriVax™-DEN candidate, we observed that ChimeriVax™-DEN2 induced noticeably higher viremia in rhesus monkeys inoculated with a mixture of equal amounts of the four chimeras ( $4.7 \log_{10}$  PFU of each virus,  $5.3 \log_{10}$  PFU total dose) compared to the other three [52]. The animals seroconverted to all four DEN serotypes after first inoculation, although the neutralizing anti-DEN2 titers in the sera were higher (mean titers on day 180 postvaccination of 1:142, 1:905, 1:127, and 1:71 against DEN1 through DEN4, respectively) (Table 4). Nevertheless, a second inoculation with the tetravalent mixture resulted in higher and more uniform titers (1:640, 1:1810, 1:452, and 1:359, respectively) demonstrating that a two-dose immunization regimen can be a good alternative to achieve the same goal [52]. No viremias were detected in these animals after the boost, indicating that the primary immunization was already completely protective.

The issue of antivector immunity was also addressed in these experiments [52,79]. For example, vaccinia recombinants expressing JE virus genes (NYVAC-JEV) failed to induce JE-neutralizing antibody response in vaccinia virus-immune volunteers [82]. The mechanism of antivector immunity in the case of ChimeriVax™ viruses would involve CTL responses against YF 17D nonstructural proteins or cytolytic antibodies against YF 17D NS1. In our studies, no statistically significant difference was observed in the levels of DEN-specific neutralizing antibodies in YF virus-immune and nonimmune monkeys that received the tetravalent ChimeriVax™-DEN vaccine (or only DEN2 chimera) (see Experiment 2 in Table 4). These data together with those obtained from ChimeriVax™-JE clinical trials indicate that antivector immunity will not be a significant factor limiting the practical use of chimeric vaccines or vice versa.

### C. ChimeriVax™-WN

ChimeriVax™-WN has been constructed using the prM-E genes from the New York-1999 strain that was introduced into the Northern Hemisphere just 2 years ago. The chimeric virus was recovered from the supernatant of transfected Vero cells and replicated to titers in the excess of  $7 \log_{10}$  PFU/mL in this culture [32]. Based on the extensive knowledge of attenuating residues in the closely related JE virus, a number of attenuating mutations were introduced singly or in different combinations into its wild-type envelope in order to obtain a safer, more attenuated virus. The wild-type chimera, as well as variants with additional mutations, were examined in mice with the result that the original construct was highly attenuated. Thus it is possible that no additional attenuation of this virus will be necessary.

The virus was also tested in horses and was shown to elicit WN-specific neutralizing antibodies and protection against challenge (J. Arroyo and R. Bowen, unpublished data).

## VI. CONCLUSION

The recent advances of molecular biology opened doors to the development of principally new recombinant flavivirus

vaccines currently championed in terms of their high promise by chimeric vaccine candidates, particularly ChimeriVax™ vaccines that were constructed based on one of the most effective and safest vaccines available, YF 17D. The accumulating body of evidence demonstrates their high replication efficiency, the highly attenuated phenotype in animal models (as well as in humans), robust immunogenicity and protective efficacy, and high genomic stability. Other important issues, such as the effect of antivector immunity and infectivity for mosquitoes, were addressed. The opportunity that we now have to help save lives of thousands of people worldwide with these new vaccines is breathtaking.

### I. CHALLENGES AND PROSPECTS FOR THE DEVELOPMENT OF HIV/AIDS VACCINES

Not since the Black Death of Europe during the middle ages has an infectious disease caused a global public health crisis on the same scale as the human immunodeficiency virus type 1 (HIV-1) pandemic. The acquired immune deficiency syndrome (AIDS), first described in the early 1980s, has reached the far corners of the globe, and has now become the leading cause of death for many populations throughout the developing world. According to recent UNAIDS estimates, at least 40 million adults and children have been infected with HIV-1, the virus that causes AIDS, and it is estimated that approximately 14,000 new infections occur daily or roughly 5 million new infections annually. The global burden of HIV/AIDS is most notable in Sub-Saharan Africa where over 70% of all infections have occurred and where the prevalence of HIV-1 has risen above 25% of the adult population in some countries within the southern region of Sub-Saharan Africa. Current projections indicate that while the epidemics in countries such as Botswana and the Republic of South Africa may have already peaked, having already reached saturation levels in at-risk populations, the next phase of the pandemic is rapidly expanding in other countries. For instance, recent reports indicate that Nigeria, Ethiopia, India, China, and Russia, nations with very large populations, are now experiencing burgeoning epidemics

that will likely have a serious regional impact on the epidemiology of the HIV/AIDS pandemic. These countries, which are now in the early growth phase of their respective epidemics, will likely experience a rapid increase in HIV incidence inevitably followed by a growing number of AIDS cases over the next decade. Even with serious efforts toward HIV/AIDS prevention and the effective implementation of public health measures, populations within these countries and their respective surrounding geographical regions are going to experience an increasing burden of disease that will be unprecedented in magnitude compared to any other single cause. To compound the problem, over 95% of HIV infections occur in resource-poor settings without ready access to antiretroviral treatment (ART) and where formidable challenges to the effective delivery and monitoring of ART still remain. In short, the HIV/AIDS pandemic represents the most serious infectious disease threat to global public health in history, and requires the urgent development of an effective vaccine that can control the epidemic spread of infection and can reduce the global burden of HIV/AIDS-related disease.

#### A. Challenges for Vaccine Development

Despite two decades of intense biomedical research into the biology of HIV and the pathogenesis of HIV/AIDS, basic questions regarding the underlying immunopathogenic mechanisms and determinants of effective antiviral immunity still remain. With the exception of those rare individuals harboring genetic mutations within genes expressing viral coreceptors (i.e., delta-32 CCR5), immunological correlates of protection in humans remain unknown or controversial. There are also inherent biological properties of HIV that make vaccine development a daunting task. Although not the focus of this chapter, it is important to note some of these

---

The authors wish to respectfully dedicate this chapter to Dr. Mary Lou Clements. Dr. Clements wrote the chapter for the previous edition of this book, and many of the studies reported here were influenced by her work prior to her untimely death on September 2, 1998 caused by the SwissAir 111 accident.

key factors including: (a) HIV's ability to establish molecular latency and persist in reservoirs of long-lived CD4<sup>+</sup> T cells; (b) its ability to infect immunoprivileged sites, such as the brain and eyes, that are relatively sequestered from immune responses; (c) its cellular tropism and preference to infect HIV-specific CD4<sup>+</sup> T lymphocytes, creating the potential for vaccine-induced CD4<sup>+</sup> T cells to provide a conduit rather than a barrier to infection; (d) its unprecedented ability to generate a diverse population of genetically distinct yet related strains (termed viral quasi-species); (e) structural features of the envelope that limit the effectiveness of neutralizing antibodies; and (f) its subsequent ability to evade vigorous attack mediated by both the humoral and cellular arms of antiviral immunity. These concepts have been reviewed elsewhere in more depth [1–6].

### B. Prospects for Achieving Vaccine-Induced Immunity

Despite the discouraging news of expanding epidemics and the many biological challenges imposed by HIV, vaccine-induced immunity may be possible. First, prospective analyses of HIV transmission in sero-discordant couples in Uganda indicate that heterosexual transmission is relatively inefficient [7]. On average, several hundred exposures are required to cause one infection in settings of sexual transmission [8] or needle stick injuries [9]. Therefore, vaccines that induce even a modest improvement in antiviral defenses may have a profound impact on the transmissibility of HIV. Second, based on an analysis of HIV isolates in acute infection, most individuals are infected with a very small infectious inoculum of limited genotypic and phenotypic diversity [10,11]. This improves the chances that even modest preexisting vaccine-induced immunity could prevent or modify infection. In addition, there are examples of natural antiviral immunity from studies of highly exposed, uninfected commercial sex workers [12,13] and long-term non-progressor [14,15] populations. Most importantly, there are also many examples of passive protection and vaccine-induced immunity in nonhuman primate models of lentivirus infection [16–28].

## II. CLINICAL TRIALS OF HUMAN IMMUNODEFICIENCY VIRUS VACCINES

During the course of the last 15 years, there have been more than 30 HIV/AIDS vaccine concepts evaluated in more than 50 clinical trials that have involved approximately 12,500 volunteers. Most of these studies were small Phase I trials to determine the initial safety and immunogenicity profile of a particular approach. During this process, selected approaches that have prompted evaluation in larger-scale Phase II and Phase III studies emerged. This chapter will examine the rationale and merits of the three major “generations” of HIV vaccine approaches that have advanced to the stage of Phase II/III clinical evaluation, and will also describe newer concepts and combinations in the vaccine pipeline being evaluated in or considered for Phase I testing.

### A. First-Generation Approaches—Envelope Glycoprotein Antigens

Initial approaches in the mid to late 1980s to produce vaccine antigens focused on recombinant protein subunit products based on safety and available technology. Most products were based on envelope glycoproteins, gp120 or gp160, because of their functional importance for virus attachment and entry, and as primary targets for neutralizing antibody. Recombinant subunit gp160 or gp120 has been produced in insects, yeast, or mammalian cells [29–33]; however, CHO-derived rgp120 emerged as the most immunogenic of the early subunit vaccines [32,33]. Several properties of subunit proteins limited the utility of this approach. For instance, serum antibody titers induced by gp120 products have a short half-life (<6 months), and although they can be boosted, the titers generally achieve their peak level after the third or fourth injections. Repeated boosting does not prolong the half-life significantly.

The rgp120 formulated in alum and produced by Genentech, the parent company of VaxGen, has progressed to Phase III efficacy evaluation in two trials. One study in the United States, Puerto Rico, and the Netherlands utilized VanGen B/B derived from HIV clade B strains LAI (one of the original T-cell line-adapted viruses) and GNE8 (a primary R5 isolate) enrolled 5108 gay and bisexual men and 309 women at high-risk of HIV infection. The other study, which is ongoing, utilizes VanGen B/E derived from HIV clade B LAI and clade E primary R5 isolate strain A244, and has thus far enrolled approximately 2500 injection drug users in Bangkok, Thailand. The participants received vaccine at 0, 1, 6 months, then an additional four booster injections at 6 month intervals. Preliminary results for the B/B study were announced at the Keystone meeting in March 2003. Overall there was no efficacy, with a 5.7% infection rate among vaccinees and 5.8% in placebo recipients. However, subset analyses suggested there may be evidence of protection among selected groups with the most extreme high-risk exposures. Although the subgroups are small, these data have stimulated additional analysis. Data from the Thailand study should be announced near the end of 2003.

The major concern about the immunogenicity of monomeric gp120 is that it can only elicit antibody and CD4<sup>+</sup> T-cell responses, and those antibodies are very type-specific, typically failing to neutralize commonly transmitted primary R5 HIV-1 isolates [34]. However, the advantage of these types of vaccine products lie in their safety. The ongoing Phase III trial analysis will hopefully teach us about the breadth, magnitude, and properties of envelope-specific antibody needed to protect against HIV-1. Further, the process of performing Phase III trials has also provided a number of lessons that will be valuable in future HIV vaccine efficacy trials (as discussed at the end of this chapter).

### B. Second-Generation Approaches—Recombinant Poxvirus Vectors with or Without Recombinant Envelope Boosting

The eradication of smallpox using replication-competent attenuated vaccinia was one of the greatest achievements

of medical science. This legacy of vaccine efficacy and the development of technology to express recombinant genes from poxviruses [35,36] (Chapter 29) led to the development of recombinant poxviruses as potential vaccine candidates for other pathogens. Importantly, the delivery of the vaccine by a vector allows the endogenous production and processing of the antigen, thereby promoting MHC class I epitope presentation and CD8<sup>+</sup> T-cell induction. Poxvirus vectors that express *gag* induce the production of pseudovirions from infected cells [37–39], and may have some immunological advantages that can be optimized by altering vector construction [40,41]. Early studies, beginning in the late 1980s, utilized live recombinant vaccinia [42,43], and they were indeed able to consistently induce long-lived CD8<sup>+</sup> cytotoxic T lymphocyte (CTL) responses in vaccinia-naïve subjects [44–46]. However, concerns over the safety of replication-competent vaccinia, diminished immunogenicity caused by prior vaccinia seropositivity, and product supply issues prompted an evaluation of alternative recombinant poxvirus approaches.

Canarypox was the recombinant poxvirus vector that became available in the mid 1990s and was evaluated in a series of clinical trials. Canarypox is grown and manufactured in chicken embryo fibroblasts (CEFs) but is replication-incompetent in mammalian cells. Therefore, it can deliver its recombinant genes to the cytoplasm, where it provides all the machinery necessary for gene expression, but is unable to propagate itself to cause primary disease and has been proven safe even in profoundly immunocompromised animals. These vectors were produced by Aventis-Pasteur (formerly Pasteur-Merieux-Connaught) and studies were performed by French and U.S. investigators in the AIDS Vaccine Evaluation Group (AVEG) and the Walter Reed Army Institute of Research (WRAIR).

The constructs included a series of products that expressed gp160 (vCP125); gp120, gp41 (transmembrane), *gag*, and protease (vCP205); vCP205 plus selected epitopes from *nef* and *pol* (vCP300); vCP300 plus E3L and K3L genes from vaccinia that inhibit dsRNA; and interferon-inducible protein kinase, PKR; and that inhibited the apoptosis of the infected cell (vCP1452). More than 1000 subjects have been enrolled in studies of recombinant canarypox vectors expressing the HIV genes. The evaluation of these products has included dose ranging, a variety of injection schedules, combined administration by parenteral and mucosal routes, and combination with rgp120 envelope products. Some phase II studies have been conducted in developing countries with groups at relatively higher risk for HIV infection.

The data from these studies have shown canarypox vectors to be well tolerated at doses above 10<sup>7</sup> pfu, although local and systemic immunogenicity increased at the higher doses. The HIV-specific antibody response after recombinant canarypox immunization alone is weak, but subsequent boosting with purified recombinant envelope subunit protein induces HIV-specific antibody titers of the same or higher magnitude and quality as three or four inoculations of the purified recombinant envelope subunit protein alone [47,48]. The sequence of recombinant canarypox priming, followed by envelope subunit protein boosting, results in a slightly longer antibody half-life than immunization with purified protein alone. The HIV-specific CD8<sup>+</sup> CTL can be

detected in fresh PBMCs from subjects immunized with recombinant canarypox virus vectors, and in a subset of individuals, the activity is detectable for > 2 years. The activity detected in classical <sup>51</sup>Cr release assays requires 2 weeks of in vitro stimulation and is detected in about 20% of subjects at any given time point [47–51]. Although these responses may be of marginal strength, recombinant canarypox-induced CTLs have been shown to lyse target cells infected with primary R5 HIV-1 isolates from multiple clades [52]. In addition, CD8<sup>+</sup> CTL effectors have been isolated from rectal mucosa (McElrath et al., unpublished observations), and both classical MHC class I-restricted cytolytic activity and nonlytic CD8<sup>+</sup>-mediated HIV-1 suppression have been demonstrated in recipients of recombinant canarypox vaccines [53].

A pair of studies, performed by the HIV Vaccine Trials Network (HVTN), evaluated vCP1452 in combination with VaxGen rgp120 B/B at U.S. (HVTN 203) and international sites (HIVNET 026 was performed in Haiti, Brazil, and Trinidad and Tobago). The primary objective of these studies was to determine a correlate of immunity and to define whether T-cell immunogenicity could be elicited and measured at a high-enough frequency to conduct a specially designed efficacy trial (HVTN 501). To qualify for that particular study design, a frequency of about 30% was required. Unfortunately, this frequency of vaccine-induced CTL response was not achieved, and the HVTN 501 efficacy trial initially designed with vCP1452 was cancelled. However, there are still plans to perform a more conventional efficacy trial in Thailand using a recombinant canarypox (vCP1521) constructed like vCP205, but with the envelope gene derived from a clade E HIV isolate.

This trial will include booster injections of the VaxGen B/E rgp 120 and will evaluate protection from heterosexual HIV transmission, and should therefore answer some of the questions raised in the subset analysis of the initial rgp120 Phase III study.

### C. Third-Generation Approaches—More Potent Gene Delivery Vehicles Alone or in Combination with DNA Vaccination

As the focus shifted away from monomeric envelope subunit vaccines in the mid 1990s, the development of several new strategies for the induction of strong CD8<sup>+</sup> CTL responses emerged while recombinant canarypox vectors were being actively investigated in clinical trials. This effort has culminated in a series of successful vaccine studies utilizing the SHIV macaque model. These studies have helped to form the basis for the current paradigm that a sufficiently high vaccine-induced CD8<sup>+</sup> CTL can control lentivirus infection. These studies utilized either recombinant modified vaccinia Ankara (rMVA) or replication-incompetent recombinant adenovirus (rAd) alone or in combination with deoxyribonucleic acid (DNA) immunization [24–28,54], and have provided a direction for the next series of large-scale clinical trials. In particular, there is interest in combinations of DNA priming followed by MVA [26,54] (Chapter 34) or rAd [27] boosting as a potent mechanism for inducing high levels of HIV-specific CD8<sup>+</sup> CTL responses.

The initial product concept being advanced into clinical trials by the NIAID Vaccine Research Center (VRC)—a new intramural program on the campus of the National Institutes of Health focused on the development of an HIV/AIDS vaccine—is based on the following basic assumptions: (a) CD8<sup>+</sup> CTL can control infection, but an antibody to the envelope will be critical for preventing infections and achieving sterilizing immunity; (b) it is essential to induce a broad immune response against a large number of epitopes; and (c) the vaccine should represent the major subtypes of viruses causing new HIV infections worldwide. The leading VRC vaccine candidate includes envelope constructs [55] as well as a *gag/pol/nef* fusion gene [56], thereby representing the majority of the HIV genome. The envelope genes are derived from viruses in clades A, B, and C, representing the subtypes causing nearly 90% of new HIV infections worldwide. The vaccine includes a cocktail of four DNA plasmids given as a series of priming injections followed by a booster injection of four replication-incompetent recombinant adenoviruses expressing a matching set of genes. All the genes have been codon-modified to reduce the content of AT-rich regions that inhibit nuclear export of message, allowing high levels of rev-independent protein expression. The DNA is delivered intramuscularly by a needleless injection system, Biojector®, that sprays the injectate into the muscle in a pattern that improves the overall gene expression. The combination of DNA priming and rAd boosting is the most potent vaccine regimen discovered to date for the induction of CD8<sup>+</sup> CTL responses.

The development of DNA vaccines is reviewed in Chapter 33, and replication-competent recombinant adenovirus vectors are discussed in Chapter 30. However, the rAd being used in the VRC vaccine approach and an approach being promoted by Merck and Co., Inc. utilize a replication-defective virus, a vehicle for gene delivery borrowed from the gene therapy field. The rAd vectors are produced by inserting the recombinant genes of interest into the E1 gene cassette of the adenovirus genome and by producing the rAd particles in a cell line that constitutively expresses complementary E1 genes (PER.C6 or 293-ORF6). In addition, portions of the E3 or E4 region are removed from the vector genome to make room for larger recombinant genes.

The extensive clinical experience of utilizing rAd vectors provides some advantages to this approach. Hundreds of patients have already been treated with rAd vectors as gene therapy for cancer, cardiovascular diseases, cystic fibrosis, and other diseases. Many of the hurdles that have faced the development of gene therapy turn out to be ideal properties for vector-based gene delivery of vaccine antigens. These include: (a) relatively transient expression; (b) lack of integration into host cell genome; and (c) induction of immune responses to the recombinant gene products. Although intravascular injection of rAd has been associated with a highly publicized case of fatal outcome in an 18-year-old patient with a rare liver condition at the University of Pennsylvania (Reuters Health Information, January 26, 2001), when given intradermally or intramuscularly, rAd vectors have been well tolerated at high doses. Importantly, the delivery of recombinant genes is efficient and immuno-

genic. This may be due to the nature of rAd production, which can achieve extremely high yields of concentrated particles, allowing the delivery of a 10- to 100-fold higher particle dose above currently available recombinant poxvirus candidates. Because this is a nonreplicating gene delivery vehicle, the effective dose delivered correlates with the overall level of recombinant gene expression and subsequent immune response.

The major challenges for the implementation of rAd vectors for vaccines include the technical aspects of building a stable vector and overcoming preexisting immunity to the adenovirus vector. Current candidate vaccines are produced using an adenovirus serotype 5 (Ad5) packaging system; Ad5 seroprevalence is high throughout the world. However, significant progress has been made to develop alternative serotype packaging systems that should overcome any problems associated with preexisting adenovirus immunity.

### **III. FUTURE CONCEPTS IN THE PIPELINE FOR HUMAN IMMUNODEFICIENCY VIRUS VACCINE CLINICAL TRIALS**

#### **A. New Deoxyribonucleic Acid Vaccine Approaches**

As noted above and in Chapter 33, bacterial DNA plasmids are being explored as a method of gene delivery and immunization in many HIV vaccine concepts. In addition to the use of DNA for priming individuals prior to boosting with recombinant virus vectors, DNA plasmids encoding HIV-derived genes are being used as a primer for subsequent envelope subunit protein administration and are being given in combination with plasmids encoding an IL-2-Ig fusion protein as an adjuvant [25]. Because of the versatility of DNA vaccine construction and the relative ease in manufacturing, new concepts in antigen design are being investigated using this delivery approach. For example, antigens designed by investigators at Epimmune Inc. include a series of T-cell epitopes from a variety of HIV-1 subtypes, relevant for major HLA class I supertypes (groups of MHC class I haplotypes that process and present identical epitopes) [57]. An artificial gene encoding the relevant epitopes is designed to facilitate the processing of individual epitopes and is delivered by DNA plasmids. Poor delivery or immunogenicity is the major challenge for DNA vaccines being developed for HIV. Although this modality allows enormous flexibility in design, immunogenicity in humans has been marginal. Efforts to improve delivery and expression are ongoing and include the use of specialized delivery devices as mentioned above under the VRC program, adjuvants such as the nonionic block copolymer (CRL1005) [27], or attachment to poly(lactide-coglycolide) (PLG) microparticles [58].

#### **B. Synthetic Peptides**

Using peptides as immunogens is an attractive approach because: (a) they are safe; (b) large quantities can be prepared relatively inexpensively; (c) they are made synthetically and are therefore free of contaminating host materials;

(d) immune responses to precise specificities can be induced; (e) multiple epitopes with desirable immunogenic properties can easily be combined in a single formulation; and (f) theoretically, they can be presented through either the MHC class I or II pathways. There are, however, major limitations of the peptide vaccine approach, which include the following: (a) the breadth of antigenic sites within a given formulation may be too narrow; (b) conformational epitopes are difficult to represent; and (c) historically, peptides have not been as immunogenic as more complex antigens. Several approaches have been taken to produce peptide immunogens as candidate AIDS vaccines. First, peptides based on the V3 loop sequence from one or multiple HIV-1 strains have been covalently linked to an oligolysine backbone and formulated with alum for intramuscular injection, or in poly(DL-lactide-coglycolide) microspheres for mucosal administration. Unfortunately, products based on this technology have not been immunogenic in humans [59]. Another approach has been to synthesize a hybrid linear peptide consisting of helper T-cell, B-cell, and CTL epitopes formulated in incomplete Freund's adjuvant [60,61]. Although this approach was found to be immunogenic in humans, the product as formulated in incomplete Freund's adjuvant as a strong emulsion caused sterile abscess formation in some participants; thus, the trial was stopped prematurely. New formulations are currently in development, and other groups have made peptide–lipid conjugates. Initial studies of a *gag*-based peptide were disappointing (unpublished observations), but newer formulations have shown more promise and are being studied in early phase clinical trials [62].

### C. Live Recombinant Virus Vectors

Live recombinant viruses as expression vectors for HIV-1 gene products hold several attractions: (a) immunogens are presented in the context of natural infection (i.e., oligomeric glycoprotein is expressed in infected cell membranes, with native conformation and glycosylation patterns); (b) antigens are processed by and presented in the context of MHC class I molecules leading to CTL responses; (c) multiple antigens, diverse strain specificities, or immune modifiers may be simultaneously expressed; (d) administration by percutaneous or mucosal routes is relatively simple; and (e) production and delivery are inexpensive. Live bacterial vectors have similar advantages although the posttranslational processing of viral protein will differ from that of mammalian processes, and the induction of MHC class I-restricted CTL may be less efficient. An advantage of bacterial vectors is that the constituents of the vector may provide additional adjuvant properties. Each approach offers unique advantages and disadvantages often related to the tropism and virulence of the parent vector. Further, preexisting immunity is an additional challenge that these types of approaches must face.

Adenovirus vectors have several desirable features, including feasibility of oral delivery with gut replication, induction of systemic and mucosal immunity after a single oral dose, and a record of safe use for the prevention of respiratory diseases in the U.S. military (the reader is referred to an excellent discussion on the development of a

live attenuated recombinant adenovirus vaccine for HIV in Chapter 30). Other viral vectors that have been investigated include polio [63–65], influenza [66], rhinovirus [67,68], and hepatitis B [69,70] chimeras. These vectors are of interest because of their ability to induce mucosal immune responses. Their major limitations are the amount of foreign genome that can be accommodated and the virulence properties of the parent vector.

### D. Live Recombinant Bacterial Vectors

Several approaches utilizing bacterial vectors have been developed as approaches for HIV/AIDS vaccines. Attenuated *Salmonella* has been developed as a vaccine vehicle to deliver recombinant HIV antigens [71,72] or recombinant plasmid DNA, and are being introduced into clinical testing (discussed in detail in Chapter 32). Recombinant bacille Calmette–Guérin (BCG) constructs that express HIV-1 *gag*, *pol*, and *env* gene products have also been developed. These products can induce antibody, helper T-cell, and CTL responses in mice [73,74] and macaques [75]. Some future improvements of BCG vectors may include the coexpression of selected recombinant cytokine genes [76]. *Listeria monocytogenes* is mentioned here as another potential live recombinant bacterial vector, but its development has advanced only to the level of testing in small animal models [77,78]. As previously mentioned, the potential virulence of the parent organism and prior immunity to the vector should be underscored as major concerns for safety and immunogenicity, respectively, in the development of live vector approaches.

### E. Replication-Defective Virus-Based Vectors or Gene Delivery Vehicles

There is a diverse array of defective virus-based vectors and gene delivery vehicles being developed as candidate HIV vaccines, but only the ones likely to reach clinical trials in the short term will be emphasized here. A vaccine expressing *gag* from a HIV-1 clade C isolate in a Venezuelan equine encephalitis (VEE) virus vector is being prepared for clinical testing and has been described in Chapter 31. The advantage of this vector as well as one derived from Sindbis virus, another alphavirus, lies in their unique abilities to target [79,80] specialized antigen presentation cells. Adeno-associated virus (AAV) [81,82], retroviruses [83], and recombinant replication-defective herpes simplex virus (HSV) [84,85] are mentioned as approaches that may provide a more prolonged antigen expression than the other gene delivery approaches discussed, but concerns about integration may limit their entry into clinical trials of preventive HIV vaccines.

### F. Replication-Defective Fungi-Based and Bacteria-Based Vectors or Gene Delivery Vehicles

Heat-killed recombinant *Saccharomyces cerevisiae* is a novel approach for delivering vaccine antigens that may enter

clinical trial evaluation within the next year. The yeast particles express HIV antigens and, when phagocytized by dendritic cells, that antigen is available for presentation in both class I and class II MHC molecules [86]. A similar approach has been suggested for *Brucella abortus* [87], but has only been tested in rodents to date.

### G. New Subunit Protein Vaccines

As noted, one of the critical needs in HIV vaccine development is to find ways of eliciting broadly neutralizing antibodies against primary CCR5 utilizing HIV isolates. One of the leading concepts for accomplishing that goal is to produce oligomeric envelope structures. Several groups have made oligomeric envelope proteins that mimic envelope structures more likely to exist in vivo [88–90]. The product from Chiron Corporation, derived from a primary HIV isolate SF162 and based on a V2-deleted gp140 envelope construct, is being prepared for clinical evaluation. In addition to producing oligomeric structures, a number of groups are pursuing methods to present a “receptor-triggered” envelope conformation to the immune system. Recently, a CD4-gp120 env single-chain fusion protein has been shown to elicit some degree of neutralizing antibody responses in mice and Rhesus macaques [91]. However, the extent to which those responses are directed against viral gp120 targets versus human CD4 epitopes contained within the fusion construct remains to be determined. Another controversial vaccine approach has involved the use of tat protein as an immunogen. GlaxoSmithKline has developed a nef-tat fusion protein being evaluated in clinical trials in combination with a monomeric rgp120 protein. This product and tat-protein-only vaccine concepts [92] are currently being evaluated in clinical trials. However, no data as of yet are available for review.

### H. Strategies for Vaccine Adjuvants and Delivery Systems

The adjuvant component of a vaccine can determine the composition, magnitude, and duration of the immune response to the antigenic component of the vaccine formulation. These concepts are being applied in HIV vaccine development and are topics discussed in more detail elsewhere [93] and in other chapters of this book. Of particular note has been the advancement of cytokine adjuvants in HIV vaccine evaluation. Granulocyte-macrophage colony-stimulating factor (GM-CSF) has been delivered with canarypox vectors, and clinical studies are in the planning phase for using IL-2-Ig plasmid in combination with the VRC plasmids expressing *gag/pol/nef* and multiclade envelope genes [94], and IL-12 in combination with a peptide cocktail.

## IV. CONSIDERATIONS FOR PHASE III TRIAL DESIGN WITH VACCINES THAT CONTROL, RATHER THAN PREVENT, INFECTION

With the current generation of vaccines being developed that are based largely on the induction of CD8<sup>+</sup> CTL responses,

it is possible that efficacy will be manifest by controlling, rather than preventing, infection. Animal models of vaccine protection from lentivirus challenge using the kinds of approaches being studied in current clinical trials have indicated that this type of approach may be successful [24–28]. It is hoped that in natural settings of HIV transmission where relatively low inoculum and transmission efficiency occur, studies of vaccines based solely on the induction of CD8<sup>+</sup> CTL may achieve some level of sterilizing immunity. However, for the design of efficacy trials, the assumption will be made that the HIV vaccines currently being tested will control, rather than prevent, infection.

This raises a number of issues that have not existed for the efficacy evaluation of vaccines for other infectious diseases. One practical issue raised is the length of follow-up period required for a study in which research questions are asked concerning disease progression, rather than the absence or presence of infection. Subsequent endpoints might include: (a) the magnitude of the peak in viral load during acute infections and the viral load set point during early-established infection; (b) the slope of the CD4<sup>+</sup> T cell counts; or (c) the length of time-to-treatment according to predetermined criteria. Another practical consideration is the mechanism for diagnosing and distinguishing HIV infection from vaccination. Most of the current vaccines will be complex in that they will likely induce responses to multiple genes. Therefore, serological assays will not be sufficient to readily distinguish between infection and vaccine-induced responses. This means that gene-based diagnostics will be necessary on a regular basis to detect HIV infection in its early stages. Another major consideration in the organization of efficacy trials for a partially effective vaccine is the standardization and maintenance of sexual risk reduction counseling, and the accurate monitoring of sexual risk-taking activities. This will require enormous time and resources, but will be essential for interpreting the outcome of the study. Increasing HIV infection risk among vaccinees could mask the impact of vaccination.

Of equal importance in the design and management of efficacy trials for HIV vaccines will be the provision of ART for subjects who become infected during the trial period. One reason for providing ART as part of the study is to make it possible to use time-to-treatment as a study endpoint. Another reason is to standardize the treatment regimens so that control of viremia can be a longer-term endpoint for the study. There are also ethical considerations, as the efficacy trials will be performed in both developed and developing countries simultaneously, and access to ART for subjects who need it will not be equal if it is not provided as part of the study. This will incur significant expenses and will add a layer of complexity at trial sites required to diagnose and manage the initial stages of HIV infection.

If the vaccine's greatest impact is on the viral load of persons subsequently infected (despite vaccination), then a potential measurement of efficacy could be the reduction of secondary transmission [95]. Designing studies within or between communities to assess the rates of spread to those not participating in these studies will be necessary to determine these types of population effects, and are not a standard element of licensure vaccine evaluation. It is intriguing to

consider the implication of recently published studies on other sexually transmitted diseases, showing vaccine-induced protection of human papilloma virus [96] and herpes simplex virus [97], on the approach to trial design. These studies highlight the ability of parenterally administered vaccines to protect women from HPV and HSV, and suggest that gender-specific efficacy trials should be considered for HIV vaccine evaluation. This type of subject selection also provides a mechanism to evaluate the secondary spread to male partners of female subjects who become infected despite vaccination.

The evaluation of "breakthrough" infections in Phase II and Phase III studies will be another critical part of defining the efficacy of HIV vaccines, and will require a level of detailed analysis of virus genotypes and host immune responses that has never been attempted on this large a scale for any other pathogen. For vaccines that control, rather than prevent, infection, it will be important to determine the specificity and breadth of immune responses necessary for control and to define the thresholds that allow immune escape and disease progression. For vaccines that only prevent a subset of virus strains from infecting the vaccinated host, it will be important to determine which viruses were excluded and why. This may be best accomplished in areas where diverse strains of HIV are responsible for multiple concurrent epidemics, where the chances for exposure to viruses that could escape preexisting immunity would be the highest.

Our aim in this chapter was to highlight some of the major challenges that exist for HIV vaccine development, and to provide a conceptual context for organizing and ranking the current products advancing to clinical trials. This discussion is by no means exhaustive. Interested readers are referred to other chapters contained in this volume and recent reviews that provide more detail. Human immunodeficiency virus is a formidable opponent and will take sustained, intense, and thoughtful effort to overcome. Although there are many biological and logistic obstacles remaining, we believe that vaccine development remains the best hope of controlling the HIV/AIDS pandemic, and that advancing new product concepts to Phase III testing is the next critical step in the process.

Dengue viruses cause classic dengue fever, an acute nonspecific febrile illness, and dengue hemorrhagic fever (DHF) [1]. The principal mosquito vector for dengue, *Aedes aegypti*, infests much of the tropics and subtropics. Unchecked expansion of vector mosquitoes over the past three decades has resulted in explosive spread of dengue viruses [2]. Dengue fever is consequently the most common arthropod-borne viral infection of humans, with over 50 million cases annually [3]. In some regions, such as the in Caribbean and South America, dengue fever has reappeared after an absence of several decades [4]. Of newer and greater concern is increasing incidence of DHF in areas where multiple dengue viruses circulate simultaneously or in sequence [5].

Flavivirus vaccines have proved effective to reduce or prevent disease from yellow fever, Japanese encephalitis (JE), and tick-borne encephalitis (TBE) viruses [6,7]. However, a licensed dengue vaccine remains elusive, and vector control and the use of personal protective measures are mainstays to prevent dengue disease. Readily available, safe, and effective dengue vaccines are urgently needed for global use, and the World Health Organization actively promotes their development [8]. This review will discuss new replicating and nonreplicating dengue vaccines (Table 1). Since the last review [9], investigational tetravalent dengue vaccines have transitioned to clinical trials. This acceleration of development suggests that the prospects for expanded clinical testing and fielding of new dengue vaccines are bright.

### I. DENGUE VIRUSES

Dengue viruses are 40- to 50-nm enveloped spherical virions with a core of single-strand positive-sense RNA complexed

with nucleocapsid protein [10]. The viral genomes are 11 kilobases in length and encode three structural proteins [capsid (C), membrane (prM, M), and envelope (E) proteins] and five nonstructural proteins (NS1, NS2a/b, NS3, NS4a/b, and NS5). The viruses preferentially infect cells of reticuloendothelial lineage, particularly macrophages and dendritic cells [11]. These antigen-presenting cells may be important in dengue pathogenesis, as they may be essential for direction of primary immune responses. After binding to cellular receptors, viruses enter the cytoplasm where their RNA is released from the nucleocapsid, translated, and transcribed [12]. Maturation of virions occurs in the cytoplasm, with assembly in the endoplasmic reticulum; progeny viruses bud into intracellular vesicles and are released from the cell surface [13]. Both structural and nonstructural viral proteins are expressed on the surface of the infected cell.

There are four serotypes of dengue viruses: dengue-1, -2, -3, and -4. These four dengue viruses are members of a single antigenic complex in the family Flaviviridae and share 60–80% sequence homology [14]. Despite significant genetic diversity among virus strains, both among and within different serotypes, there is good congruence between traditional serological classification of dengue isolates and classification based on genetic relatedness.

Dengue virus infections cause a spectrum of disease, ranging from asymptomatic infections to infections complicated by hemorrhage, shock, and death. Classical dengue fever is commonly encountered in adults and older children, presenting as a self-limited incapacitating acute illness with fever, muscle pains, headache, and an occasional rash [15]. Dengue viruses have proved to be a major cause of febrile illness among U.S. troops and travelers in dengue-endemic tropical areas [16,17]. In younger children, however, dengue

virus infection may result in mild illness associated only with upper respiratory symptoms.

Illness may be complicated in <1% of all cases of dengue by DHF, manifested by plasma leakage that can lead to a bleeding diathesis (positive tourniquet test), frank hemorrhage (e.g., spontaneous petechiae, gastrointestinal bleeding, epistaxis), or shock. Dengue hemorrhagic fever is a potential outcome of dengue virus infection that currently cannot be predicted. However, individuals with preexisting antibody from an earlier dengue virus infection who experience a secondary dengue virus infection have been shown to be at 100-fold increased risk for DHF [18]. Anamnestic antibody responses to dengue viruses are commonly found in individuals with DHF, along with evidence of enhanced cellular responses (increased  $\gamma$ -IFN, T-cell activation markers) [19,20]. In areas where dengue is endemic, DHF predominantly occurs in children and is fatal in about 0.5–5% of cases. However, DHF may be seen in adults when there is introduction of a new dengue virus into a community decades after transmission of another virus serotype [21].

## II. IMMUNITY TO DENGUE VIRUSES

Infection with dengue virus of one serotype results in apparent lifelong monotypic immunity against that serotype, but not against any other serotype [22]. Thus, separate infections with all four dengue viruses are theoretically possible in a single host. Following infection, antibody and cell-mediated immune responses develop over several days. Appearance of IgM and IgG antibodies detectable by enzyme immunoassay, and of neutralizing antibodies detectable by plaque assay, coincides with cessation of fever and decrease in viremia [23]. Neutralizing antibodies may persist for decades [24]. Cell-mediated immune responses are evident during the acute phase of illness; both T-cell activation and cytokine release (TNF- $\alpha$ , IL-1, IL-6, and  $\gamma$ -IFN) have been documented [25]. These features may help to eliminate infected cells and hence decrease viral burden following infection.

Several dengue virus antigens (components of the dengue virus that induce protection against subsequent infec-

tion) have been implicated in the generation of both humoral and cell-mediated responses [26]. Attempts to stimulate immune responses mimicking those that follow natural infection with dengue virus have focused on E protein, the major surface protein of the dengue virion that contains the dominant antigens for eliciting neutralizing antibody responses [27]. B-cell epitopes that stimulate nonneutralizing antibodies are found on other structural proteins (prM, M) and nonstructural protein 1 (NS1). There may also be a protective role for these antibodies that may serve to limit virus replication after infection.

Protection from infection with dengue viruses (defined as prevention of virus replication and/or generation of host responses to virus) has been attributed to the presence of neutralizing antibodies to dengue virus [28]. Maternally derived neutralizing antibody appears to protect infants against infection until approximately 6 months of age [29]; additionally, monkeys are protected against challenge following transfer of immune sera [30]. In practice, development of neutralizing antibodies at a titer  $\geq 1:10$  following infection has been used as a surrogate marker for protective immunity to dengue viruses.

The role of cell-mediated immune responses in protection against infection or disease with dengue viruses is uncertain. Adaptive T-cell responses may ameliorate or abort progression to disease, and thus may be closely associated with recovery from infection. Recent hospital-based studies run from the Armed Forces Research Institute of Medical Sciences laboratory in Bangkok suggest the importance of cellular responses for disease manifestations and for long-term protection from subsequent exposure to dengue viruses [31–37]. Responses to antigens implicated in the generation of cell-mediated immunity, such as NS3 and NS5 nonstructural proteins, may restrict virus replication; the resulting diminution in viral burden lessens disease duration. Importantly, cell-mediated responses may provide some cross-reactive immunity as T-cell epitopes may be conserved across all four dengue virus serotypes [38].

The issue of protection against dengue virus infection is further complicated by the potential for subneutralizing concentrations of cross-reactive antibody to promote virus

replication (antibody-dependent enhancement) [39]. In addition, increased and/or unregulated cell-mediated immune responses may play a role in the pathogenesis of DHF in some cases of secondary dengue [40]. A vaccine that stimulates an inadequate or altered humoral immune response, or that leads to an exaggerated cell-mediated immune response following infection, may have potential untoward consequences. Conversely, a successful vaccine will stimulate balanced humoral and cellular immunity that protects against but does not enhance the severity of dengue virus infection. A central observation that patient viremia titer is associated with disease outcome [41] suggests that vaccines that keep virus replication below a given threshold may suffice to prevent disease [42,43]. Evaluation of protection against viremia will be aided by new methods that rapidly quantitate viral burden in natural and experimental infection [44].

During the first half of the 20th century, wild-type dengue viruses were administered to volunteers to better understand the vector biology and the pathophysiology of dengue fever and to assess the protective efficacy of candidate dengue vaccines [45,46]. With a better understanding of dengue pathogenesis, dengue challenge studies in a few adult volunteers in a controlled setting have been revisited using GMP-produced dengue challenge viruses (M. Mammen, personal communication). Immunological evaluation showed the following (J. Scherer, personal communication): (1) volunteers that developed clinical illness had the greatest amount of immune activation, (2) immune activation was detectable before the development of clinical symptoms, and (3) activated T cells were detectable after clinical illness resolved.

### III. DENGUE VACCINE DEVELOPMENT

An effective dengue virus vaccine would protect children residing in endemic areas as well as travelers to endemic or epidemic areas to include tourists, business travelers, expatriates, and military personnel. In many endemic regions, three or even four dengue viruses may cocirculate or circulate sequentially, resulting in multiple possible exposures and the potential for reinfection with different viruses. Hence, a dengue vaccine would have to contain appropriate viral antigens to confer long-term protection against infection with all four dengue viruses, or provide immunity that inhibits viral replication shortly after infection (infection-permissive immunity). It must protect against development of clinical illness and particularly against onset of severe dengue including DHF. A dengue vaccine that is capable of protecting 80% or more of recipients against clinical diseases due to any of the four viruses without predisposing to enhanced disease would certainly be considered a success.

The ideal dengue vaccine will be safe, immunize with one dose, stimulate neutralizing antibody in over 90% of recipients, protect against all dengue viruses, be efficacious in children, be stable, and be inexpensive. However, successful dengue vaccine development has been hindered by the lack of animal models of disease and known, reliable indicators of attenuation of the dengue virus. In the past, empirical testing established if a candidate vaccine was adequate for further testing. Recent advances in possible new animal models and

in molecular dissection of the viral genome may bypass these obstacles [47]. Challenge studies in a few adult volunteers in a controlled setting will further accelerate our understanding of dengue pathophysiology and will enable us to down-select available dengue vaccine candidates before launching large-scale Phase 3 vaccine field trials involving tens of thousands of children in dengue-endemic areas.

### IV. REPLICATING DENGUE VACCINES

These vaccines include live attenuated dengue viruses, derived either empirically by classical methods in tissue culture or using genetic engineering of infectious clones. The former are the best-established approaches to dengue vaccine development. In addition, vectored viruses offer an alternative strategy for delivery and amplification of selected dengue genes *in vivo*.

#### A. Live Attenuated Dengue Vaccines

Most viral vaccines licensed in the United States are live-attenuated virus vaccines (yellow fever, measles, mumps, rubella, polio, adenovirus 4, adenovirus 7, varicella, influenza) that offer the possibility of single dose vaccination. Dr. Albert Sabin developed the Army's first dengue live attenuated dengue vaccine (LAV) via serial passage of dengue-1 in mouse brain. The vaccine became attenuated after seven passages and protected volunteers from homotypic challenge [46,48]. Wisseman and colleagues expanded this work using the dengue-1 MD-1 vaccine strain [49]. Subsequently, a plaque-picked, temperature sensitive mutant of dengue-2 virus isolated in Puerto Rico (PR-159/S1) was developed as a vaccine during the 1970s [50,51]. The seroconversion rate for dengue-2 PR-159/S1 was 61% in flavivirus naive volunteers, but 90% in volunteers who had previously received yellow fever vaccine [52].

During the 1980s, vaccine development efforts focused on dengue viruses serially passaged in primary dog kidney (PDK) cells, a nonpermissive cell line. The Mahidol University in Thailand and the Walter Reed Army Institute of Research (WRAIR) in the United States selected several candidate attenuated live vaccines for clinical evaluation. Increasing viral passage in PDK cells was associated with diminished reactogenicity, decreased viremia, and lower antibody responses [9,53]. The principal symptoms of headache and muscle pain after vaccination were generally mild and transient, while signs of systemic illness, such as fever, were infrequent. Crucially, both centers discovered that combining two or more dengue strains into a single vaccine results in no apparent increase in reactogenicity over that observed with monovalent vaccines.

At the WRAIR, a series of pilot studies identified six monovalent dengue vaccines suitable for advanced development: dengue-1 45AZ5 at either PDK 20 (passage level 20 in PDK cells) or PDK 27, dengue-2 S16803 PDK 50, dengue-3 CH53489 PDK 20, and dengue-4 341750 at PDK 20 or PDK [6]. Subsequent Phase 1 trials allowed empiric down-selection from 18 candidate tetravalent formulations [53a,53b]. A single best formulation was identified for expanded clinical testing, formulation #17 comprised of dengue-1 PDK 27,

dengue-2, dengue-3, and dengue-4 PDK 6 (Sun et al., personal communication). Vaccine protective efficacy was demonstrated in rhesus monkeys where 18 of 20 animals were protected from monovalent challenge following vaccination with dengue-1 PDK 20, dengue-2, dengue-3, and dengue-4 PDK [20]. Challenge experiments in human subjects are under way. In total, safety and immunogenicity of at least one dose of tetravalent vaccine has been evaluated in 145 volunteers, including some with previous partial immunity to flaviviruses [53b,54].

The Mahidol University group led by Dr Natth Bhamarapravati has successfully developed alternate live vaccines with attenuated dengue-1, -2, -3, and -4 viruses [55]. These viruses were tested singly and in combination and were found to be safe and immunogenic in Thai volunteers [56,57]. The success of the Mahidol dengue vaccine program has led to commercial development with Aventis Pasteur (AvP). Testing of this vaccine in monovalent and tetravalent preparations was completed using flavivirus-naïve American volunteers at the WRAIR and revealed unexpected interference by dengue-3 virus in the tetravalent vaccine [58,59]. After reformulation, the tetravalent vaccine is being evaluated in Phase 2 trials in children in Thailand (J. Lang, 50th Annual Meeting of the American Society of Tropical Medicine and Hygiene, November 2001, Atlanta, GA) (59a).

## B. Live Infectious Clone Dengue Vaccines

A successful attenuated dengue virus vaccine must retain the ability to infect in order to establish a protective immune response. Attenuated viruses have been obtained empirically, but the critical mutations have not been fully identified [60]. The availability of full length, infectious cDNA clones for dengue-4 [61], dengue-2 [62], dengue-1 [63], and recently dengue-3 (Bangti Zhao, personal communication) opens exciting possibilities for development of genetically engineered dengue vaccines that are either more attenuated or have increased genetic stability. These attempts include attenuated infectious clones, molecularly attenuated deletion mutants, and chimeric dengue virus vaccines. Although, in many cases, these approaches remain empirical because of our limited understanding of the mechanism(s) of attenuation for flaviviruses and the mutations responsible, they have significantly advanced our understanding of virus replication and may suggest future vaccine development strategies.

### 1. Infectious Clones of Live Attenuated Dengue Vaccine

One strategy is to clone naturally attenuated variants from wild virus populations ("swarms") or from existing laboratory-attenuated vaccines to create safer vaccines. Infectious clones offer the advantages of consistent starting materials for vaccine production, separation of the vaccine virus from potential adventitious agents present in cell substrates, and the provision of a starting point for site-directed mutagenesis and chimeric viruses. Theoretical disadvantages include a reduced number of virus "quasispecies" that may reduce immune responses among heterogeneous human populations and a lack of certainty that cloned viruses based on a

"consensus sequence" truly represent the attenuated vaccine virus.

The WRAIR, working with the NMRC and the FDA, has produced infectious clones from traditionally attenuated (PDK cell passaged) vaccine viruses. Full-length infectious clones of dengue-1 45AZ5 PDK 20, dengue-2 S16803 PDK 50, dengue-3 CH53489 PDK 20, and dengue-4 341750 PDK 20 have been produced. The infectious clones of the dengue-1 and dengue-2 vaccine viruses were evaluated in rhesus monkeys and performed similarly to the vaccine viruses from which they were derived in terms of viremia and elicited neutralizing antibodies (M. Mammen, personal communication).

### 2. Molecularly Attenuated Vaccine Viruses

Another approach has been to engineer mutations that might be expected to limit the replicational capability of flaviviruses in the host, for example, by modification of crucial cis- and trans-acting elements such as replicases, proteases and their recognition sites, and transcriptional and translational regulatory elements. The National Institutes of Health produced a full-length infectious clone of dengue-4 [61]. Using this strategy, various deletion mutations in the 3' non-coding region were introduced to attenuate the virus for man while maintaining adequate growth in Vero cells [64]. Compared with the original dengue 4 parent viruses, several viable deletion mutant viruses have altered phenotypes in vitro and in vivo; some may also have an altered host range as evidenced by their variably restricted replication in mammalian or mosquito cells. The 3' deletion dengue-4 vaccine has been administered to more than 100 volunteers at the Johns Hopkins University [65]. Thus far, the dengue-4 vaccine is safe and immunogenic with minimal reactogenicity.

FDA researchers produced a mutant dengue-2 virus with properties that suggest it may be attenuated for humans [66]. The mutations consist of three changes to the stem and loop structure at the far 3' end of the genome (a small portion of that stem and loop structure was replaced with the sequence from West Nile virus). A dengue-1 construct protects monkeys from viremia when challenged with wild-type dengue-1. Immunogenicity has been comparable to wild-type dengue-1 virus infection, while viremia has been delayed and greatly reduced, suggesting that there may be reduced reactogenicity in human recipients (MP Mammen, Jr., personal communication). All MutF vaccine recipients were protected from challenge a year (3/3) and 17 months (2/2) following a single dose [67]. A Phase 1 clinical study of dengue-1 MutF vaccine candidate is planned.

### 3. Intertypic Chimeric Vaccine Viruses

Yet another and possibly even more novel approach has been to make chimeric dengue virus vaccines by using an attenuated infectious cDNA clone as a carrier or backbone for the structural antigen genes from the other three virus serotypes. Chimeric viruses derived from the full-length dengue-4 cDNA infectious clone, which had been substituted with either dengue-1 or dengue-2 structural genes, elicited serotype-specific antibodies in rhesus monkeys and conferred protection against challenge with the homologous

virus (i.e., the structural protein donor) [68]. As one approach to a tetravalent dengue vaccine, the NIH plans to create three intertypic chimeras replacing structural genes (prM and E) of the backbone virus with corresponding structural genes of the other serotypes [68]. It is expected that growth characteristics in cell culture and replication in humans will mimic the attenuated backbone vaccine virus, while the neutralizing antibody response will be directed against the new prM and E proteins expressed on the virus surface.

The CDC laboratory in Ft. Collins has produced an infectious clone of the Mahidol/AvP dengue-2 vaccine virus [69]. The CDC uses the dengue-2 vaccine virus infectious clone as the backbone (and dengue-2 component) to produce intertypic chimeric viruses for dengue-1, -3, and -4 [70]. Improved immunogenicity in mice was seen using the structural genes (C-prM-E) from wild-type viruses rather than vaccine viruses, and rhesus monkey studies are planned.

### C. Vectored Dengue Vaccines

Work by Oravax (now Acambis) with a yellow fever–JE virus chimera, suggests that flavivirus chimeras offer a viable vaccine approach [71–73] (see Monath chapter in this volume). Acambis, backed by AvP, has subsequently developed chimeric dengue vaccine viruses using the infectious clone of the yellow fever 17D vaccine virus as the backbone. Chimeric viruses presenting the structural genes of dengue-1 through dengue-4 are immunogenic in monkeys with minimal viremia [74]. The monovalent vaccines each protect rhesus monkeys from challenge with wild-type homotypic dengue viruses. A Phase 1 trial of dengue-2 chimera is in progress following successful completion of the JE chimera clinical study [75]. Current concerns about the chimeric approach center around the consequences of producing incomplete immunity, i.e., immunity for the structural proteins for dengue-1 through -4 but only nonstructural protein-directed

immunity to the single dengue or yellow fever backbone virus.

Vaccinia vectors have been extensively utilized for expression of dengue genes and several recombinant viruses have been tested as vaccines in animal models [76–79]. Recently, novel highly attenuated strains of vaccinia virus (NYVAC, MVA) [80,81] or poxviruses with a host range limited to nonhuman species (ALVAC) [82] have been engineered to express flavivirus genes. Studies of the NYVAC and ALVAC recombinant vaccines with inserted JE structural genes were carried out in monkeys and humans [83,84]. The data from these trials revealed that the potency of these vectored vaccines was limited, particularly in vaccinia-immune individuals.

## V. NONREPLICATING DENGUE VACCINES

The nonreplicating vaccines are a diverse group including recombinant subunit vaccines, nucleic acid vaccines, and inactivated virus vaccines (Table 1). Several investigators have developed candidate recombinant subunit or inactivated dengue vaccines that have demonstrated at least partial efficacy in mice and in nonhuman primates (Table 2). Among the most promising is a purified inactivated vaccine (PIV) vaccine for dengue-2 virus, which induced “sterile immunity” in some rhesus macaques following the administration of two doses (Putnak et al., manuscript in reparation). Vaccination with nucleic acid sequences encoding protective epitopes is another promising approach [85], which has been used to immunize experimentally against flaviviruses such as St. Louis encephalitis [65], JE [66], and dengue [86] (Table 2). None of these vaccines has yet progressed to clinical trials, although the dengue-1 DNA vaccine developed at Naval Medical Research Command (NMRC) and the dengue-2 PIV developed at WRAIR are awaiting clinical evaluation.

**Table 2** Preclinical Results with Nonreplicating Dengue Vaccine Candidates

Vaccine (dengue virus types)	Antigen composition	Induces neutralizing antibody	Induces T-cell responses	Protects mice	Protects monkeys
<i>E. coli</i> subunit (1–4)	E (B domain)	Yes	NT <sup>a</sup>	Yes (dengue-2)	NT
Baculovirus subunit (4)	80% E	Yes	Yes	Yes	No
Baculovirus subunit (2)	E + MBP	Yes	NT	NT	NT
Baculovirus subunit (2)	100% E aggregates	Yes	NT	Yes	No
Yeast subunit (2)	VLPs	Yes	NT	NT	NT
Mammalian cell subunit (2)	VLPs	Yes	NT	Yes	NT
Nucleic acid (1)	prM-E (92–100%)	Yes	NT	NT	Yes (partial)
Nucleic acid (1)	prM-E + CpG DNA	Yes	NT	NT	Yes (partial)
Nucleic acid (2)	prM-E + LAMP	Yes	Yes	NT	NT
Nucleic acid (2)	prM-E + GM-CSF	Yes	Yes	NT	NT
Nucleic acid (2)	prM-E (100%)	Yes	Yes	NT	Yes (partial)
Purified inactivated (2)	Whole virions	Yes	NT	Yes	Yes

Abbreviations used: E, envelope; prM, premembrane; MBP, maltose-binding protein; VLPs, viruslike particles; CpG, cytosine–guanine dinucleotides; LAMP, lysosome-associated membrane protein; GM-CSF, granulocyte, monocyte, colony-stimulating factor.

<sup>a</sup>NT, not tested or results not available.

Although concerns about the ability to produce large amounts of recombinant or inactivated materials in a highly immunogenic form have largely been overcome [87], other concerns about the long-term safety and efficacy of nonreplicating vaccines remain. These relate to the duration of protective immunity, the ability to elicit effective cell-mediated immune responses (see dengue immunology section), and perhaps most importantly, the potential risk for enhanced disease once neutralizing antibody levels decline. Despite these concerns, viable roles for recombinant and inactivated vaccines remain, e.g., for protection during short-term travel to endemic areas, as alternatives to live vaccines and to supplement the immune responses generated by live or vectored vaccines. The high degree of structural and antigenic conservation among dengue viruses suggests that common strategies for vaccine development may be successful.

#### A. Recombinant Dengue Vaccines

Recombinant subunit dengue vaccines have been produced from structural proteins C, prM, and E and nonstructural (NS) proteins NS1, NS2A, NS2B, and NS3, expressed in a variety of systems, including *E. coli*, insect, yeast, and mammalian cells. Attempts to express full-length dengue antigens in *E. coli* in an immunogenic form were unsuccessful and have now largely been abandoned [88]. However, the successful expression in *E. coli* of a truncated version of dengue E protein (the approximately 110 amino acid B domain) fused to maltose-binding protein has been reported [89], and a tetravalent vaccine made using this approach was immunogenic for mice [90].

Insect cells may be more efficient than *E. coli* for expressing near-full-length dengue antigens because these cells are natural hosts for the virus. In particular, recombinant baculovirus has been used to produce dengue E subunit antigens in *Spodoptera frugiperda* (Sf9) insect cells [91–94]. These antigens, truncated at the C terminus to remove the hydrophobic membrane anchor domain, are secreted from Sf9 cells in a soluble form. However, mixed results have been obtained with soluble baculovirus-expressed dengue subunit antigens in animal models. An unpurified dengue-4 E antigen vaccine, while immunogenic and protective in mice, failed to protect rhesus monkeys against viremia [95]. Another crude dengue-2 E antigen fused to maltose binding protein conferred partial protection to mice but was not tested in monkeys [96,97]. More highly purified baculovirus-expressed E antigen preparations also conferred little or no protection against virus challenge [98] (Putnak, unpublished results). A full-length dengue-2 E protein formed large, intracellular aggregates, which were partially purified by detergent lysis and size exclusion chromatography [99]. Mice immunized with this particulate antigen with alum adjuvant made high-titer dengue-2 virus-neutralizing antibodies and were protected against virus challenge. This suggests that particle-based baculovirus-expressed dengue subunit vaccines may be equivalent or superior to soluble vaccines, at least in mice.

Recently, expression of the dengue virus structural gene antigens in yeast has been reported to produce 30-nm, viruslike particles, which induced virus-neutralizing antibodies in rabbits [100]. However, studies of the protective

efficacy of this immunogen in mice and nonhuman primates have not been reported. Recombinant subunit flavivirus antigens produced in mammalian cells have demonstrated utility for making effective vaccines [101]. Expression of the prM and E genes of dengue-2 virus in Chinese hamster ovary cells gave rise to secreted, viruslike particles, which immunized and partially protected mice against a nonlethal challenge [102]. These vaccines have not been tested yet in primates.

Current results with subunit vaccines in animal models are promising, but more work is required in the areas of protein purification and the identification of safe and effective adjuvants before the full potential of recombinant subunit vaccines can be realized. Future development of subunit vaccines also remains uncertain without a good animal disease model to help assess the risk of DHF. Subunit vaccines may be further improved by the addition of NS1 and NS3 antigens, which may provide additional protective epitopes. However, multicomponent, tetravalent vaccines may eventually prove to be too expensive to produce.

#### B. Nucleic Acid Dengue Vaccines

Initial dengue nucleic vaccines, made by cloning dengue-2 prM gene with 92% of the E gene (prM-92% E) into two different plasmid expression vectors, proved immunogenic in mice [86]. There was a positive correlation between neutralizing antibody titers and the levels of expression of the E antigen *in vitro*. Coadministration of the vaccine with pUC 19 plasmid DNA containing immunostimulatory CpG sequences elicited higher antibody titers and conferred partial protection to 3-week-old mice [103]. A dengue-1 DNA vaccine was tested using different gene inserts, including prM-92% E, prM-80% E, prM-100% E, and 80% E gene without prM [104]. Expression of the prM-100% E construct resulted in the formation of extracellular, viruslike particles and induced the highest and most persistent neutralizing antibody titers in mice. Similar results were also reported for a dengue-2 prM-100% E vaccine [105].

Subsequently, the dengue-1 prM-100% E vaccine was evaluated in rhesus macaques that received up to four 1-mg doses of vaccine administered intramuscularly (im) or intradermally (id) with or without CpG DNA [106]. The im route conferred more rapid seroconversion, higher and more persistent antibody titers, and partial protection against viremia upon virus challenge compared to id doses. Protection correlated with the presence of neutralizing antibodies; cell-mediated responses were not apparent in vaccinated animals. The CpG DNA had no effect. A parallel experiment with the DEN-1 prM-100% E vaccine in *Aotus* monkeys yielded similar results, except the im and id routes were comparable [107]. In both models, an anamnestic antibody response was observed after virus challenge, indicating a lack of sterile immunity.

To improve cellular immune responses, dengue-2 prM-100% E DNA was codelivered with lysosome-associated membrane protein (LAMP) trafficking sequences (which increase E antigen processing and presentation through the MHC class II pathway) or a plasmid expressing mouse granulocyte macrophage colony-stimulating factor (GM-CSF)

[108]. The vaccine with LAMP induced more rapid and higher rates of seroconversion and higher neutralizing antibody titers in mice than vaccine alone. Supplementing the vaccine with GM-CSF also resulted in significantly higher seroconversion rates and increased neutralizing antibody titers.

The gene gun is an alternate delivery device for delivery of DNA vaccines that uses compressed helium to deliver DNA coated onto gold microspheres to the epidermis. Effective immunization can be completed with microgram rather than milligram amounts of DNA, and may be more efficiently targeted to antigen-presenting cells of the dermis. The gene gun has been used recently to deliver dengue-2 prM-100% E DNA vaccine to mice and rhesus monkeys (Putnak R, manuscript in preparation). Mice vaccinated by gene gun made high-titer neutralizing antibody responses following inoculation with a single 0.5- $\mu$ g dose, and good CTL responses following two 0.5- $\mu$ g doses. In rhesus monkeys, two 2- $\mu$ g doses of DNA delivered by gene gun resulted in universal seroconversion, and 2 of 3 vaccinated animals were protected against viremia after virus challenge 1 month following the second dose. However, none of the protected animals demonstrated sterile immunity.

### C. Inactivated Dengue Vaccines

There are several licensed inactivated whole virus vaccines, such as inactivated polio vaccine (IPV), which are safe and effective. Recently, a formalin-inactivated vaccine candidate made in mammalian cells was developed for dengue-2 virus [109]. This vaccine, which is highly purified and formulated with alum, elicited high-titer virus-neutralizing antibodies in mice and protected them against virus challenge. In rhesus monkeys, two 7.5- $\mu$ g doses elicited high-titer virus-neutralizing antibodies and conferred nearly complete protection against viremia [87]. Dengue PIV vaccine lots have also been produced for the other serotypes (Putnak, unpublished results). If they are as immunogenic as the dengue-2 PIV, it should be possible to use this approach for producing a tetravalent vaccine for dengue.

However, as with inactivated RSV and measles vaccines, questions relating to duration of immunity and the possible potentiation of immune enhancement must still be addressed [110]. In the event of an inadequate CD8 memory T-cell response, vaccinees could be at increased risk for enhanced disease should neutralizing antibodies fall below protective levels. However, these are only theoretical concerns and there are assays that can be used for measuring T-cell activation and cytotoxic T-cell memory in Phase 1 trials of candidate vaccines.

An inactivated or other nonreplicating vaccine could also serve to boost antibody levels once cellular immunity has been established using a live or nucleic acid-based vaccine. Recent recommendations for polio have established a precedent for the combined use of live-attenuated vaccine and IPV to prevent that disease. Such a strategy was reported for dengue-2 virus, where vaccination with prM-E DNA followed by boosting with a recombinant E protein (B domain) subunits elicited better immune responses in mice than the DNA vaccine alone [111].

## VI. CONCLUSION

Following successes with live attenuated 17D yellow fever vaccine, formalin-inactivated JE and TBE vaccines, and cell-culture-derived JE vaccine, decades of efforts to develop live attenuated dengue vaccines may be nearing a conclusion. Two empirically derived attenuated tetravalent dengue vaccines are in Phase 2 clinical testing in the United States and in Thailand, and their pace toward licensure seems to be accelerating with the entry of commercial partners. The availability of dengue–yellow fever chimeras (Chimerivax, Acambis) may alter the equation by providing a third option based on a different live vaccine technology. The maturation of these candidates will expedite development of standardized viremia and antibody assays, further evaluation of protective responses in dengue infection, and promote investment in field study sites.

Moreover, the advent of novel molecular techniques to express viral subunit proteins and to construct infectious clones has also led to rapid exploration of dozens of candidate vaccines. While few candidates have advanced to the clinic, an enormous amount of information on dengue virus biology and immunology has been gained in the process. New viruses derived from infectious viral clones hold promise as stable live vaccines, if proven effective. Results with dengue nucleic acid vaccines are encouraging, but more work is needed to demonstrate tetravalent seroconversion and protection in animals and safety in clinical trials. The future possibility of licensed dengue vaccines seems assured, with first- and second-generation candidates entering into clinical testing.

### I. THE HEPACIVIRUS GENUS

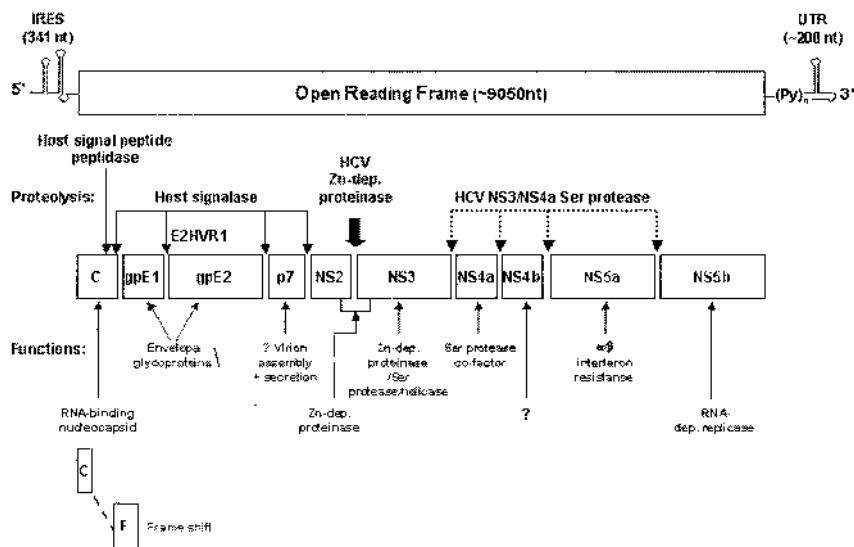

Hepatitis C viruses (HCV) are classified as members of the Hepacivirus genus within the Flaviviridae family [1] and are positive-stranded RNA viruses containing genomes of approximately 10,000 nucleotides [2]. The genomes encode a polyprotein precursor of about 3000 aa that is cleaved co- and post-translationally to yield a variety of virion and nonstructural (NS) proteins (Figure 1) [3]. Translation is mediated through an internal ribosome entry site (IRES) situated within the 5' untranslated region (UTR) of the RNA genome [4]. Recently, a -2/+1 ribosomal frame-shift has been observed to occur around aa11 of the C protein resulting in the synthesis of the F protein. The sequence of the F protein is partially conserved within the genus but its function is unknown [5,6]. However, the basic charged character of the F protein may also imply a nucleocapsid-like function. Unfortunately, HCV cannot be grown efficiently or reproducibly in cell culture, and limiting viral levels in infected individuals has rendered large-scale purification of virus unfeasible. This has meant that information on the structure of the virion is largely derived from expression studies with cloned cDNAs. Such studies have revealed cotranslational processing of the polyprotein precursor via host signalase to yield the presumptive structural proteins [the nucleocapsid (C) and envelope glycoproteins gpE1 and gpE2] [7–9]. gpE1 and gpE2 have been shown to translocate into the lumen of the ER where they remain tightly anchored in the form of a noncovalently bound heterodimer [10–12]. Deletion of the C-terminal transmembrane anchor regions (TMR) of either gpE1 or gpE2 results in secretion of the respective ectodomain from cDNA-transfected cells via the Golgi apparatus, although this is an inefficient process in the case of gpE1 [8,13]. The nucleocapsid is also cleaved by host signal peptide peptidase to yield a smaller species (p19 or p21) which appears to be the form found within virions circ-

ulating in the bloodstream [14,15]. C has the ability to self-associate into core particles [16] and is phosphorylated [17].

A large variety of NS proteins are thought to be processed downstream of the structural protein region (Figure 1) [3]. p7 is processed through the action of host signalase [18] and in the related pestiviruses has been shown to be required for virion assembly and/or secretion [19]. Further downstream proteins are processed from the precursor polyprotein through the action of viral-encoded proteases encoded by NS genes 2, 3, and 4a [20–22]. The NS proteins associate together on the ER to form a viral replication complex and various individual functions have been assigned (Figure 1). The 3' UTR region comprises a 3'-terminal 98 nt region that is highly conserved, which is located immediately downstream from a short pyrimidine-rich tract. The latter is preceded by a more variable region immediately downstream of the polyprotein precursor terminator codon [23,24].

Being RNA viruses encoding error-prone RNA replicases that lack the proofreading abilities of host DNA polymerase, the HCV genomes and encoded proteins are highly variable. The 5' and 3' UTRs are highly conserved as is the C gene and encoded nucleocapsid protein, but the rest of the viral genes/proteins exhibit considerable heterogeneity (Table 1) [25].

In addition, the N-terminal 30 aa of gpE2 (E2HVR1) is hypervariable and using the chimpanzee infection model, it has been shown to contain antibody-binding viral neutralizing epitopes that are under considerable selective pressure [26–31]. At least six different basic genotypes have been distinguished phylogenetically along with numerous subtypes (Figure 2), with type 1 being the most common genotype in the United States, China, and Japan, and it being also common in Europe (Figure 3). Unfortunately, due to the lack of an in vitro virus-neutralizing antibody assay, the number of serotypes is unknown. Recent progress in developing mouse infection models may facilitate further studies

in this important area [32]. It has been estimated that there are around 170 million HCV carriers worldwide [33].

## II. NATURAL IMMUNITY AND IMMUNE CORRELATES

Recent studies in the chimpanzee challenge model and of multiply-exposed humans have demonstrated that there is significant natural immunity against HCV. In one chimpanzee study [34], an animal was infected by intrahepatic administration of an infectious RNA derived from HCV strain HCV-1 (of the 1a subtype). This subtype is the most common clade in the United States (Figure 3). Following resolution of the ensuing acute infection and disappearance of viremia, the animal was shown to be resistant to an intravenous rechallenge with homologous virus. No viremia was observed following rechallenge, indicating that sterilizing immunity was generated by the original infection. When rechallenged subsequently with a heterologous 1a strain, the animal experienced very transient, minimal viremia unlike the substantial viremia observed in control animals. Resolution of the infection in the rechallenged animal was confirmed by showing the subsequent absence of viral RNA from the blood and liver. Furthermore, when rechallenged again with a heterologous 1b strain, the most common clade worldwide (Figure 3), only a transient viremia was observed prior to disappearance of the virus from plasma and the liver [34]. Very similar results were obtained in separate chimpanzee studies in which animals were challenged and then rechallenged i.v. with different infectious viral inocula. Only transient viremia occurred when animals that recovered initially from a 1a infection were rechallenged with either a heterologous 1a strain or a heterologous 1b strain [35,36]. Additional chimpanzee studies indicate the existence of cross-protective immunity between HCV types 1

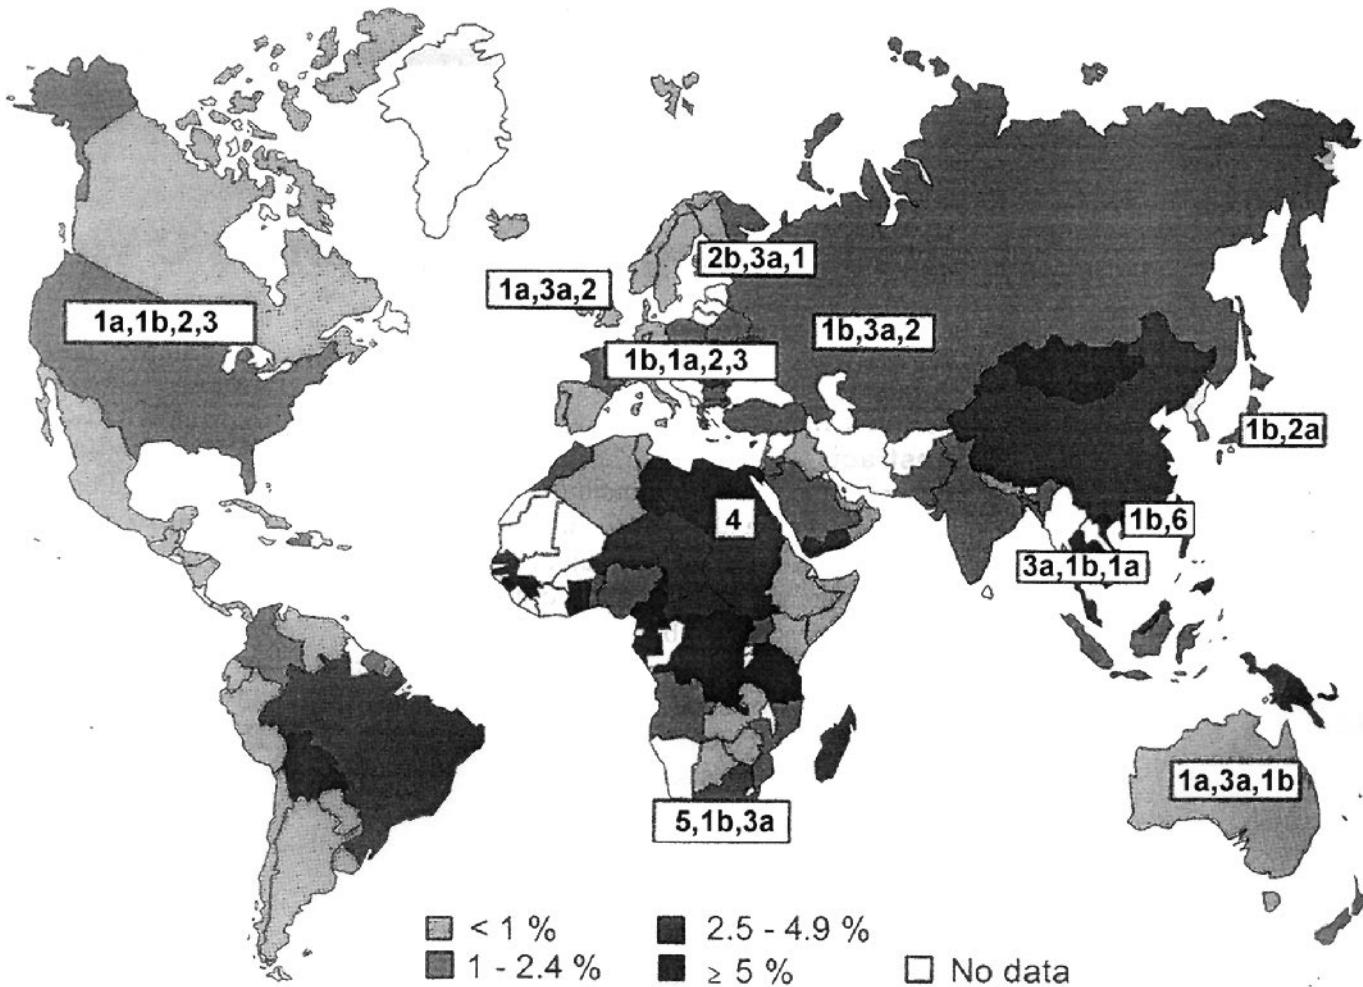

**Figure 2** Phylogenetic analysis of nucleotide sequences from part of the HCV NS5b region amplified from HCV-infected blood donors and patients from several countries. (From Ref. 140.)

and 3 (A. Weiner, unpublished). The latter HCV type is commonly found in intravenous drug users (IVDUs).

Similar findings have also been reported in a prospective study of IVDUs from the United States. Strikingly, the incidence of persistent viremia in IVDUs who had recovered from a previous infection was 12× lower than that in IVDUs who had not experienced a previous infection, as shown using multivariate analyses [37]. As seen in the chimpanzee studies, peak viral loads were substantially higher (by almost 2 logs) in the first-time infections as compared with the re-infections [37]. Also, HIV co-infection produced persistent HCV infection in all cases, indicating the role of the immune response in HCV recovery [37]. Intriguingly, it has now been shown that HIV patients co-infected with HCV have lowered peripheral immune responses to HCV as compared with patients with HCV monoinfections, even in the absence of severe CD4<sup>+</sup> T-cell depletion [38].

Collectively, these chimpanzee and human data provide evidence for the existence of significant immunity to HCV and, importantly, for the existence of cross-protective immunity within and between commonly occurring HCV clades. It is important to note, however, that not all re-infections were resolved without progressing to chronicity (3/9 became chronically infected [37]), indicating that natural immunity to HCV is not complete and not as effective as for the hepatitis A and B viruses. It should also be mentioned that earlier studies in the chimpanzee model have concluded a lack of protective immunity to HCV [39]. This apparent contradiction may be due to the earlier studies measuring immunity more in terms of sterilizing immunity, rather than the ability to prevent the development of chronic infection, as in the more recent studies.

It was first noted that early and broad MHC class II-restricted CD4<sup>+</sup> T helper responses to HCV are associated with recovery from acute, symptomatic infections of man (Figure 4) [40,41]. Subsequently, using the valuable chimpanzee model again, it was shown that recovery could occur in the absence of any antibody to the viral envelope glycoproteins but in the presence of an early and broad MHC class I-restricted CD8<sup>+</sup> cytotoxic lymphocyte (CTL) response to the virus [42]. This association of HCV-specific CD4<sup>+</sup> T helper and CD8<sup>+</sup> CTL responses with resolution of acute infection has been confirmed in many human studies [43–48], although the relative importance of each type of cellular immune response is unknown at present. A recent study sheds further light on the potential mechanism of recovery from clinically asymptomatic, acute infections of man. Shortly following infection, activated HCV-specific CD8<sup>+</sup> T cells appeared in the peripheral blood that were associated with an increase in serum alanine aminotransferase (ALT) levels (signifying liver damage), and with a small decrease in viral RNA levels. These activated CD8<sup>+</sup> cells did not secrete gamma interferon. Shortly afterwards, a 5-log reduction in viral load occurred commensurate with the appearance of HCV-specific, gamma interferon-secreting CD8<sup>+</sup> cells with a nonactivated phenotype (CD38-negative). This large reduction in viral load was not accompanied by an increase in serum ALT levels, suggesting that a noncytolytic, viral clearance mechanism mediated by gamma interferon might be operative (Figure 5) [47]. This conclusion is consistent with the demonstrated anti-HCV activity of gamma interferon in cell cultures containing HCV replicons [49]. In contrast, individuals who develop chronic, persistent infection show weaker cellular immune responses to the viruses that are not

**Figure 3** Approximate HCV prevalence and genotype distribution. (From Ref. 141.)

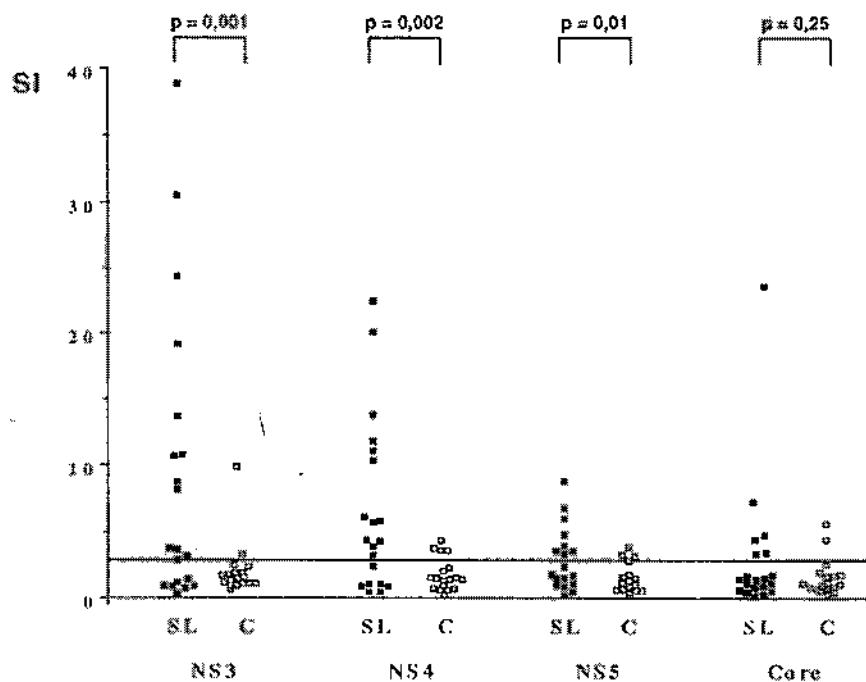

maintained over time (Figure 4) [43–47,50] and that have dysfunctional CD8<sup>+</sup> T-cell effector functions [51–53].

The association of HCV-specific, cellular immune responses with recovery is further reinforced by data from several studies showing that memory T-cell responses to the virus can be detected in long-term convalescent individuals [50], in nonviremic and HCV antibody-negative, healthy family members of HCV patients [54], and in other individuals who lack HCV antibody and RNA but who may have been exposed to the virus earlier [55]. However, further work is necessary to define the relative roles of HCV-specific CD4<sup>+</sup> and CD8<sup>+</sup> T-cell responses in protection as well as the mechanism of action.

The kinetics of induction of HCV-specific T-cell responses to multiple epitopes may be crucial in determining the outcome of infection, because the ability of the virus to mutate and thus evade CD8<sup>+</sup> T-cell responses has been demonstrated convincingly in the chimpanzee model [56]. The latter study suggests that if a multispecific T-cell response is made early in infection, then it is harder for the virus to mutate several epitopes simultaneously and, therefore, more likely to result in resolution of infection. Host and

viral factors involved in determining the breadth, strength, kinetics, and decline [51,52] of HCV-specific cellular immune responses will deserve much attention in the future. In this regard, certain MHC class I and II alleles are associated with recovery in humans [57–59].

The role of anti-envelope antibody in resolution of HCV infection is unclear at present. Initially, it was found that nearly all chronically infected humans have significant antibodies to gpE1 and gpE2, as measured in ELISA assays, and that there was not a clear relationship between the induction of these antibodies and resolution of acute infection [60]. These findings were extended in other studies showing that in man and chimpanzees, it was more likely to find anti-envelope antibody (as measured in ELISA assays) in chronically infected individuals than in resolvers of acute infection [61–63]. This contrasts with the situation found for many infectious agents, e.g., the hepatitis B virus, where anti-envelope antibody is a strong correlate of immunity. It should be noted, however, that a true *in vitro*, viral-neutralizing antibody assay has not been developed, due to the lack of a reliable cell culture system for HCV, and so the presence, level, and affinity of neutralizing antibody cannot be easily

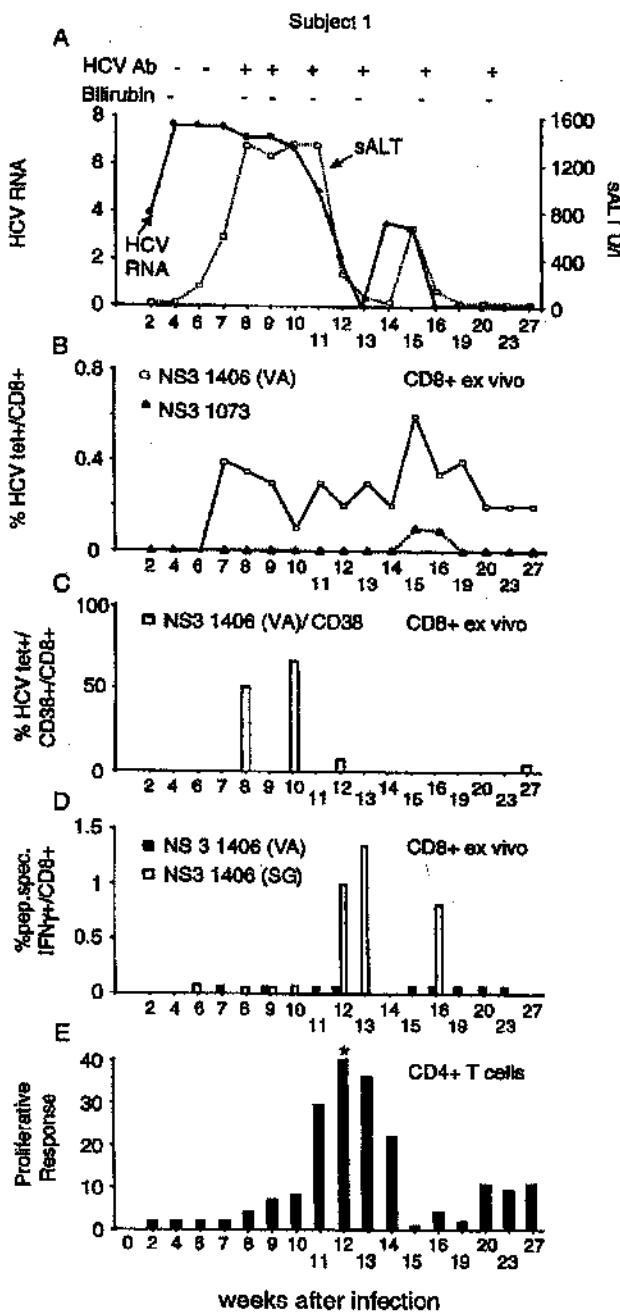

**Figure 4** Proliferative CD4<sup>+</sup> T-cell response of the first sample in the acute phase of disease to recombinant HCV proteins (HCV-NS3, -NS4, -NS5, and -core) of peripheral blood mononuclear cells (PBMCs) from 38 patients with acute hepatitis C. Patients are grouped according to the final outcome of disease in self-limited hepatitis C (SL,  $n = 20$ ) and patients with chronic evolution (C,  $n = 18$ ). Results are shown as SI—<sup>3</sup>H-thymidine incorporation of antigen-stimulated PBMCs (cpm)/unstimulated control (cpm). Values  $\geq 3$  are considered significant. All patients with self-limited disease displayed a significant proliferative T-cell response against at least one of the viral proteins, while patients with chronic evolution mounted no or only transient antiviral T-cell responses. NS3 and NS4 revealed the most frequent and most vigorous responses. In four patients, the proliferative response against NS5 was not tested in the first sample. (From Ref. 40.)

monitored. However, the presence of neutralizing antibody has been demonstrated using the chimpanzee model. Serum derived from a patient was shown capable of neutralizing the infectivity of virus taken from the same patient, 2 years earlier. However, the same viral inoculum could not be neutralized using serum from the patient obtained many years later [64]. The infectivity of various viral inocula in chimpanzees was also shown to be inversely proportional to the level of immune complexes, providing further evidence for the existence of neutralizing antibody [65]. Additional evidence for the generation of neutralizing antibody comes from several studies showing the efficacy of human Ig preparations, derived from numerous donors, in preventing the transmission of HCV following blood transfusion [66], liver transplantation [67], and between sexual partners [68]. Chimpanzees that received human Ig prior to experimental viral challenge also showed a clear inhibition of acute hepatitis and viremia throughout the lifetime of the antibodies [69]. When combined with clinical evidence for worse HCV-associated disease in hypogammaglobulinemics [70,71], the combined data clearly suggest that HCV infection does induce neutralizing antibody.

Why then is there a lack of correlation between anti-envelope antibody and the outcome of infection? Several possibilities exist; firstly, it has been shown that antisera raised against the N-terminal region of gpE2, the so-called

E2 hypervariable region 1 (E2HVR1), can neutralize the infectivity of homologous virus in the chimpanzee model [30]. Preliminary studies have reported that the early induction of anti-E2HVR1 may correlate with resolution of acute infection in humans [72,73]. Many studies have also suggested that this region mutates readily in response to the specific, humoral immune response, thus evading the binding of anti-E2HVR1 [27,29,31]. If this is a principal neutralizing domain of the virus, then it is possible to imagine how the virus might evade the antibody response. This might also explain the apparent, protective efficacies of complex human Ig preparations, if they contain highly plural anti-E2HVR1 antibodies.

A second theory revolves around the observation that infectious HCV virus has a very low density in sucrose gradients ( $\sim 1.06$  g/ml) [74] and that this fraction contains low-density lipoproteins that can bind and mask the virus, at least partially, from the action of neutralizing antibody [75,76]. A third possibility is that HCV may be transmitted between adjacent hepatocytes in the liver because giant, multinucleated hepatocytes are observed in the HCV-infected liver. In conclusion, the role of anti-envelope antibody in the protective immune response is poorly defined at present, although it is most likely a complex situation. While it is well established that humans and experimentally infected chimpanzees can resolve acute infections in the absence of de-

**Figure 5** HCV-specific T-cell responses in subject I during asymptomatic, resolving acute HCV infection. (A) Course of infection. (B) Percentage of CD8<sup>+</sup> lymphocytes that were tetramer-positive at each time point. CD8<sup>+</sup> T-cell responses were tested directly ex vivo using HLA-A2 tetramers complexed with five different HLA-A2 restricted epitopes. CD8<sup>+</sup> T-cell responses against two epitopes [NS3 1073 and NS3 1406 (VA)] were detectable. (C) Percentage of NS3 1406 (VA)-specific CD8<sup>+</sup> T cells expressing the activation marker CD38. (From Ref. 47.)

tectable anti-envelope antibody, but in the presence of early and broad T-cell responses, this does not rule out a role for neutralizing antibodies in the protective immune response in all individuals.

### III. VACCINE STRATEGIES

#### A. Aims

In view of the current knowledge regarding protective immune responses to HCV, many investigators are focusing on vaccines capable of priming specific, broad cellular immune responses, including both MHC class II-restricted CD4<sup>+</sup> 1 helper responses as well as MHC class I-restricted CD8<sup>+</sup> responses. Conventionally, it has proven difficult to achieve the latter through the use of soluble proteins combined with adjuvants, although there has been recent progress in this area using recombinant HCV proteins combined with the ISCO Ms adjuvant. Therefore most activities designed to achieve the priming of CD8<sup>+</sup> T cells to the virus have centered around the use of DNA vaccines, using either bacterial plasmids or various viral vectors. In this way, HCV proteins are synthesized endogenously within the cytosol where they can then be processed within the proteasome and the resulting peptides are transported to the cell surface in association with MHC class I antigens, thus stimulating CD8<sup>+</sup> T-cell responses. In addition, some groups have also aimed at priming anti-envelope antibody responses via protein or DNA immunization involving either the gpE1/gpE2 heterodimer or either envelope glycoprotein alone. Other strategies have centered around creating a consensus E2HVR1 peptide that can prime broadly cross-reactive, neutralizing antibody. Due to the lack of a system for propagating HCV in vitro, the prospect of using a killed or attenuated HCV viral vaccine is unfeasible at present.

#### B. Adjuvanted, Recombinant HCV Protein Vaccines

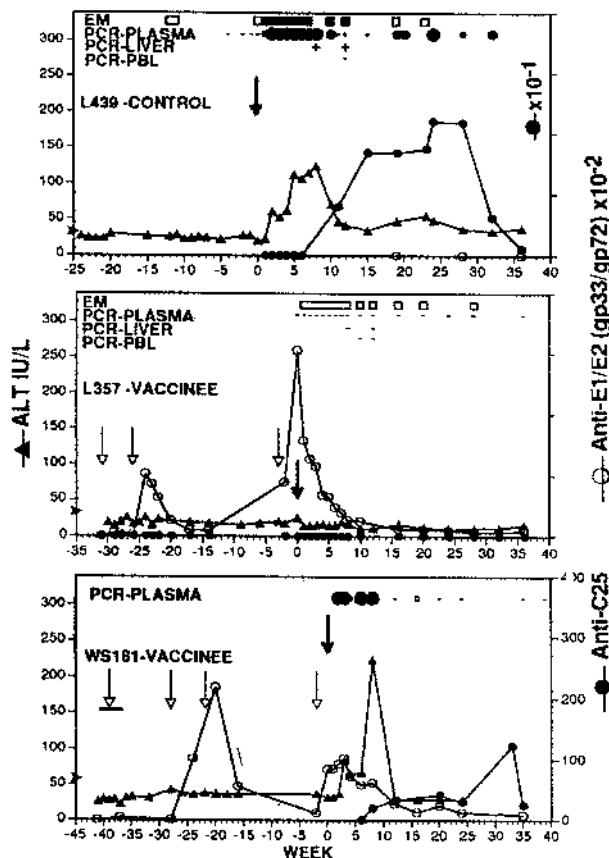

A vaccine comprising the recombinant gpE1/gpE2 heterodimer combined with an oil/water microemulsified adjuvant has been tested for efficacy in the chimpanzee model [77–79]. The heterodimer was derived from HeLa cells infected with a recombinant vaccinia virus expressing a C-gpE1-gpE2-p7-NS' gene cassette derived from the HCV-1 strain (1a clade). Following cleavage by host signalase in the er, gpE1 and gpE2 translocate into the lumen of the er where they remain associated together and tightly anchored via type 1 transmembrane domains located at the C termini of both molecules [7–13]. Following extraction in nonionic detergent and affinity purification using GNA-lectin (that specifically binds the high mannose chains found on the heterodimer), the purified subunit proteins were used to immunize naïve chimpanzees along with the adjuvant. Generally, 30–40  $\mu$ g of the subunits were administered intramuscularly (i.m.) on approximately months 0, 1, and 6, and a homologous viral challenge was given i.v., 2–3 weeks after the third immunization. Encouragingly, of seven

animals receiving the vaccine, five were completely protected against the challenge, with no signs of viral infection in any of the assays, including sensitive RT-PCR assays for viral RNA (Figure 6) [77]. These five apparently sterilized animals were the highest responders to the vaccine in terms of elicited titers of anti-gpE1/gpE2 [77]. Sterilization did not correlate with antibody titers to E2HVR1 but did correlate with the titer of antibodies that block the binding of recombinant E2 to the CD81 ligand [80]. The latter has been shown to bind intact virus and could be involved in the receptor for HCV [81]. In addition, the two lowest responders

that became infected following challenge eventually resolved the acute infection without becoming chronic carriers (Figure 6) [77–79]. In contrast, most control animals become chronically infected following viral challenge [77–79]. Given that the prime, practical goal of an HCV vaccine would be to prevent the development of chronic infection following exposure to the virus, this study provided much encouragement for the development of an effective vaccine challenge [77,79].

This work has now been extended to address the key question of whether the vaccine protects against experimental challenge with a heterologous 1a viral strain. Initial data were derived from three vaccinees, previously protected against homologous viral challenge, that were then reboosted with vaccine prior to rechallenge with the HCV-H strain (another member of the 1a clade common in the United States). While sterilization was not achieved, two of the three animals exhibited an amelioration of the acute infection followed by resolution [78,79]. Using additional chimpanzees, including five naïve animals that had not been challenged with HCV previously, it has now been shown that out of a cumulative total of 10 vaccinees challenged with the heterologous HCV-H strain, while all 10 animals experienced acute infections, only 1 developed chronic, persistent infection. In contrast, most control animals challenged with HCV-H become chronic carriers (7/9;  $P = 0.005$ ; M. Houghton, unpublished). Interestingly, the single carrier of HCV-H generated in the vaccine group actually elicited the highest anti-gpE1/gpE2 antibody titer of the group, indicating that such antibodies alone are not sufficient for protection [77–80]. Presumably, vaccine-mediated T-cell responses and/or the host's immune response to HCV replication following challenge are also involved in the protection observed.

Another group has also immunized a chimpanzee with insect cell-derived recombinant gpE1 and gpE2 (from HCV strain N2), in addition to a peptide spanning the E2HVR1 (from HCV strain #6). gpE1 and gpE2 were each expressed and purified separately and lacked the C-terminal transmembrane anchors. The E2HVR1 peptide was conjugated to keyhole limpet hemocyanin and Freund's adjuvant was employed to augment immune responses. Their conclusion, from a series of immunizations and challenges with HCV strain #6 in the same animal, was that sterilization was dependent on high anti-E2HVR1 titers rather than anti-gpE2 or anti-gpE1 titers [82,83]. The outcome of challenging with other viral strains was not reported, however. It should also be noted that insect-derived gpE2 (truncated at the C terminus) has been shown to bind poorly to a putative HCV receptor, CD81, as compared with gpE2 derived from mammalian cells [80]. The latter group also showed that the full-length gpE1/gpE2 heterodimer, derived from mammalian cells, bound to CD81 with high affinity as did intracellular forms of gpE2, truncated at the C terminus. However, secreted forms of gpE2 were not effective at binding CD81. Because deglycosylation of secreted gpE2 restored CD81-binding activity, it appears that the addition of complex carbohydrate during secretion either masks the CD81-binding site or changes the conformation to an inactive form [84]. The physiological significance of these find-

**Figure 6** HCV-1 challenge of vaccinated and control chimpanzees. Control and immunized chimpanzees (L, Laboratory for Experimental Medicine and Surgery in Primates; W.S., White Sands) were challenged with  $\approx 10$  CID<sub>50</sub> of HCV-1. The presence (solid boxes) or absence (open boxes) of hepatocyte ultrastructural changes observed in the electron microscope (EM) is indicated. The approximate relative levels of HCV-1 RNA detected in plasma using reverse transcriptase (RT)-PCR assays are reflected by sizes of the shaded circles (open circles denote borderline positives; minus signs denote undetectable levels). The results of RT-PCR assays of liver and PBL extracts are recorded as either + or -. The arrows in the ALT axes indicate the mean  $\pm$  3.75 SD of prechallenge values; open vertical arrows denote time of subunit vaccine administration, and the solid vertical arrow denotes viral challenge on week 0. IU/L, international units per liter. (From Ref. 77.)

ings is unclear at present, because the method of HCV virion secretion and the nature of the virion carbohydrate are unknown.

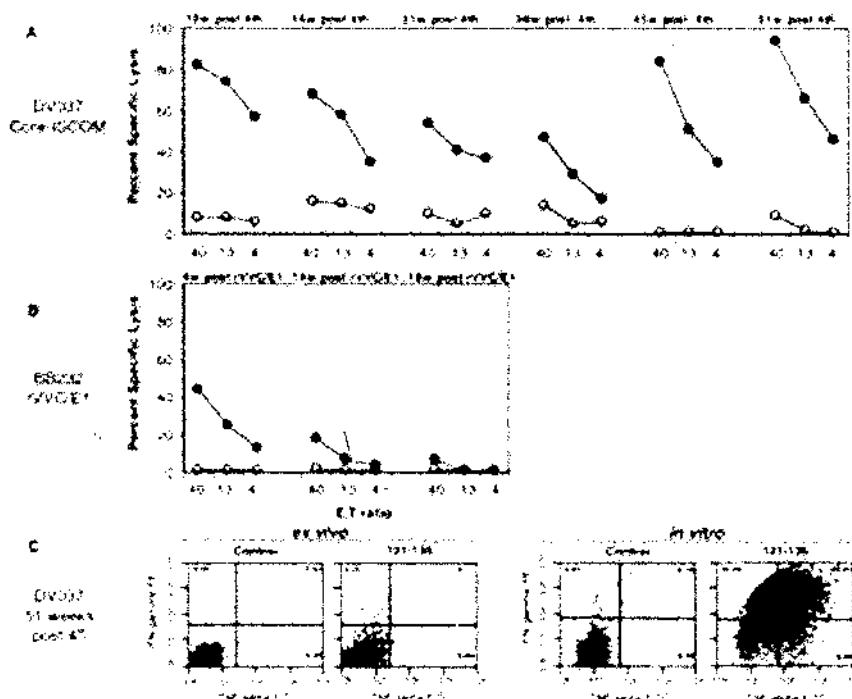

Intracellular, C-terminally truncated forms of gpE2 have been shown to be immunogenic in human volunteers, although efficacy in the chimpanzee challenge model has not yet been demonstrated (M. Houghton, unpublished). However, the gpE1/gpE2 heterodimer is generally considered to be a more native reflection of the HCV virion than either ectodomain alone and, as mentioned above, has demonstrable prophylactic efficacy in the chimpanzee. Therefore recombinant gpE1/gpE2 represents an encouraging human vaccine candidate.

Some work has been directed to the synthesis of viral-like particles (VLPs) by expressing the structural genes in different cells. In insect cells, expression of the C-gpE1–gpE2 gene cassette has been reported to result in the generation of 40–60-nm VLPs within cytoplasmic cisternae [85]. Following partial purification, these VLPs appear to be immunogenic in small animals and, as such, represent a potential vaccine candidate for humans [86]. Similar-sized VLPs have been observed in the process of budding into the lumen of the er, following expression of the same gene cassette in mammalian cells using a Semliki Forest viral vector [87]. HCV gene expression was observed to induce convoluted membranes or membranes similar to those seen in infected livers

[87]. However, some viral or host factor is limiting the release of the VLPs into the lumen and from being secreted into the cell media [87].

Because the E2HVR1 region of gpE2 has been shown to possess viral neutralizing epitopes and to be highly mutable, attempts have been made to select for a cross-reacting version using phage display of mimotopes. Rabbit antisera raised against one mimotype was highly cross-reactive with the E2HVR1 of many viral isolates and reacted to discontinuous epitopes [88]. Such mimotypes or consensus E2HVR1 peptides may be valuable components of an HCV vaccine. In this regard, a consensus E2HVR1 peptide sequence has been fused to the B subunit of cholera toxin and expressed in plants through the use of a tobacco mosaic viral vector. Crude extracts were then administered intranasally to mice, which then generated cross-reactive E2HVR1 antibodies that were capable of capturing virions [89].

Recombinant C protein is also being studied as a potential component of an HCV vaccine for several reasons. Firstly, broad HCV-specific CD4<sup>+</sup> and CD8<sup>+</sup> T-cell responses, including those of the C protein, are associated with recovery from HCV infection [42–44,46,47]. Secondly, the C protein is the most conserved HCV polypeptide and contains CD4<sup>+</sup> and CD8<sup>+</sup> epitopes that are highly conserved among the different HCV genotypes, which should therefore facilitate the generation of cross-protective immu-

**Figure 7** Longevity of the CTL responses primed by vaccination with recombinant HCV core in ISCOMs adjuvant. Peripheral blood mononuclear cells from rhesus macaques DV037 (A) and BB232 (B) were restimulated in vitro with the epitope peptide 121–135. After CD8<sup>+</sup> enrichment, cells were tested for cytotoxic activity against autologous B-LCLs sensitized with the epitope peptide 121–135 (●) or an irrelevant peptide (○). (C) Freshly isolated PBMCs from DV037 51 weeks after its last immunization (two left panels) or in vitro restimulated PBMCs from the same time point (two right panels) were restimulated for 12 hr with peptide 121–135 or a control peptide and stained for surface CD8 and intracellular IFN- $\gamma$  and TNF- $\alpha$ . Lymphocytes were gated by side vs. forward scatter light and then for CD8-PerCP. Plots show log fluorescence intensity for TNF- $\alpha$ -FITC and IFN- $\gamma$ -PE. (From Ref. 94.)

nity [90,91]. Thirdly, recombinant C protein has been shown to self-assemble into particles [16] with concomitant high immunogenicity in animal models. Substantial CD4<sup>+</sup> T-cell priming and high anti-C antibody titers have been obtained in mice and sheep [92,93].

In general, immunization with adjuvanted polypeptide subunits does not result in cross-priming, a process in which the antigen is deposited within the cytosol of antigen-presenting cells and processed peptides then placed on the MHC class I-presentation pathway, resulting in stimulation of CD8<sup>+</sup> CTLs. However, through the use of the ISCOM adjuvant, a particulate adjuvant comprising cholesterol, phospholipid, and naturally occurring saponins, it has been possible to prime strong CD8<sup>+</sup> CTL activity (and CD4<sup>+</sup> activity) in rhesus macaques, using a recombinant C antigen derived from *E. coli* (Figure 7) [94]. Cytotoxic lymphocytes to at least two epitopes were identified. This approach is a promising and practical option for the development of an HCV vaccine capable of priming cross-reactive HCV-specific T-cell responses associated with protection.

There are numerous CD4<sup>+</sup> and CD8<sup>+</sup> epitopes that are conserved among the different HCV genotypes. These reside within the various HCV-encoded virion and nonstructural proteins [90,91,95]. The inclusion of a multiplicity of these epitopes will facilitate the vaccine-mediated generation of broad cellular immune responses to the virus, which could then result in the elicitation of cross-protective immunity against different HCV genotypes. One such approach involves the assembly of "HCV polytope vaccines" consisting of a consecutive sequence of these conserved HCV T-cell epitopes, in the form of a recombinant polypeptide or DNA vaccine. Focusing the immune response on a collection of highly conserved epitopes that can be presented by diverse human MHC class I and class II antigens may optimize the generation of strong, cross-protective immunity and possibly avoid the "dilution" of the immune response to variable, more mutable HCV epitopes.

Other approaches being explored to generate cellular immune responses include the fusion of recombinant HCV proteins with bacterial pore-forming toxoids. Certain detoxified bacterial toxoids have the ability to induce pore-mediated endocytosis in antigen-presenting cells, thus resulting in the generation of strong CD8<sup>+</sup> and CD4<sup>+</sup> T-cell responses to the toxoid and fused HCV moiety [96]. Electrically mediated uptake of synthetic HCV peptides has also been reported to result in priming of reactive CTLs in electroporated Balb/c mice [97]. Host heat-shock proteins are known to be good mediators of CD8<sup>+</sup> MHC class I-restricted immune responses to associated foreign protein sequences [98]. As such, this approach may be applicable to the development of HCV vaccines, provided that harmful, auto-immune responses are not generated. Another intriguing avenue of research involves the use of influenza-based virosomes to deposit recombinant HCV proteins or synthetic HCV peptides on the MHC class I pathway, resulting in the generation of viral-specific CD8<sup>+</sup> CTLs. Comprising liposomes with influenza hemagglutinin and neuraminidase on the surface, these VLPs allow fusion with the membrane of antigen-presenting cells and the subsequent deposition of the HCV moiety in the cytosol. This then facilitates associ-

ation of peptides with MHC class I molecules and TAP-mediated transfer to the surface of the cell where priming of reactive CTLs occurs [99].

### C. HCV DNA Vaccines

The discovery that naked DNA or RNA administered i.m. or i.d. results in expression of encoded antigens and the elicitation of specific humoral and cellular immune responses has opened up a new area of vaccinology [100–103]. Advantages of using a DNA vaccine relate to the ease and cost of manufacture, the gene-mediated synthesis *in vivo* of native and often complex protein structures (that would otherwise be difficult to produce in the form of recombinant proteins), good stability (that renders the use of DNA vaccines particularly suitable to the needs of developing countries), and the ready ability to employ multiple genes, gene cassettes, or plasmids to elicit broad immune responses against heterogeneous pathogens such as HIV, HCV, and malaria, for example. Another important feature relates to the ability of DNA vaccines to stimulate CD8<sup>+</sup> MHC class I-restricted CTL responses via the endogenous synthesis of proteins *de novo* in the cytosol. Disadvantages, however, can include a weaker potency as compared with other vaccine formulations as well as safety issues revolving around their potential to integrate into the host genome, thereby increasing the risks of mutagenesis and carcinogenesis.

Additional safety issues may also be of concern, depending on the infectious agent under study. In the case of HCV, relatively long-term expression of the C gene has been reported to exert multiple pathogenic, oncogenic, and regulatory functions in transfected cells and animals. Its role in inducing steatosis and hepatocellular carcinoma in transgenic mice has been documented [104,105], as has its ability to co-promote cellular transformation *in vitro* [106]. There have been numerous other reports demonstrating the ability of the C gene product to bind to a member of the TNF-alpha superfamily [107], modulate apoptosis [108], induce oxidative stress [109,110], activate cellular and viral promoters [111], and affect other regulatory functions [112]. While the pathogenic significance of these findings in infected humans, if any, remains to be determined, it may be prudent in the meantime to omit the C gene from a potential HCV DNA vaccine (although the intermittent use of a recombinant C polypeptide subunit vaccine is unlikely to pose such a safety risk). Similarly, the 5' terminal region of the NS3 gene (encoding the protease domain) has been linked with transformation of cells and carcinogenesis in nude mice [113].

Most of the work performed so far with HCV DNA vaccines has been performed in small animals, with very little done using nonhuman primates. This is important because, while most DNA vaccines are immunogenic in mice and other small animals, such results are harder to reproduce in higher animals. Furthermore, even the rhesus macaque is a questionable model for immunogenicity of DNA vaccines in humans. Many studies have immunized mice with plasmids expressing the envelope genes of HCV, generally using the immediate-early CMV promoter and intron to achieve high expression levels. Accordingly, the generation of humoral and cellular immune responses to gpE2 has been widely

reported, including cross-reactive anti-gpE2 antibodies between subtypes 1a and 1b [114–120]. The use of a DNA vaccine encoding intracellular forms of gpE2, rather than secreted forms, has been emphasized in order to elicit anti-gpE2 antibodies capable of preventing the interaction between gpE2 and CD81, the latter being a candidate HCV receptor [84]. Boosting DNA-primed mice with recombinant gpE2 has been reported to elicit higher anti-gpE2 titers than repeated DNA or protein immunizations [121]. Immunogenicity of gpE2 DNA vaccines has also been demonstrated in rhesus macaques [118].

As with DNA vaccines targeting other infectious agents, the mode of injection drastically alters the immune response. Administration of a gpE2 DNA vaccine by gene gun, in which DNA is physically administered intraepithelially on gold microparticles, resulted in anti-gpE2 titers that were 100× higher than if delivered by needle, i.m. [120]. This increase in vaccine potency should translate to the use of lower doses in humans, thus lessening safety concerns.

Other methods to improve the potency of DNA vaccines include the application of an electric field at the site of DNA injection (so-called “electroporation”). In the case of a gpE2 DNA vaccine, electroporation led to 10-fold increases in expression levels and in concomitant anti-gpE2 responses. The latter also included cross-reactive anti-E2HVR1 antibodies that were not obtained without the use of electroporation. This technique also resulted in significant increases in gpE2-specific CD4<sup>+</sup> T helper and CD8<sup>+</sup> CTL responses [122]. However, the potential of electroporation to increase the rate of integration of the DNA vaccine into the host genome remains to be evaluated.

Other improvements include the formulation of DNA vaccines into particles, thereby increasing the uptake by antigen-presenting dendritic cells with corresponding increases in immunogenicity [123]. Lipid formulations of DNA that result in improved transfection efficiency *in vivo* as well as better uptake by dendritic cells have been shown to be part of an encouraging immunization regimen for rhesus macaques against SHIV challenge and have applications to HCV and other infectious diseases [124].

Only one small HCV DNA vaccine study in the chimpanzee model has been reported so far. In an attempt to optimize immunogenicity, the ectodomain of gpE2 (aa 384–715) was fused to the CD4 C-terminal, transmembrane region (TMR) that facilitated sequestration of the encoded gpE2 glycoprotein to the outer cell surface, rather than being anchored in the lumen of the ER via the use of the homologous TMR. Ten milligrams of DNA were administered using a bioinjector into the quadriceps of two animals on weeks 0, 9, and 23, followed by experimental challenge with homologous, monoclonal virus 3 weeks later. Humoral and cellular immune responses to the vaccine were observed in only one animal, but following challenge, viremia was lowered as compared with a control animal and hepatitis occurred earlier, as a result of the primed immunity. Importantly, both vaccinees resolved their acute infections quickly, whereas the control, unvaccinated animal became chronically infected following viral challenge. This result is promising, but further studies are warranted due to the small number of animals and because one of the vaccinees had

already experienced an experimental HCV infection, prior to vaccination, that would have conferred immunity [125].

In order to recapitulate the broad T-cell responses associated with protective immunity against HCV infection, many groups are investigating DNA vaccines capable of priming HCV-specific CD4<sup>+</sup> and CD8<sup>+</sup> T-cell responses to many HCV gene products. A DNA vaccine encoding NS3, NS4, and NS5 not only primed broad and specific antibodies, CD4<sup>+</sup> T helper and CD8<sup>+</sup> CTL responses, but also conferred protection to the immunized BAL B/c mice against challenge with syngeneic, SP2/0 myeloma cells expressing NS5 [126]. Co-expression of the GM-CSF cytokine gene has also been shown to augment cellular immune responses to these NS gene products when administered as a bicistronic plasmid to Buffalo rats [127].

Many studies have been conducted with DNA vaccines containing the HCV C gene, as this encodes the most conserved viral protein and is known to contain important T-cell epitopes. Immunogenicity in mice has been reported [128–131] and, in addition, the co-administration of either IL2 or GM-CSF has been shown to augment humoral and cellular immune responses to C in mice [129]. On the contrary, co-immunization with a plasmid expressing IL4 resulted in the elicitation of a Th0 phenotype and a concomitant suppression of C-specific CTLs [129]. The use of transgenic mice expressing human HLA-A2.1 has also shown the ability of NS3 DNA vaccines to induce specific CTLs to the same immunodominant epitope observed in humans [132].

Finally, it is also noteworthy that defective RNA vaccines have been shown to be very effective at protecting against flaviviral infections [133]. Conferring good protective immunity in the absence of integration into the host genome, this approach has great promise for HCV and other infectious diseases.

#### D. HCV Vaccines Using Disabled Viral or Bacterial Vectors

The use of a defective or attenuated viral or bacterial vector to deliver vaccines has several potential advantages. Firstly, a wide tropism of the host vector leads to the efficient delivery of the vaccine genes and encoded antigens. Preferably, this tropism includes antigen-presenting cells leading to a very effective priming of the immune response, thereby requiring only one immunization for long-lasting immunity. The use of a vector already used as a vaccine itself offers further obvious advantages with respect to manufacturing, distribution, and user acceptance. Finally, many vectors allow the insertion of multiple genes thus facilitating the induction of a broad, cross-protective immune response, particularly useful against heterogeneous agents such as HCV.

One such promising approach for HCV has been the use of an attenuated rabies viral vector into which either the HCV gpE1–gpE2–p7 gene cassette was inserted, or just the ectodomain of gpE2 linked to the CD4, C-terminal TMR, and cytoplasmic domain. In the case of the latter construction, recombinant rabies virions were produced that actually

contained the hybrid gpE2 within the virion. Virions expressing gpE1–gpE2–p7 were immunogenic in mice eliciting CTL responses to gpE2 [134]. Similarly, defective Semliki Forest viruses containing the HCV NS3 gene produced long-lasting NS3-specific CTLs after one immunization in mice transgenic for human HLA-A2.1 [135]. As observed in HCV-infected patients, the immune response was directed to one immunodominant epitope within NS3. Defective recombinant adenoviruses expressing the HCV C–gpE1–gpE2 gene cassette have also been shown to prime HCV-specific CTLs in mice immunized i.m., although the induction of anti-gpE1/gpE2 antibodies required further immunization with purified gpE1/gpE2 glycoproteins [136]. Replication-defective adenoviruses expressing C and gpE1 also primed long-lasting, specific CTL responses in mice [137]. Recombinant canary pox viruses, expressing an HCV gene cassette containing C–gpE1–gpE2–p7–NS2–NS3, elicited HCV-specific humoral and cellular immune responses in mice, although the optimum immunization regimen required first priming with a plasmid DNA expressing the HCV genes prior to boosting with the recombinant canary pox virus [138].

Attenuated *Salmonella typhimurium* transformed with a plasmid expressing the HCV NS3 gene has also been shown to elicit NS3-specific CTLs in mice transgenic for human HLA-A2.1. The bacterium was administered orally and the resulting CTL responses persisted for at least 10 months [139].

#### IV. SUMMARY

Recent studies in man and in the chimpanzee model provide evidence for significant natural immunity to HCV infection. Broad and early HCV-specific CD4<sup>+</sup> and CD8<sup>+</sup> T-cell responses are associated with recovery from acute infections. In contrast, chronic evolvers have a delayed, weaker T-cell response that deteriorates further with the onset of chronicity. The virus also mutates readily to evade both specific CD8<sup>+</sup> CTLs as well as neutralizing antibodies directed to the hypervariable region in gpE2. Chimpanzee challenge studies, using recombinant envelope glycoprotein vaccines, have demonstrated prophylactic efficacy and the feasibility of protecting against the development of chronic infection following experimental challenge with both homologous and heterologous viral strains. The application of broad technologies to HCV vaccination should result in effective vaccines which, although may not be 100% effective, should be very useful in lowering substantially the current incidence of HCV infection with its ensuing clinical sequelae. Vaccine immunotherapy, especially as an adjunct to antiviral treatment regimens, deserves clinical investigation.

### I. WORLDWIDE IMPORTANCE OF AN EFFECTIVE ROTAVIRUS VACCINE

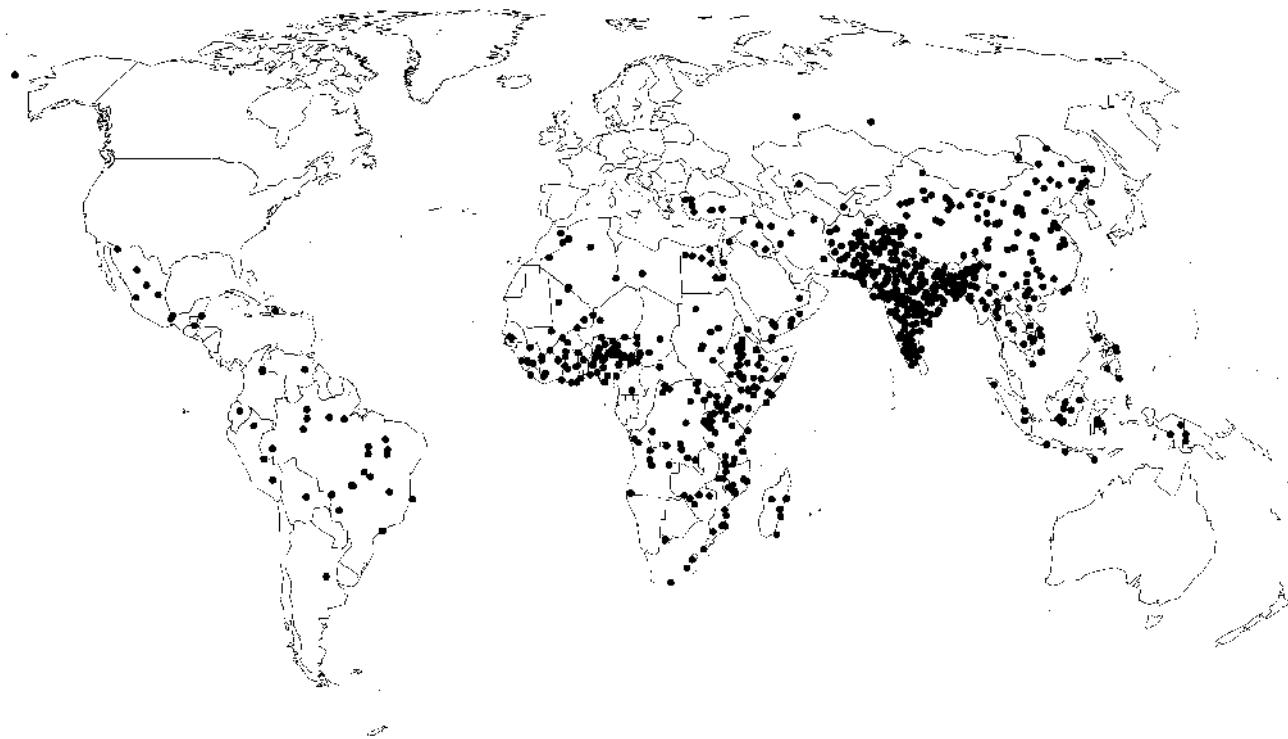

Diarrheal diseases are among the most common illnesses of mankind, and the first or second most common cause of death, hospitalization, and doctor visits among children worldwide [1,2]. They almost always result from infection and, over the past three decades, more than 25 different infectious agents have been identified as etiological agents of diarrheal diseases. For most children, episodes of diarrhea are self-limited, the disease is mild, and recovery occurs within several days. However, in some children, the disease can be severe, progressively leading to dehydration, hospitalization, and death. Of the many diarrheal illnesses, rotavirus has been identified to be the most common cause of severe diarrhea in children.

Several key features define the epidemiology of rotavirus diseases and suggest approaches to the prevention and control of the disease with vaccines [3]. First, infections are universal and all children worldwide are infected in their first 3 years of life. This suggests that improvements in food and water sanitation are unlikely to alter the incidence of disease; therefore, other approaches are necessary. First infections with rotavirus that occur several months after birth are often associated with severe diarrhea. Immunity to the disease develops after the first infection, so second infections are usually not associated with illness and the incidence of rotavirus disease diminishes with increasing age [4]. Despite global efforts to diminish the severity of diarrhea through the use of oral rehydration, diarrhea related to rotavirus remains a major cause of hospitalization and death.

Global interest in the development of rotavirus vaccines has been driven by the burden of fatal disease in developing countries (Figure 1) and the burden of rotavirus diseases on medical and societal costs in industrialized countries [5,6]. In developing countries, rotavirus is estimated to cause 450,000–600,000 deaths each year (Figure 2). This represents about 5% of the 12,000,000 deaths worldwide annually among children <5 years of age, or about one death per 270 children born worldwide (ca. 135,000,000 births per year) [7]. In both developed and industrialized countries, rotavirus accounts for between 20% and 60% of hospitalizations for diarrhea, and recent surveys suggest that one child in every 30–120 will be hospitalized for rotavirus diarrhea before their fifth birthday. In the United States, efforts to include a rotavirus vaccine in the national immunization schedule were prompted by estimates that rotavirus diarrhea results in 600,000 doctor or emergency room visits, 55,000 hospitalizations, and 20–40 deaths each year [6]. The cost of this illness has been estimated to exceed US\$400 million in medical expenses and more than US\$1 billion when societal costs (e.g., parents' lost work time) are included.

### II. THE ROTAVIRUS PARTICLE AND ITS ROUTE OF PATHOGENESIS

Conventional electron microscopy revealed the rotavirus particle as a double-shelled structure with icosahedral symmetry [8,9]. The outer shell is composed of two proteins, VP4 and VP7, which form capsomeres that radiate from the inner

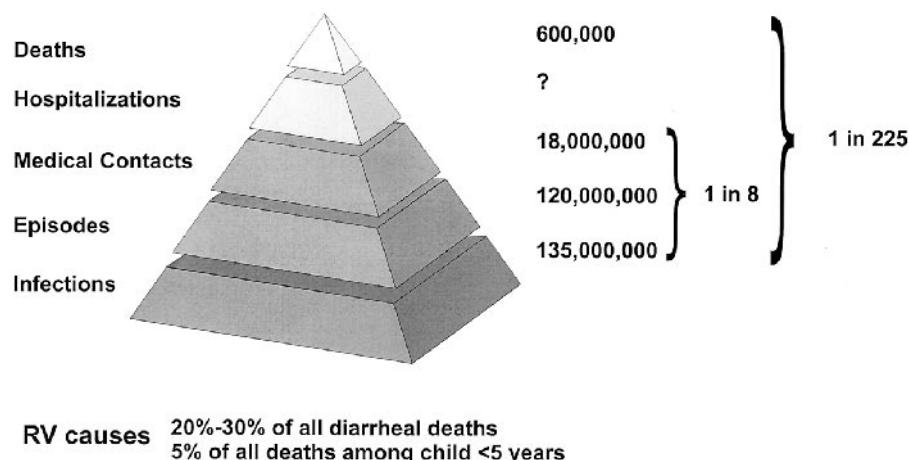

**Figure 1** Estimated global distribution of annual deaths due to rotavirus diarrhea in children under 5 years of age. (From Glass RI, et al. *Nat Med* 1997; 3:1324–1325.)

capsid comprising the major structural protein VP6 [10]. This inner shell surrounds a core containing 11 segments of double-stranded RNA and three additional structural proteins: VP1, VP2, and VP3. A much greater definition was obtained using cryoelectron microscopy (Figure 3). With this technique, it was revealed that the rotavirus core is surrounded by a third protein shell composed of VP2, thus establishing the mature rotavirus particle as triple-layered

[11,12]. These particles appear to be ca. 75 nm in diameter, but the 60 VP4 dimers anchored to the VP6 intermediate shell extend by an additional 11–12 nm beyond the surface of the outer shell, thus making the entire particle ca. 100 nm in diameter.

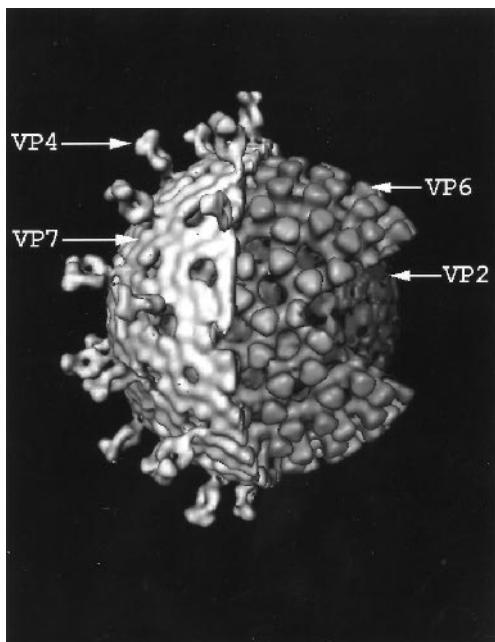

The replication cycle of rotavirus is activated by the cleavage of the VP4 protein by trypsinlike proteases, but its VP5\* and VP8\* products remain virus-associated [13]. After

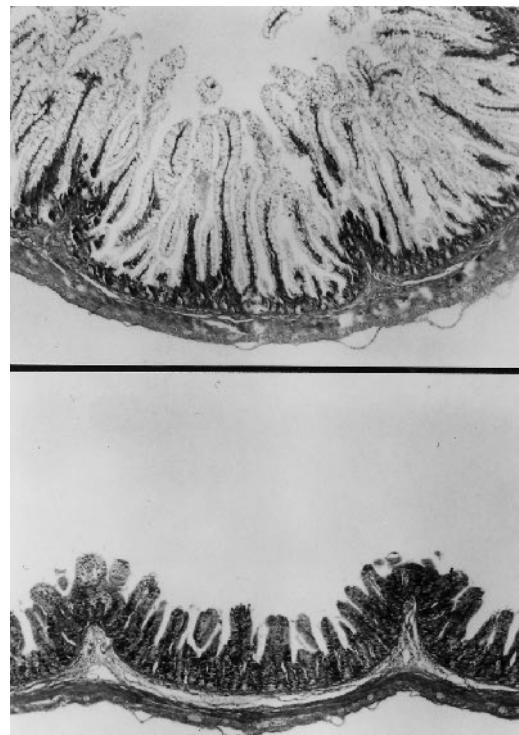

**Figure 2** Estimated annual global burden of rotavirus infections, episodes of serious disease, and deaths.

attachment to receptors via VP8\*, the virion passes into the cytoplasm where the outer capsid proteins are removed [14]. This stimulates the VP1 transcriptase to synthesize 11 viral mRNAs that are capped by VP3 and translated into six structural proteins and six nonstructural proteins (NSP1–NSP6) [10]. Viral assembly begins when the full complement of 11 plus-sense mRNA accumulates within the precursor particles containing several structural and nonstructural rotavirus proteins [15]. These particles mature stepwise by the addition of the capsid layers and the removal of nonstructural proteins, the final event occurring within the rough endoplasmic reticulum [16].

Rotavirus replication in its host occurs primarily, if not solely, in the mature enterocytes at the tips of the intestinal villi [17]. Thus, the transmission of this virus may be strictly fecal-oral. Following infection of calves and piglets, the cells at the villus tips become denuded (Figure 4), which results in the shortening and stunting of the villi [18]. In the underlying lamina propria, mononuclear cell infiltration is observed. Similar responses have been observed in infected children [8,19]. It has been proposed that the gastrointestinal symptoms of vomiting and diarrhea associated with rotavirus infection are due to the loss of the mature villus enterocytes and the retarded differentiation of the uninfected immature enterocytes [17,20]. Recently, it was reported that the nonstructural NSP4 protein of rotavirus can induce diarrhea in infant mice after intraperitoneal inoculation

**Figure 3** Computer-generated image of the triple-layered rotavirus particle. The cutaway diagram shows the outer capsid composed of VP4 spikes and VP7 layer, intermediate VP6 layer, and inner VP2 layer surrounding the core containing 11 double-stranded RNA segments and VP1 and VP3 proteins. (From Dr. B. V. V. Prasad, Baylor College of Medicine.)

**Figure 4** (Top) Normal histological appearance of the ileum from an 8-day-old gnotobiotic piglet. Normal mature vacuolate absorptive cells cover the villi. (Bottom) Ileum from an 8-day-old gnotobiotic piglet after oral inoculation with the virulent human rotavirus strain Wa. Severe atrophy and early crypt hyperplasia are evident. (From Dr. L. A. Ward, Ohio Agricultural Research and Development Center, The Ohio State University, Wooster, OH.)

[21,22], possibly by the activation of a calcium-dependent signal transduction pathway [23]. Whether NSP4 acts as an enterotoxin and stimulates gastroenteritis in humans remains to be determined.

### III. NATURAL ROTAVIRUS INFECTION PROTECTS AGAINST SUBSEQUENT ROTAVIRUS DISEASE

Rotavirus infection of animals or humans has been shown in numerous studies to be highly protective against subsequent rotavirus illnesses. In one of the earliest studies, it was found that neonates infected with the rotavirus during the first 2 weeks of life were protected against severe rotavirus disease but were not protected against rotavirus reinfection [24]. More recent studies on protection after neonatal rotavirus infection conducted in India provided similar conclusions [25,26]. Symptomatic or asymptomatic rotavirus infection of young children has been reported in multiple studies to provide at least partial, and sometimes complete, protection against subsequent rotavirus illness. For example, in one of

the most recent studies, it was found that subjects followed from birth to 2 years of age often have two or more rotavirus infections during this period, but the severity of rotavirus-associated illness plummeted as the infection number increased [4]. This occurred even though there were several rotavirus serotypes that circulated within the study population during the evaluation period. The interpretation of this and similar observations has led to divergent approaches in rotavirus vaccine development as will be discussed. Regardless of the approach used, it is universally agreed upon that the protection elicited by natural rotavirus infection provides both a rationale for the development of live, orally deliverable rotavirus vaccine candidates and a standard against which to evaluate the effectiveness of these vaccines.

#### IV. DEVELOPMENT OF ATTENUATED ROTAVIRUSES AS VACCINE CANDIDATES

Within a few years after the discovery of human rotaviruses and the recognition that they are the primary cause of severe gastroenteritis in young children, clinical trials evaluating rotavirus vaccine candidates were already underway [17]. The first candidates evaluated in young children were animal rotavirus strains. The use of animal rotaviruses, or the Jennerian approach, has continued, either directly or indirectly, in the development of several of the current live rotavirus vaccine candidates. This approach is based on the finding that, although animal rotaviruses have been found to infect humans [27], the transmission of rotavirus diseases from animals to humans still appears to be relatively uncommon, probably due, at least in part, to natural genetic barriers. Furthermore, when animal rotavirus strains are developed for use as human vaccine candidates, they are passed in cell culture—a procedure that should cause them to be further attenuated. The prediction that cell culture-grown animal rotaviruses are attenuated has been supported by clinical trial results in that vaccine candidates developed from animal rotaviruses have caused few, if any, symptoms typically associated with rotavirus diseases after administration to young children [17,28].

The first rotavirus isolated in cell culture was also the first to be evaluated in clinical trials. This bovine virus (NCDV), attenuated by >260 passages in cell culture, produced no adverse effects when administered to newborn calves [29]. Likewise, when prepared for human use, this virus (RIT 4237) produced no disease in young children, even when administered at a dose of  $10^8$  TCID<sub>50</sub> [30]. Administration of the vaccine during initial efficacy trials conducted in Finland resulted in serum antibody responses in 50–70% of children aged 5–12 months and was associated with >80% protection against clinically significant rotavirus disease [31,32]. When evaluated in subsequent trials, particularly those conducted in settings of developing countries, the administration of this candidate vaccine resulted in less protection and its development was discontinued [33–35].

The development and evaluation of another bovine rotavirus and a simian rotavirus followed soon after the initial studies with RIT 4237. The bovine strain (WC3),

isolated from a calf in Pennsylvania, was evaluated in humans after 12 passages in cell culture. Following the administration of  $10^7$  pfu to several hundred young children in immunogenicity and efficacy trials in both developed and developing countries, between 70% and 100% developed serum rotavirus antibody responses [36]. However, efficacy was inconsistent and even insignificant in two of four studies [37–39]. The simian (rhesus) rotavirus strain MMU 18006 (rhesus rotavirus, RRV) was evaluated at doses of  $10^4$ – $10^5$  pfu in >1000 young children after nine passages in primary or secondary monkey kidney cells and seven passages in diploid fetal rhesus monkey lung cells [17]. This vaccine typically induced self-limited febrile responses in approximately one-third of vaccinees >5 months of age, but in only a small fraction of younger infants [40–42]. MMU 18006 was highly immunogenic and induced serum rotavirus antibody responses in nearly every vaccinee. However, its ability to stimulate protection against subsequent rotavirus disease was, like the other candidates, inconsistent [34,43–48]. Based on these inconsistencies, both the WC3 and RRV vaccine candidates were modified to include gene segments encoding at least one of two neutralization proteins (i.e., VP7 and VP4) derived from different serotypes of human rotaviruses. The rationale for this, and results of clinical trials in which these “reassortant” vaccine candidates have been evaluated, will be described in detail in the “Development of Attenuated Rotaviruses as Vaccine Candidates” and the “Design, Production, and Clinical Evaluation of Live Rotavirus Vaccine Candidates Developed from Evidence that Neutralizing Antibody Is the Essential Effector of Protection.” The only other animal strain developed for evaluation as a vaccine candidate in humans was derived from a lamb. This vaccine, which has been administered to >1000 children in China [49], will also be described in a subsequent section.

The other rotaviruses developed for use as live virus vaccine candidates have all been derived from infected humans. Because humans are the natural hosts for these strains, it has been suggested that the immune responses they stimulate in infected humans, even after growth in cell culture, may be greater and more consistent than those elicited after the administration of animal strains. Furthermore, because the protection they produce will be directed against rotaviruses that also naturally infect humans, it has also been postulated that they may stimulate greater protection against these strains than that elicited by vaccination with animal rotaviruses. Although several live rotavirus vaccine candidates derived from human strains are under evaluation, the general validity of these suggestions has not yet been determined. However, it is clear that not all vaccines derived from human rotavirus strains elicit greater protection in immunized subjects than that found after immunization with animal strains [50,51].

Several of the human rotavirus strains that have been developed and evaluated as vaccine candidates were obtained from neonates. Neonatal rotavirus infections are typically endemic in some hospital settings and do not normally cause disease in this population. Although these neonatal strains are often readily distinguishable from the circulating community strains responsible for illnesses in

older subjects, this is not always the case. Studies reported over a decade ago suggested that the VP4 proteins of neonatal strains belonged to the P[6] genotype [52,53], but this distinguishing feature has vanished with multiple reports of P[6] community strains and non-P[6] neonatal strains. Therefore, it is unclear whether the absence of disease in infected neonates is due to the strains causing the infections, or to the innate resistance of full-term newborns to rotavirus disease. Even so, several neonatal strains have been developed as rotavirus vaccine candidates based on the suggestion that they might be naturally attenuated and based on reports that they elicit at least partial protection against clinically significant rotavirus disease [24–26]. Although neonatal strains continue to be evaluated as vaccine candidates, as will be discussed below, the first examined (i.e., strain M37) stimulated poor immune responses and no protection against subsequent rotavirus diseases after administration to young children [50,51].

The other human rotaviruses that have been developed as vaccine candidates were derived from community strains. Initial trials with several of these strains suggested that they might be insufficiently attenuated, even after 16 passages in cultured cells [54]. Some community strains were further attenuated by cold adaptation, but this resulted in a significant reduction in their immunogenicities [54]. Interest in attenuating a virulent human rotavirus for use as a vaccine candidate was revived following a report that an initial symptomatic or asymptomatic infection with a circulating community strain resulted in 100% protection against subsequent rotavirus diseases over a 2-year period [55]. Although a vaccine (i.e., strain 89-12) derived from one of the subjects infected with this virus was not fully attenuated, even after 33 passages in cell culture, 94% of young children administered the vaccine developed rotavirus antibody responses [56]. After an individual virus within the passage 33 preparation was isolated and passed several more times in the cell culture, it appeared to be further attenuated without a measurable reduction in its immunogenicity [57]. The new preparation is being extensively evaluated in clinical trials. A listing of the live rotavirus vaccine candidates that have been evaluated in clinical trials and their current status is presented in Table 1.

## V. THEORIES REGARDING THE EFFECTORS OF PROTECTION AFTER LIVE ROTAVIRUS INFECTION

The mechanism of protection against rotavirus diseases following a live virus infection has been examined in humans and, more extensively, in animal model studies. However, the outcome of these studies has left open a crucial question: Is neutralizing antibody (NA) the only significant effector of protection after these live rotavirus infections? The lack of a definitive answer to this question has led to two distinctly different approaches in the development of live rotavirus vaccine candidates that persist today. If NA is essential for protection, it is expected that a live rotavirus vaccine should contain multiple strains of rotavirus with serotype-specific epitopes to protect against rotaviruses belonging to the numerous serotypes that have been identified. If, on the other hand, effectors of protection other than classical NA play important roles in the prevention of rotavirus diseases, it is possible that vaccination with a single strain of rotavirus may be sufficient to protect against illnesses due to infections with numerous distinct serotypes. The vaccine candidates being developed and evaluated today are direct outcomes of these contrasting opinions regarding the crucial importance of NA in protection. Studies that support each of the two approaches will be presented below along with the results of efficacy trials in which each approach was utilized.

Before listing these studies, three points should be noted. The first is that intestinal NA is generally accepted as an important effector of protection after live rotavirus infection if it is present in sufficient titer. The only conflict concerns the roles of other effectors. The second is that even though distinct serotypes of rotaviruses have been defined based on differences in NA against the VP4 and VP7 proteins generated after the hyperimmunization of animals, some NA epitopes are shared between serotypes [17]. Thus, it is possible that protection against multiple rotavirus serotypes will be generated by vaccination with a single strain of rotavirus through NA produced against these shared epitopes. The third is that even when the background studies and clinical trial results have been presented, questions regarding the better approach will remain, at least until candidate

**Table 1** Live Rotavirus Vaccine Candidates that Have Been Evaluated in Clinical Trials

Vaccine candidate	Type of vaccine	Status of vaccine
RIT 4237	Single-strain bovine virus	Discontinued
WC3	Single-strain bovine virus	Developed into reassortants
RRV	Single-strain simian virus	Developed into reassortants
LLR	Single-strain lamb virus	Being evaluated
M37	Single-strain neonatal virus	Discontinued
RV3	Single-strain neonatal virus	Being evaluated
I321	Single-strain neonatal virus	Being evaluated
116E	Single-strain neonatal virus	Being evaluated
89-12	Single-strain infant virus	Being evaluated
RRV-TV (Rotashield™)	Tetravalent reassortant viruses	Withdrawn from U.S. market
WC3-QV (RotaTeq™)	Quintivalent reassortant viruses	Being evaluated

vaccines representative of each have been thoroughly compared in efficacy trials, possibly head to head.

## VI. EVIDENCE THAT NEUTRALIZING ANTIBODY IS AN ESSENTIAL EFFECTOR OF PROTECTION AGAINST ROTAVIRUS DISEASE IN HUMANS INDUCED BY LIVE ROTAVIRUS INFECTION

It has been established that antirotavirus antibody bathing the gut in adequate concentration is protective against rotavirus diseases [58]. However, it is impractical to provide meaningful passive protection for the duration of susceptibility in a young child. Therefore, it is necessary to actively immunize to provide adequate protection. Rotavirus immunization or natural infection induces a broad range of circulating and secretory antibody responses as well as cell-mediated immune responses [59]. Attempts to correlate levels of serotype-specific serum NA with the specificity of protection following immunization have failed [30,31,60–62]. However, clues regarding the role of serotype specificity in the protection against rotavirus diseases have been derived from epidemiological evidence, vaccination/challenge studies in animals, and experimental vaccination of infants.

It has frequently been stated that the only severe rotavirus infection is the first infection [24,55]. This suggests the possibility that serotype cross-reactive antibodies provide adequate protection against all rotavirus serotypes. However, there have been severe rotavirus disease episodes recorded in children, and even adults, with demonstrated serological evidence of prior rotavirus infection [63,64]. Although second episodes of severe human disease caused by the same serotype have been reported, second clinical infections in infants have more often been associated with serotypes different from the first [4,65]. Thus, the epidemiological evidence regarding the importance of NA in protection against rotavirus diseases is equivocal.

Published differences in conclusions concerning the importance of rotavirus serotype in protective immunity from vaccination/challenge experiments in animals have also never been resolved. Early studies revealed cross-protection between simian and murine rotavirus serotypes in mice [66,67]. Other studies showed cross-protection between bovine rotavirus and human serotype rotavirus in calves [68] and in piglets [69]. The latter studies supported the use of bovine rotavirus in the first extensive vaccination studies in infants. However, contrasting evidence was also obtained in vaccination/challenge studies in domestic animals. Cross-protection studies with distinct bovine serotypes in calves and with distinct porcine serotypes in swine revealed only serotype-specific immune protection against virus challenge [36].

Evidence regarding the importance of NA in the protection against rotavirus, which is of most importance to pediatric practice, is that obtained from clinical trials in infants. The first vaccine trials in infants were performed with bovine strain RIT 4237, which is serotypically unrelated to human rotaviruses. This vaccine provided protection against human rotavirus diseases in several early trials

but failed in later trials [31,33,70]. Subsequently, trials with another bovine rotavirus strain (WC3) also showed inconsistent protection against human diseases [37–39]. Other clinical trials based on an assumption of heterotypical protection were conducted in infants with the simian RRV strain. RRV is related to a common human rotavirus serotype (G3; see below). It protected against rotavirus diseases in certain trials in which the natural challenge was not predominately G3, but failed to protect in others [48,71,72].

The common thread of experience with these three animal rotavirus vaccines was that they often protected against heterotypical human rotaviruses, but the unexplained inconsistency of this protection rendered them inadequate for universal application. However, recognizing the apparent clinical safety of these animal rotaviruses, attempts were made to enhance their protective efficacy by incorporating into them viral genes encoding outer capsid neutralization proteins of common human rotavirus serotypes. The resulting “reassortant” rotavirus vaccines, both those of simian RRV and bovine WC3 origin, have been consistently protective in infant clinical trials, with some quantitative variability. Therefore, empirical evidence that vaccine candidates of animal rotavirus origin need to be reassorted with human serotype rotaviruses to provide consistent protection represents the most definitive evidence of the importance of human serotype-specific antigenic stimulation for maximal efficacy. The specific and distinct contributions of the heterotypical and homotypical antigen-specific immune responses to the protection of the infant host are not yet well understood. Nevertheless, extensive clinical trial experience suggests that a combination of the responses to serotype-heterotypical and serotype-homotypical antigenic determinants contributes to effective protective immunity induced by reassortant rotavirus vaccines.

## VII. DESIGN, PRODUCTION, AND CLINICAL EVALUATION OF LIVE ROTAVIRUS VACCINE CANDIDATES DEVELOPED FROM EVIDENCE THAT NEUTRALIZING ANTIBODY IS THE ESSENTIAL EFFECTOR OF PROTECTION

The outer capsid proteins of rotavirus, VP4 and VP7, determine the specificity of the NA response and thereby establish serotype. Orally administered NA directed against either VP4 or VP7 is protective in experimental animals [73,74]. The importance of NA in active immunity after immunization or natural infection is less clearly defined, but is presumed to play a role. The NA response, most easily measured in the serum, is assumed to represent the most accurate available indicator of the “take,” magnitude, and specificity of immune responses leading to protection against rotavirus disease in the intestine.

### A. VP7 Surface Protein

Early studies established that NA in hyperimmune serum was directed primarily against VP7 [75]. Neutralization

assays conducted with hyperimmune serum separated rotaviruses into at least 14 serotypes [76,77]. VP7 serotypes are termed G (glycoprotein) types and rotavirus strains are considered to belong to different G types when a  $\geq 20$ -fold difference in titer is detected in cross-neutralization tests using polyclonal antisera. Ten of 14 G types have been identified in humans [10]. G types 1–4 and 9 are the major human serotypes [78], but serotypes G8 [79] and G5 [80] are regionally important. G1 is the most frequently detected rotavirus in infected humans [78], but it is impossible to predict which serotype will predominate at a given time or in a particular location. G types 3 and 4 have commonly been detected in animals, but the animal isolates may be distinguished from the human strains [81]. G types 1, 2, and 9 have been found almost exclusively in humans [10].

The sequence of VP7 for each of the 14 G types has been determined [82]. A comparison of the VP7 sequences has enabled the detection of regions that are divergent among serotypes and could be involved in encoding serotype-specific epitopes [83]. It is noteworthy that VP7 sequences are highly conserved among rotaviruses belonging to the same G type, even among strains separated in the time and location of isolation [84]. This indicates that rotavirus evolution may be slow. Studies of monoclonal antibody-selected escape mutants have identified epitopes in VP7 responsible for evoking NA [83–86], the most predominant of which are located in regions designated A (aa 87–99), B (aa 145–150), and C (aa 211–223) [84].

## B. VP4 Surface Protein

VP4 protrudes from the outer capsid in the form of 60 spikes [87–89]. Activation of rotavirus infectivity is associated with trypsin cleavage into two components, VP5\* (60 kDa) and VP8\* (28 kDa) [82], and both components remain attached to the virion. VP4 also induces NA, and VP4 serotypes are termed P types (protease-sensitive). Greater NA responses may be directed against VP4 than VP7 following oral immunization or natural infection [90]. VP4 molecules possess both serotype-specific and cross-reactive antigenic sites. Serotype-specific sites reside primarily on the smaller VP8\* component, whereas the larger VP5\* component contains mostly cross-reactive sites [91].

Because of extensive cross-reactivity, it has proven very difficult to develop a complete classification of rotavirus VP4 types by serology alone. No battery of polyclonal hyperimmune antisera or monoclonal antibodies that adequately characterizes most VP4 types has been produced. Therefore, a supplementary system of classification of P types by gene sequencing, which has allowed identification of at least 20 P “genotypes,” has evolved. In practice, the P serotype (when known) is indicated by an open number whereas the genotype is indicated by a bracketed number (e.g., P1a[8]) [17]. Most rotaviruses of human origin include P1a[8] VP4 coupled with G1, G3, or G4 VP7, or P1b[4] VP4 coupled with G2 VP7 [92], but recently, an increasing number of differing combinations have been detected. Although it is assumed that VP4 contributes to cross-protection between different rotavirus serotypes through its cross-reactive epitopes, this has not been experimentally demonstrated.

## C. Reassortant Rotavirus Vaccine Candidates

### 1. Primate × Human Reassortant Rotaviruses

The G3 simian RRV strain was highly immunogenic in infants but irregularly protective against diseases [48,71,72]. It was postulated that the addition of human VP7 serotype specificity to RRV by gene reassortment might yield an improved vaccine [93]. RRV reassortants containing VP7 genes from G1, G2, and G4 human rotaviruses were, therefore, generated, and these reassortants, along with RRV, were combined into the tetravalent RRV (RRV-TV) vaccine. Safety profiles of the reassortants were similar to RRV, with fevers in infants sometimes observed 3–5 days after inoculation [94]. RRV reassortants tested individually or in combination exhibited immune response rates (serum IgA or serum NA to RRV) in  $\geq 80\%$  of recipients. However, the NA response rates to human serotypes G1, G2, G3, or G4 were consistently  $< 50\%$  and normally  $< 20\%$  [62,95].

When the RRV-G1 and RRV-G2 monovalent vaccine strains were tested for efficacy in Finland, each was equally effective even though natural challenge was almost exclusively with G1 strains [96]. A comparative efficacy trial of RRV and RRV-G1 conducted in Rochester, NY in 1987 found that RRV provided protection against G1 natural challenge (66%) that was nearly as effective as that provided by the G1 reassortant (77%). Two years earlier, RRV had provided no protection against G1 natural challenge at this site. No explanation was established for this discrepant result [61]. In a study with the complete RRV-TV vaccine conducted in Peru, in which G1 and G2 rotaviruses were circulating, there was no significant protection against either serotype [97]. Upon reanalysis using a more precise scoring system for disease, significant levels of protection were induced by RRV-TV when only more severe cases of rotavirus diarrhea were considered [98]. In a similar study in Brazil, three doses of RRV-TV provided 57% protection against G1 rotavirus challenge but other serotypes were not circulating [99].

In five other efficacy trials, RRV-TV was uniformly protective, commonly preventing approximately 50% of all rotavirus disease and  $\geq 70\%$  of “severe” rotavirus infections [34,94,101–103]. Three of these trials involved a comparison of RRV-TV with the monovalent RRV-G1 vaccine. In one large U.S. trial [100], the natural challenge was primarily G1 rotavirus, and RRV-TV and the monovalent vaccine were equally protective. In another large U.S. trial [101], the natural challenge viruses in year 1 were also G1, and RRV-TV and monovalent RRV-G1 vaccine provided similar protection. In the second year of this trial, 35% of the challenge viruses were not G1, and only the RRV-TV vaccinees exhibited protection against these non-G1 rotaviruses. A trial conducted in the southwestern United States involved natural challenge primarily of G3 strains [34]. In the first year, the RRV-TV vaccine provided 53% protection against all cases of G3 rotavirus disease, whereas the monotypic RRV-G1 vaccine provided only 20% protection. Results of these last two studies suggest that protection with RRV or its reassortants was at least partially serotype-specific even though no correlation was found with serotype-specific NA titers [62,103]. Because of its ability to

consistently elicit good protection against rotavirus disease in vaccinated infants and its low reactogenicity in this population during prelicensure studies, RRV-TV was licensed and marketed in the United States beginning in 1998. Unfortunately, postlicensure surveillance indicated an association between RRV-TV vaccination and intussusception (bowel blockage), and the vaccine was withdrawn [104].

## 2. Bovine × Human Reassortant Viruses

The first vaccine reassortant using a bovine rotavirus genome was constructed to include the VP7 gene from human rotavirus G1 strain WI79 in the genome of the WC3 bovine rotavirus. When administered orally at a dose of  $10^{7.3}$  pfu, this reassortant retained the excellent safety characteristics of its WC3 parent. Two doses administered to infants induced NA responses of G1 specificity from 22% [61] to 55% [105], but this incidence was less than the nearly 100% NA response to WC3 (represented by the VP4 of the reassortant). Surprisingly, when the mirror image reassortant (human rotavirus VP4 P1a included in the WC3 rotavirus genome) was tested, the NA responses were again predominantly against the WC3 parent [54,106]. A mixture of both single gene reassortants induced vigorous NA responses to both parent viruses. However, a double NA gene reassortant was also constructed, bearing both human G1 and P1a genes within an otherwise WC3 virus genome. When administered to infants, the immune response to this reassortant was disappointing (<50% developed NA responses to either WC3 or the human strain). This suggested that a virus with two human rotavirus outer capsid proteins was less immunogenic in humans than rotaviruses with a single human surface protein accompanied by a nonhuman rotavirus surface protein. The reason for this is unknown.

Two efficacy studies conducted with the univalent human G1 reassortant revealed high levels of protection against circulating G1 strains. Administration of two doses in an initial trial of 77 infants produced 100% protection [61]. In a subsequent trial involving 312 infants given three doses of vaccine or placebo, efficacy was 64% against all rotavirus diarrheal diseases and 87% against clinically significant rotavirus diarrhea [107]. The use of this vaccine in these two studies also produced >50% reduction in all episodes of severe diarrhea, total days of diarrheal illness, and diarrhea episodes requiring the attention of a physician. Serological studies of a subset of the infants given three doses of vaccine in these trials revealed the development of G1 serotype-specific neutralizing antibodies at an incidence of 70% (H. F. Clark, unpublished results).

Serotype G2 and G3 reassortants on a WC3 background were next constructed. Because human serotype VP4 responses also potentially contribute to protective immunity, reassortants of serotypes G1, G2, G3, and P1a, all at a titer of approximately  $10^7$  pfu, were combined into a quadrivalent human bovine reassortant rotavirus vaccine (QHBRV). The QHBRV was evaluated in a placebo-controlled, multicenter study in the United States after the administration of three oral doses of vaccine or placebo to

439 infants [108]. No adverse effects were associated with vaccination and the response rates were approximately 90% for rotavirus IgA antibody and 57% for G1 NA. The vaccine was 75% efficacious against all rotavirus diseases (G1 and G3 strains) and 100% against severe rotavirus disease.

In order to include all of the traditionally prevalent human rotavirus G types in the vaccine, a single gene reassortant was created with a G4 VP7 protein on a WC3 rotavirus background. This reassortant was added to the QHBRV to yield a quintivalent vaccine, now designated RotaTeq™. This vaccine candidate is currently being tested in expanded efficacy trials and in very large safety trials, both in the United States and internationally.

## VIII. EVIDENCE THAT THE NEUTRALIZING ANTIBODY IS NOT AN ESSENTIAL EFFECTOR OF PROTECTION AGAINST ROTAVIRUS DISEASE IN HUMANS INDUCED BY LIVE ROTAVIRUS INFECTION

Evidence that NA is not the only product of the adaptive immune system responsible for the prevention of rotavirus diseases has been provided from three types of studies. These include studies on immunity after natural or experimental rotavirus infection of both animals and humans, studies associated with vaccination of humans with live rotaviruses, and studies with animals using experimental rotavirus vaccines. Initial studies on experimental infection of piglets and calves suggested that NA was a critical component of protection against diseases following subsequent rotavirus challenge [109–111]. Later studies, however, indicated the opposite (i.e., mechanisms other than NA appeared to be important in protection) [68,112,113]. For example, an avirulent strain of bovine rotavirus produced little or no NA against a virulent challenge strain in gnotobiotic calves, yet provided excellent protection against rotavirus disease following challenge [112]. A subsequent study conducted with mice showed no correlation between either serum NA or rotavirus IgG titers following experimental infection with homologous or heterologous rotavirus strains and the protection against murine rotavirus shedding [114]. In contrast, there was an excellent correlation between serum and stool rotavirus IgA titers and protection in this model [115,116].

Studies in naturally infected humans have also suggested that NA is not the only effector of protection. In 1983, Bishop et al. [24] reported, for the first time, that neonatal rotavirus infections are protective against severe disease following subsequent rotavirus exposure. The serotypes of the neonatal strains and the rotaviruses circulating in the community during that period were dissimilar. Later reports have also generally found neonatal rotavirus strains to be distinctly different from circulating strains, yet provide protection against rotavirus illness. For example, Aijaz et al. [26] reported that approximately one-third of neonates born in the Bangalore region of southern India between 1988 and 1994 became infected with G10P[11] rotaviruses. During that period, there was a sharp reduction in the incidence of rotavirus-induced infantile gastroenteritis from 45.3% to

1.8% among hospitalized children with diarrhea. These G10P[11] strains appeared to have only two gene segments of human rotavirus origin (both nonstructural protein genes) and the remainder appeared to be derived from bovine rotaviruses. Furthermore, these strains were not found in children with rotavirus diarrhea, thus suggesting a possible association between neonatal rotavirus infections and a decline in disease incidence due to heterotypical rotaviruses. During the same period, G9P[11] rotavirus strains were isolated from neonates in the New Delhi region of India. These strains also appeared to be human × bovine rotavirus reassortants and neonates infected with these strains experienced 46% fewer attacks of rotavirus diseases than infants without neonatal rotavirus infections [25].

As already noted, natural rotavirus infections in older infants have been reported to provide substantial protection against subsequent rotavirus disease, particularly against severe disease. When repeat illnesses do occur, they are often, but not always, caused by rotavirus serotypes that are different from those responsible for the first infection, thus suggesting that NA plays some role in protection following these first infections. However, there is also evidence that NA is not solely responsible for the observed protection. In a study with Bangladeshi children, it was found that subjects who experienced clinically significant rotavirus diseases had substantially less rotavirus-specific NA at the time of their illnesses than age-matched well children [117]. Interestingly, multivariate logistic regression models demonstrated that only NA titers to heterotypical rotaviruses were independently associated with protection against rotavirus disease. These data suggested that immunity to rotavirus disease might be mediated by factors other than NA. More recently, in a study conducted in Mexico, it was reported that although repetitive rotavirus infections occurred in a cohort of infants followed from birth to 2 years of age, the severity of their illnesses, particularly moderate-to-severe illnesses, decreased dramatically with subsequent rotavirus infections [4]. In fact, no moderate-to-severe rotavirus illnesses were found after the second infection even though the four major G serotypes of human rotavirus (i.e., G1–G4) were each well represented within the circulating rotavirus strains found during the study period. Although titers of NA to different rotavirus serotypes have been reported to broaden with sequential infection, these results can be interpreted to suggest that protection, at least against more severe rotavirus diseases, was not strictly serotype-specific.

Studies on the vaccination of humans with live rotaviruses have provided mixed signals regarding the importance of NA in the protection against rotavirus disease. The first rotavirus vaccine candidate, the bovine RIT 4237 strain, was highly efficacious when first evaluated in Finland, particularly against severe disease, even though it was serotypically unrelated to circulating rotavirus strains [28,31,32]. Likewise, the first trial with the WC3 bovine rotavirus vaccine candidate conducted in Philadelphia found it also to be efficacious against heterotypical rotaviruses [37]. Neither of these bovine strains was, however, consistently protective against rotavirus diseases and the evaluation of both as single-strain vaccine candidates was discontinued. Based on results of clinical trials with WC3, this candidate vaccine was

modified to contain genes for VP4 and VP7 proteins from human rotaviruses by reassortant formation. These WC3 reassortants, which are expected to produce NA against multiple serotypes of human rotaviruses, are being actively evaluated as a vaccine candidate. A similar outcome was found in clinical trials with the rhesus rotavirus vaccine candidate, and it, too, was modified by reassortment with human rotaviruses to create the tetravalent RRV (RRV-TV) vaccine. Although RRV-TV contained genes encoding VP7 proteins belonging to the major G types of human rotavirus (i.e., G1–G4), <20% of vaccinees administered three doses of RRV-TV typically developed rises in NA to prototype human rotaviruses belonging to any of these G types [100,101]. Furthermore, no correlation was found between titers of serum NA to specific G types and protection against rotaviruses belonging to these G types [103]. In spite of this, RRV-TV consistently elicited about 50% protection against all rotavirus disease and >70% protection against severe disease.

Studies conducted with nonliving subunit rotavirus vaccine candidates in experimental animal models have clearly shown that protection against rotavirus shedding after challenge is not dependent on classical NA. These studies have been conducted primarily with mice and have utilized several different immunogens, adjuvants, and routes of vaccine delivery. In this model, active immunity is against fecal rotavirus shedding rather than against rotavirus disease because mice are susceptible to rotavirus diarrhea for only their first 14 days of life, too short a time period in which to develop active immunity. Using this adult mouse model, it was found that intranasal administration of either of three types of subunit vaccines [i.e., psoralen-inactivated, double-layered (dl) rotavirus particles; viruslike particles (VLPs) composed of only the rotavirus VP2 and VP6 proteins; or an *Escherichia coli*-expressed chimeric murine rotavirus VP6 protein], along with a powerful mucosal adjuvant, elicited nearly complete protection against murine rotavirus shedding [118–120]. All three immunogens lacked the VP4 and VP7 rotavirus neutralization proteins and were, therefore, unable to elicit classical NA. Although protection could not be associated with measurable NA, it was also found that immunization of mice with triple-layered, inactivated rotavirus particles containing VP4 and VP7 was more effective than the dl particles, but only if they were homotypical relative to the challenge strain [118]. These results implied that protection was not dependent on NA in this model but was enhanced by its presence. Additional studies with these immunogens administered to mice by intramuscular or oral routes have provided similar conclusions [118,119,121].

## IX. DEVELOPMENT OF LIVE ROTAVIRUS VACCINE CANDIDATES BASED ON THE HYPOTHESIS THAT THE NEUTRALIZING ANTIBODY IS NOT THE ONLY EFFECTOR OF PROTECTION

If effectors of protection other than NA are induced by live rotavirus immunization, it is important to establish their

identities, their duration of production, and their effectiveness in the prevention of rotavirus infection and disease. Studies using the adult mouse model have implicated CD8 T cells in the resolution of rotavirus infection and, possibly, in the protection against reinfection [122–124]. CD4 T cells clearly play indirect roles in rotavirus immunity by providing helper functions for B-cell and CD8 T-cell development and have been suggested to provide direct effector roles in mice as well [125,126]. Finally, anti-VP6 IgA has been reported to protect mice against rotavirus shedding [127]. Because the epitopes responsible for stimulating protective T cells and non-NA could potentially reside on any structural—and, possibly, nonstructural—rotavirus protein, they might have little association with rotavirus serotype. Furthermore, effectors stimulated by any group A rotavirus may protect against many, if not all, group A rotaviruses. This has led to the development of several vaccine candidates consisting of single rotavirus strains.

The bovine rotavirus vaccine candidates, RIT 4237 and WC3, and the simian RRV vaccine candidate were the first to be developed, but the evaluation of all three was discontinued due to inconsistent efficacy. Neonatal strain M37 was also developed, evaluated, and discarded due to poor immunogenicity and lack of efficacy [50,51]. However, several live, single-strain, rotavirus vaccine candidates remain under active development. These include one animal (lamb) strain, three neonatal strains, and one strain obtained from a symptomatically infected child. The G10P[12] lamb strain was developed at the Lanzhou Institute in China and has been administered to ca. 20,000 children with no evidence of side effects [49]. It has been reported that inoculation with this lamb strain can stimulate NA against multiple human G types in >50% of vaccinees. However, these observed increases in antibody titers against heterotypical strains may be a reflection of the older-than-usual ages of the vaccinees and the likelihood that many had experienced previous natural rotavirus infections. The ability of this vaccine strain to elicit protection in previously uninfected infants is unknown.

The neonatal strains under development as vaccine candidates have all been reported to elicit substantial protection against subsequent rotavirus disease. The first is a G3P2A[6] strain that was endemic in neonatal nurseries in Melbourne, Australia from 1975 to 1980 [128]. This vaccine candidate has been reported to be safe and moderately immunogenic after administration to children (35–58% sero-converted). Furthermore, vaccinees in a recent Phase II trial were protected against a circulating G1P1A[8] strain when they demonstrated a rotavirus immune response following vaccination [49]. The other two neonatal strains were obtained from subjects in India. In the 1980s, researchers in New Delhi and Bangalore routinely identified rotavirus infections among newborns that remained in the hospital for three or more days postdelivery [25,129]. These infections were not associated with diarrhea but the neonates shed viruses for up to 10 days, developed robust immune responses, and were protected against diarrhea upon reinfection. When further examined, these neonatal strains were found to have gene segments of both human and animal rotaviruses that appeared to have reassorted in nature [130–

132]. The G9P[10] strain from New Delhi, 116E, contained 10 genes from a human rotavirus and a single gene, VP4, from a bovine rotavirus. In contrast, the G10P[10] strain from Bangalore, I321, was primarily of bovine rotavirus origin but contained two nonstructural genes from a human rotavirus. When vaccine preparations of these strains were evaluated in small Phase I trials with either adults or previously infected children in the United States, they appeared to be safe and partially immunogenic (D. I. Bernstein, R. L. Ward, unpublished results). Further plans to develop these vaccine candidates are underway in India.

The vaccine candidate developed from a rotavirus that caused symptomatic infection was obtained during an efficacy trial of the bovine rotavirus WC3. When WC3 was evaluated in Cincinnati during the 1988–1989 rotavirus season, it had no significant impact on the development of subsequent rotavirus illnesses [38,55]. In contrast, children with either symptomatic or asymptomatic natural rotavirus infection during the first year were fully protected against rotavirus diseases during the following year and only 2 of 60 even had detectable asymptomatic reinfections. In contrast, of the 82 subjects not infected during the first year, 9 had symptomatic and 20 had asymptomatic infections in the second year [55]. Exposure to a variety of serotype G1 rotavirus strains circulating during this second year was based on their RNA electropherotypes. All rotavirus isolates from ill subjects obtained during the first year were also serotype G1, but surprisingly, these were essentially indistinguishable from one another based on electropherotype. Therefore, the protection elicited against multiple G1 strains during year 2 was induced almost solely by infections with a single rotavirus strain in year 1. It followed, therefore, that if attenuation of this G1[P8] strain did not ablate its protective capacity, it should make an excellent vaccine candidate, at least against serotype G1 strains. Furthermore, if the protection that it stimulates is at least partially through mechanisms other than NA, it may be broadly protective as a single-strain rotavirus vaccine. Consequently, rotavirus from the stool of one ill subject from the 1989 trial was developed as a vaccine candidate and designated 89-12. Attenuation of strain 89-12 was performed by 33 passages in cultured monkey kidney cells.

When the 89-12 rotavirus vaccine candidate was evaluated for safety and immunogenicity in adults, in previously infected children, and, finally, in infants, it was found to be generally safe and highly immunogenic [133]. It was then tested for efficacy in healthy infants aged 10–16 weeks at four centers in the United States [56]. Two doses of either  $10^5$  focus-forming units or placebo were administered to 108 or 107 subjects, respectively. Low-grade fever after the first dose was the only side effect more common in vaccinees than placebo recipients (21 vs. 5 subjects;  $P = 0.001$ ). An immune response to rotavirus was detected in 94% of vaccinees and in only 4% of the placebo recipients. During the first rotavirus season, rotavirus disease was detected in 18 placebo recipients and two vaccinees (efficacy: 89%). Ten placebo recipients but no vaccinees presented for medical care associated with rotavirus disease. In the second year, efficacy decreased to 59% but only one case of severe rotavirus gastroenteritis was found in vaccinees, whereas 10 severe cases were found

in placebo recipients. The overall efficacy for the 2 years was 76% against any rotavirus gastroenteritis, 84% against severe disease, and 100% against very severe rotavirus G1 disease. Because G1 rotaviruses predominated during both years, the efficacy against heterotypical rotaviruses was not determinable. This vaccine candidate has been further attenuated by additional cell culture passages [57] and the new preparation is being extensively evaluated in larger trials and in countries where non-G1 community strains are typically isolated.

## X. VACCINE STRATEGIES NOT UTILIZING LIVE ROTAVIRUSES

Because live virus vaccines have potential disadvantages such as side effects due to insufficient attenuation, adverse reactions associated with viral replication, or insufficient efficacies against rotavirus disease, nonliving rotavirus vaccine candidates are being developed. None, however, has been administered to humans and, at this time, only two candidates are being actively evaluated in animal model studies. These are viruslike particles and recombinant VP6 proteins. The VLPs being evaluated are composed of baculovirus-expressed VP2/VP6 proteins as well as those that additionally contain one or both outer capsid neutralization proteins. Challenge studies conducted with the adult mouse model have shown that intranasal inoculation with the VP2/VP6 particles along with a powerful mucosal adjuvant stimulated nearly complete protection against murine rotavirus shedding [119]. Similar studies conducted with *E. coli*-expressed chimeric VP6 proteins of murine or human rotavirus origin found that these immunogens elicited nearly complete protection of mice against murine rotavirus shedding after either intranasal or oral immunization [120]. These combined studies clearly established that protection was not dependent on NA in this model system. In contrast to the results found in mice, intranasal immunization of gnotobiotic piglets with the VP2/VP6 VLPs and adjuvant did not elicit protection against shedding or diarrheal illness induced by a virulent human rotavirus [134]. However, when this method of immunization was used in piglets following oral administration of an attenuated strain of human rotavirus, it did stimulate substantial protection against the virulent human strain [135]. Viruslike particles have also been administered parenterally to rabbits along with adjuvants and were found to elicit substantial protection against lapine rotavirus shedding, particularly if they contained one or more outer capsid proteins, even if these proteins were from a different serotype than the challenge strain [136]. If humans are protected by these nonliving vaccine candidates as well as mice and rabbits, they offer promise as second-generation rotavirus vaccines.

## ACKNOWLEDGMENTS

We thank Harry Greenberg (Stanford University) and Osamu Nakagomi (Akita University) for their critical reading of this chapter and their helpful suggestions.

### I. INTRODUCTION

Respiratory syncytial virus (RSV) and parainfluenza virus types 1, 2, and 3 (PIV1, PIV2, and PIV3) are responsible for more than 40% of viral respiratory tract disease leading to hospitalization of infants and children. For this reason, there is a need to develop vaccines effective against these viruses. Because RSV and PIV3 cause severe lower respiratory tract disease in early infancy, vaccines for these viruses must be effective in immunologically immature recipients who have circulating maternal antibodies. To date, several strategies for immunization against disease caused by these viruses have been explored including peptide vaccines, inactivated or subunit vaccines, vectored vaccines (e.g., vaccinia-RSV or adenovirus-RSV recombinants), and live-attenuated virus vaccines. The most promising approaches are summarized in Table 1. The status of these approaches is reviewed. In addition, the immunologic basis for the disease potentiation seen in vaccinees immunized with formalin-inactivated RSV during subsequent RSV infection is reviewed. The efficacy of immunization in the presence of maternal antibodies is discussed.

### II. VACCINE DEVELOPMENT FOR RESPIRATORY SYNCYTIAL VIRUS

#### A. General Considerations

Respiratory syncytial virus, a single-stranded negative-sense RNA virus of the Paramyxoviridae family, is the leading viral agent of severe lower respiratory tract disease in the pediatric population. This virus is also a major cause of respiratory disease in the elderly, especially in nursing home patients [1,2]. Respiratory syncytial virus causes pneumonia

and bronchiolitis and is unusual in its ability to infect very young infants despite the presence of maternally acquired serum antibodies. A number of significant obstacles have hindered the development of an RSV vaccine. First, because the peak incidence of severe RSV disease is in 2-month-old infants, immunization should be initiated within the first month of life so that protective levels of immunity are achieved by 2 months of age [3,4]. Because most infants in the first months of life possess maternally acquired anti-RSV serum antibodies, the results obtained from evaluation of experimental vaccines in older seronegative subjects cannot be directly extrapolated to the very young infant. Maternally acquired antibodies suppress the immunogenicity of subunit and vectored RSV vaccines parenterally administered through a poorly defined immunologic mechanism termed antibody-mediated immune suppression [5–8].

Passively acquired antibodies can decrease the infectivity and the immunogenicity of live-attenuated viral vaccines that are parenterally administered, such as live-attenuated measles virus vaccines. Measles vaccine virus is sensitive to neutralization by passively acquired antibodies, and therefore its administration must be delayed until the level of maternal antibody has decreased to a level that does not interfere with replication of the vaccine virus. The loss of infectivity of a live virus vaccine mediated by passive serum antibodies can be circumvented by administration of the vaccine by a mucosal route [9], as has been successfully accomplished for polioviruses. Passively acquired serum antibodies have limited access to the respiratory or gastrointestinal mucosa and, therefore, infection and immunization via mucosal surfaces can proceed despite the presence of antibodies in the serum. However, in breast-fed infants, antibodies in breast milk may influence the infectivity of mucosally administered vaccines. Immunization or infection in the

**Table 1** Respiratory Syncytial Virus and Parainfluenza Virus Type 3 Vaccines that Have Been Tested in Clinical Trials

Vaccine type	Designation or type	Preclinical testing	Status of clinical trials	References describing clinical trials
<i>Respiratory Syncytial Virus</i>				
Formalin-inactivated RSV (1960s)	FI-RSV, Lot 100	Induced antibodies with high ELISA titer but low neutralizing activity, partially protective in rodents; retrospective studies showed enhanced pulmonary histopathology	In Phase I trials, induced antibodies with high ELISA titer but low neutralizing activity; poor protective efficacy; severe adverse events, 2 deaths. Studies terminated.	[20,21]
Live-attenuated mutants, biologically derived (1960s to present)	<i>ts</i> mutants <i>cp</i> -RSV <i>cpts</i> mutants	Attenuated, immunogenic, and protective; some were genetically stable	Multiple Phase I trials completed, ongoing <sup>a</sup>	[62,94,95,98,113]
Live-attenuated mutants, recombinantly derived (current trials)	Multiple combined point mutations, deletions, insertions, and other alterations; chimeric viruses	Increased level of attenuation compared to biologically derived viruses; immunogenic and protective	Multiple Phase I trials completed, ongoing	Unpublished
Live <i>wt</i> RSV given IM (1970s)	Live RSV	Immunogenic; protective against lower respiratory tract infection in seronegative rodents	Poor immunogenicity; lack of protective efficacy in children with maternal RSV-specific antibodies. Studies terminated.	[61]
Purified F glycoprotein (1980s to present)	PFP-1, PFP-2	Induced antibodies with high ELISA titer but low neutralizing activity; some rodent studies showed enhanced histopathology	Moderately immunogenic in Phase I trials in seropositive subjects, including high-risk children and the elderly; under evaluation for maternal immunization	[37–48]
Purified recombinant RSV G protein fragment fused to a streptococcal G protein fragment (current trials)	BBG2Na	Immunogenic and protective	Phase I completed	[70]
<i>Parainfluenza Virus Type 3</i>				
Bovine PIV3 (1990s to present)	BPIV3	Attenuated, immunogenic and protective	Phase I completed <sup>a</sup>	[143–145]
Live-attenuated mutant (1990s to present)	<i>cp</i> -45	Attenuated, immunogenic and protective; genetically stable	Phase I, II completed <sup>a</sup>	[161]

<sup>a</sup> The use of biologically derived, live-attenuated mutants is likely to be superseded by the improved, related recombinantly derived mutants, with the possible exception of PIV3 *cp*45.

presence of passively acquired antibodies can be protective even when high levels of serum neutralizing antibodies are not induced [10]. The mechanism for such protection is not well defined, but cellular immunity is implicated based on the finding that CD4+ and CD8+ T cells contribute to protection in a mouse model of RSV passive/active immunization [11].

A second obstacle to immunization against RSV is that immunity induced by infection with wild-type RSV itself

does not completely protect against reinfection. Multiple upper respiratory infections occurring throughout life are a hallmark of this virus. Although subsequent infections typically are partially restricted by host immunity, severe disease can occur during the second infection [3]. Animal models suggest RSV infection may have immunosuppressive effects that thwart induction of immunologic memory in the respiratory tract [12]. Protection against disease caused by RSV in the lower respiratory tract can be achieved, but two

or more infections are often required. Therefore immunization against RSV, like that against poliovirus, likely will require multiple doses of vaccine to achieve the level of immunity needed to prevent serious disease.

Third, the immune response to the F glycoprotein of RSV is reduced in the very young infant independent of the immunosuppressive effect of maternal antibodies [13]. This reduced immune response of the infant is also seen for the antibody response to the influenza A virus hemagglutinin protein [14] and to the PIV3 hemagglutinin-neuraminidase protein [15].

The fourth obstacle to RSV vaccine development is that circulating field strains exhibit an antigenic dimorphism. Two antigenic subgroups designated A and B have been defined that are approximately 25% antigenically related by reciprocal cross-neutralization analysis [3,6,16]. Second infections by RSV are often caused by virus belonging to the heterologous subgroup, indicating that antigenic diversity is responsible in part for the high frequency of second infections, and more importantly, for lower respiratory disease upon second infection [3,17]. An effective RSV vaccine should protect against disease caused by virus of either subgroup.

Fifth, during vaccine trials in the 1960s, immunization of infants and young children with an inactivated RSV vaccine unexpectedly primed for enhanced RSV disease during subsequent natural infection (discussed in more detail later in this chapter) [18,19]. This observation, in the context of comparable observations for inactivated measles virus vaccine, dictated that vaccine development for RSV should proceed with great caution.

In summary, a successful RSV vaccine will (1) immunize very young immunologically immature infants even in the presence of maternally acquired serum antibodies, (2) induce a level of resistance to disease in the lower respiratory tract comparable to or greater than that of primary infection with wild-type virus, (3) induce resistance to both subgroup A and B strains of RSV, and (4) immunize without potentiating RSV disease during subsequent natural infection.

## B. Nonreplicating Antigens

### 1. Inactivated Virus Vaccine and Disease Potentiation

Inactivated RSV is not currently being considered as a vaccine candidate, but an understanding of the unexpected disease potentiation observed in the formalin inactivated RSV (FI-RSV) vaccine recipients during subsequent natural infection is important for RSV vaccine development in general. Recent observations, in the context of the previous observations in the 1960s and 1970s, have permitted the formulation of a plausible mechanism for disease potentiation seen in the FI-RSV vaccinees or reproduced in experimental animals receiving FI-RSV or subunit vaccines (discussed below). We previously summarized the literature on this subject [20]; the major findings are summarized here.

Two main factors are thought to have contributed to enhanced disease in FI-RSV vaccinees. First, FI-RSV failed

to induce a high level of resistance to RSV replication. FI-RSV vaccinees developed a high titer of serum antibodies to the F glycoprotein as determined by enzyme-linked immunosorbent assay (ELISA), but these antibodies had a low level of neutralizing activity and likely had insufficient anti-viral activity *in vivo*. Interestingly, immunization of cattle with inactivated bovine RSV (BRSV) also led to dissociation between ELISA binding to F protein (high titer) and virus neutralization (low titer) in vaccinated animals [21]. In contrast, live virus BRSV immunization of cattle induces a high level of neutralizing antibodies. In addition, it is unlikely that appreciable amounts of secretory antibodies were induced in the respiratory tract of the FI-RSV infant vaccinees because the FI-RSV vaccine was given parenterally. Thus, with local and systemic humoral immunity to RSV being largely deficient in FI-RSV vaccinees, pulmonary RSV replication was not restricted in the vaccinees during subsequent natural infection. Pulmonary RSV replication may then have provided the stimulus for immune mediators to cause enhanced disease. It is also unlikely that FI-RSV induced a CD8+ T cell response, which is also known to contribute to resistance to RSV in experimental animals.

The second factor postulated to be involved in the enhanced disease in the vaccinees was a state of heightened CD4+ T cell activity induced by immunization with FI-RSV. This mechanism was previously suggested by the increased lymphocyte proliferative response of peripheral blood lymphocytes of FI-RSV human vaccinees to RSV antigens. Studies in rodents demonstrated that the mechanism underlying the disease potentiation in FI-RSV immunized animals was completely dependent on Th2 type CD4+ T cells. This dependence of disease potentiation on Th2 T cells contrasts with the predominantly Th1 T cell response to RSV infection. Thus the imbalances in the immune response of FI-RSV immunized mice outlined above were accompanied by another imbalance, an altered ratio of T-helper subsets present in the pulmonary inflammatory cell infiltrate. Pathologic effects in some rodent studies were shown to be mediated by oligoclonal lymphocyte responses [22].

Considering the quantitative and qualitative differences in the cellular immune responses to infection or FI-RSV noted in both humans and rodents, we suggest that in the infant recipients of the FI-RSV vaccine a heightened CD4+ T cell response occurred at the sites of RSV replication in the bronchioles and alveoli. Thus the enhanced disease in vaccinees was a Th2 CD4+ T-cell-mediated pulmonary delayed-type hypersensitivity reaction. These observations with FI-RSV have important implications for the development of RSV vaccines. It is reasonable to predict that to be useful in RSV immunoprophylaxis, immunogens will have to induce (1) both serum and mucosal antibodies with high neutralizing activities and (2) a cellular immune response similar to that induced by infection with wild-type RSV, and dissimilar from that induced by FI-RSV.

### 2. Respiratory Syncytial Virus Subunit Vaccine

The major protective antigens of RSV, the fusion (F), and attachment (G) glycoproteins that induce neutralizing and

protective antibodies [3,23], are the target antigens for inclusion in an RSV subunit vaccine. Initial studies found that rodents could be successfully immunized with purified F or G glycoprotein antigens and protected against wild-type RSV challenge [24,25]. The F or G glycoproteins used in these studies were purified by physical techniques from virions, by immunoaffinity chromatography from insect cells infected with an F-glycoprotein recombinant baculovirus, or from lysates obtained from RSV-infected mammalian cell culture [24,26–28], and they were protective in rodents [28,29]. However, the protection observed was incomplete in that significant resistance to virus replication was observed only in the lower respiratory tract, while the challenge virus efficiently replicated in the upper respiratory tract [28,29]. This pattern of resistance differed from that induced by prior infection with RSV, which provided complete protection of both sites of the respiratory tract. These findings suggest that immunization against RSV is most effective when administered by the mucosal route. Studies in mice using topically applied F glycoprotein coadministered with cholera toxin or with the B subunit of cholera toxin (CTB) demonstrated protective efficacy for the upper respiratory tract, while simultaneous parenteral administration of F and mucosal immunization with F and CTB induced a level of efficacy similar to that induced by live virus infection [30]. Other investigators examined the feasibility of using the purified fraction 21 of *Quillaja saponaria* (QS-21) as an adjuvant with purified F glycoprotein and found that use of this adjuvant in immunization of mice (as compared with immunization using aluminum hydroxide and F) induced an immune response characterized by higher IgG2a antibody levels, higher neutralizing antibody titers, and decreased neutrophil infiltration of the lungs [31]. Further evaluation of this formulation will be necessary to determine its stability and its effect in infection-permissive hosts.

Disease potentiation in rodents, as indicated by enhanced pulmonary histopathology, was not observed in initial studies of F-protein immunized animals following RSV challenge; however, subsequent studies raised concern about aberrant immune responses to immunization with nonreplicating antigens (reviewed in Refs. 20 and 32). The unusual pattern of antibody response of FI-RSV human vaccinees (antibodies against the F glycoprotein that exhibited high titers of ELISA binding antibodies but low neutralizing activity) was subsequently observed in rodents immunized with either FI-RSV or with purified F glycoprotein [29,33]. In contrast, the neutralizing activity of RSV F-specific antibodies induced by infection of rodents RSV recombinant vaccinia virus expressing the RSV F glycoprotein was similar to that induced by wild-type RSV infection [34]. These observations strongly suggest that purification of the F glycoprotein resulted in altered immunogenicity, perhaps by disrupting conformationally dependent neutralizing epitopes present in the protein. Furthermore, immunization with purified F glycoprotein produced in mammalian or insect cells was shown to result in enhanced pulmonary histopathology in cotton rats challenged with RSV 3–6 months following immunization [33]. The pattern and magnitude of the cellular infiltration and the pattern of cytokine mRNA expression in the lungs of these RSV-challenged animals was

similar to that present in FI-RSV immunized RSV-challenged cotton rats [32,33,35]. Despite efficient induction of ELISA antibody in rodents, the purified F subunit vaccine was poorly immunogenic in seronegative chimpanzees. The purified F subunit vaccine candidate induced only low levels of serum neutralizing antibodies (~1:50) in young seronegative chimpanzees after three doses [36]. This finding in chimpanzees suggests that subunit vaccines likely would be weakly immunogenic in seronegative humans. Maternally acquired antibodies also likely would further diminish the immunogenicity of parenterally-administered subunit vaccines.

A series of clinical safety and immunogenicity studies has been performed in seropositive adults and children using different formulations of the purified F glycoprotein vaccines (designated PFP-1 or PFP-2) [37–42]. The vaccines were observed to be safe in seropositive subjects. The immunogenicity of the F subunit vaccine in humans was poor when used at a single dose of 5 or 20 µg [37,39]. However, when seropositive individuals received two doses of 50 µg, 100% responded by ELISA to the F glycoprotein and 70% responded with significant rise in titer of RSV-neutralizing antibodies [42]. These findings suggest that the purified F subunit vaccine might be useful as a vaccine for boosting the antibody levels of previously infected patients, especially those with underlying diseases that place them at high risk for severe RSV disease. Such patients include the elderly or individuals with cystic fibrosis, bronchopulmonary dysplasia, cardiovascular disease, or immunodeficiencies. The subunit vaccine might represent a more immunogenic vaccine for boosting the immunity of these subjects than would live virus vaccines, which are highly restricted in replication in seropositive subjects [43]. Trials have been conducted in several of these high-risk populations. Piedra et al. [44] conducted a double-blind, placebo-controlled study in 17 RSV-seropositive cystic fibrosis (CF) patients 12 months to 8 years of age using the PFP-2 vaccine candidate at a dose of 50 µg purified protein, compared with 17 patients administered saline placebo. The PFP-2 vaccine caused mild local reactions and induced a significant neutralizing antibody response in two-thirds of the vaccinees and a significant RSV F glycoprotein ELISA antibody response in most of the vaccinees. In a follow-up study, 29 of those 34 CF children who participated in the previous study were enrolled in an open label study, in which a second vaccine administration was found to be safe [45]. Groothuis et al. [46] performed a small, blinded study using a 50 µg dose of the PFP-2 vaccine in 10 RSV-seropositive patients with bronchopulmonary disease over a year of age, compared with 11 matched vaccinees receiving influenza vaccine. PFP-2 vaccine appeared to be safe and moderately immunogenic by serologic response in that population.

Two trials have been conducted with this RSV subunit vaccine candidate in the elderly, a high-risk adult population. A dose of 50 µg PFP-2 was found to be safe and moderately immunogenic in healthy older adults (60–80 years old) in an outpatient study comparing 33 vaccinees and 31 saline placebos [47]. A subsequent open label study in 37 frail institutionalized persons over age 65 showed that this vaccine was well tolerated without significant side effects. The

vaccine was less immunogenic in this population, with only 53% of vaccinees mounting a greater than or equal to fourfold increase in IgG antibody titer to the F protein [48].

Studies with a novel recombinant RSV chimeric FG subunit vaccine were conducted in parallel with those of the F subunit vaccine described above. This vaccine consisted of a purified FG chimeric protein in which the anchor regions of the F (COOH-terminal) and G (NH<sub>2</sub>-terminal) glycoproteins were deleted, and the two ectodomains of the proteins were expressed as a fusion protein with F sequences being at the NH<sub>2</sub>-terminal end of the chimera [49]. This FG protein was expressed in insect cells by a recombinant baculovirus, and the FG protein, which was secreted into the medium, was purified by immunoaffinity chromatography. The FG subunit vaccine had several properties in common with purified F subunit vaccine. First, immunization with FG glycoprotein was protective in rodents, with protection largely confined to the lungs [34,50,51]. Second, the serum antibodies that were induced had a high ELISA titer but low neutralizing activity [34]. Third, enhanced pulmonary histopathology was observed in RSV FG-immunized cotton rats following RSV challenge [34]. Immunization of African green monkeys with FG glycoprotein did not induce enhanced pulmonary histopathology upon challenge, although the vaccine was weakly immunogenic and only marginally protective in the lower respiratory tract in these studies [52]. In addition, it was found that the immunogenicity of the G component of the FG vaccine was very low [34]. When FG glycoprotein was intranasally administered to mice with cholera toxin B (CTB) as a mucosal adjuvant, local IgA and IgG antibodies against RSV were induced in the respiratory tract of mice and protection of the upper respiratory tract was observed [53]. It is now recognized that the source of CTB used in these studies almost certainly contained minute quantities of contaminating cholera toxin, which would have been responsible for adjuvant activity. Cholera toxin B purified from recombinant sources that does not contain contaminating holotoxin does not exhibit adjuvant activity for coadministered antigens. The feasibility and safety of this FG chimera approach will require further evaluation.

Studies of the immune response to the FG subunit vaccine expanded previous studies of F subunit vaccine in two important ways. First, studies of cell-mediated immunity induced by FG demonstrated that CD4+ T cells were efficiently induced by immunization with FG, but CD8+ cytotoxic T cells were not [54–56]. Second, rodent studies demonstrated that antibodies induced by FG had low neutralizing activity in vitro and had low functional activity in vivo; that is, they failed to provide passive protection. Increased pulmonary histopathology was not observed in the passively immunized animals following RSV challenge, suggesting that antibody was not the major mediator of the inflammatory response. Rather, the histopathology observed in the FG-immunized, RSV-challenged animals appears to be mediated by T cells.

Another RSV subunit vaccine candidate is a recombinant fusion protein, designated BBG2Na, consisting of a central conserved domain of the RSV attachment (G) protein (amino acid residues 130–230) fused to the C-terminus

of the albumin-binding domain (BB) of streptococcal protein G [57]. This construct contains five linear B cell epitopes that map to residues 152–163, 165–172, 171–187 (two overlapping epitopes), and 196–204. Passive transfer of antibody and peptide immunization studies suggested that each of the epitopes is protective [58]. The vaccine candidate itself was previously shown to protect the upper and lower respiratory tracts of mice against intranasal RSV challenge [57]. In mice, CD4+ T cells induced by parenteral immunization with this protein fragment mediated protection of the upper respiratory tract against infection [59]. Neonatal rodent responses to this vaccine candidate were not inhibited by the presence of RSV maternal antibodies [60]. Safety trials using the BBG2Na vaccine candidate in healthy young adults have been initiated [61].

In summary, four major characteristics of current formulations of RSV F and FG subunit vaccines make them unlikely to be successful vaccines in seronegative humans. First, the poor immunogenicity of these vaccines in seronegative chimpanzees suggests that it will be difficult to deliver a sufficient number of doses in the neonatal period, when virus protein antigens are least immunogenic in humans, to induce a protective level of immunity. Second, the antibodies that are induced by such vaccines generally have a low level of functional activity in vivo that likely will not protect vaccinees. Third, maternally acquired serum antibodies can be expected to significantly suppress the immune response to parenterally administered vaccines. Fourth, the humoral and cellular immune responses to immunization with the RSV subunit vaccines are very similar to those induced by the deleterious FI-RSV vaccine. This similarity suggests that immunization of humans with an RSV subunit vaccine might result in disease potentiation, as was seen with FI-RSV. However, the safety profile of BBG2Na and its ability to induce neutralizing antibody and CD4+ T cell responses, in the context of the known immunogenicity of RSV G protein in young infants [62], suggest that continued cautious evaluation of this immunogen is warranted. While subunit RSV vaccines might not be ideal immunogens in young infants, they might prove useful in protecting older high-risk subjects against RSV lower respiratory tract disease.

### 3. Other Approaches

Synthetic peptide, anti-idiotype antibodies, and immunostimulating complex (ISCOM) formulated RSV vaccines are being developed as candidate vaccines [63–66]. Bacterial expression of RSV F protein has been developed using *Staphylococcus xylosus*, a nonpathogenic coagulase-negative gram-positive bacterium present on the skin [36]. Other investigators have generated an RSV G glycoprotein produced in *Salmonella* that was found to induce neutralizing antibodies in cotton rats [67]. The major drawback associated with the expression of viral glycoproteins in prokaryotes is the general lack of posttranslational folding and processing that may result in the expression of antigens lacking critical neutralization epitopes. Sufficient information on the safety, immunogenicity, and efficacy of these preparations is not available at this time to determine if they

offer an advantage over the more extensively evaluated subunit vaccines. Furthermore, the phenomenon of immune-mediated disease potentiation means that any non-replicating, subunit-type vaccine must of necessity be developed with considerable caution. Plasmid DNA immunization with vectors encoding a DNA copy of the RSV F [68] or G [69] protein has been moderately immunogenic in rodent studies. This strategy is of interest because expression of viral proteins from similar vectors has been demonstrated to persist for several months in animal studies. Prolonged expression of vaccine antigens *in vivo* might circumvent the suppressive effects of maternal antibodies. However, the safety, immunogenicity, and feasibility of DNA immunization in human infants are unknown.

Immunization with live RSV administered by a parenteral route is another unusual approach that has been tested. A live RSV vaccine parenterally administered was evaluated for efficacy in a double-blind, placebo-controlled field trial in 510 children 6–47 months of age [70]. The rationale for that study was that intramuscular administration of a live respiratory virus that does not cause viremia or spread to the respiratory tract would be safe because immunization would be without direct risk of causing respiratory tract disease. The immunization might result in a dual response to native antigens present in the whole virus and possibly to antigens expressed by abortively infected cells outside the respiratory tract. Only 68 of 98 initially seronegative children (as determined by ELISA assay) developed antibody to RSV. Most of the 30 initially seronegative children who did not develop antibody were less than 12 months old, which suggested that levels of maternal antibody that could not be detected by ELISA inhibited replication of the vaccine virus. That trial did not demonstrate any benefit of the attenuated RSV vaccine after 2 years of follow up [70].

### C. Live Virus Vaccines

#### 1. Vectored Vaccines

Vaccinia virus, a live-attenuated virus vaccine previously used to prevent smallpox in humans, was used as a model to evaluate the immunogenicity and protective efficacy of a viral vector expressing RSV antigens. Vaccinia virus (strain WR)-RSV (vac-RSV) recombinants expressing each of the RSV proteins (except the polymerase L) were evaluated separately in BALB/c mice and cotton rats to determine the immunogenicity of each antigen and its contribution to resistance to intranasal RSV challenge [23]. These studies showed that the G and F glycoproteins were the only proteins that induced detectable RSV-neutralizing antibodies [71]. Each glycoprotein independently induced a high level of RSV-neutralizing antibodies and long-lasting resistance to RSV challenge, with F appearing to be somewhat more immunogenic than G. The N and M2-1 proteins also independently induced resistance to RSV challenge, and further analysis with the vac-M2 recombinant showed that MHC class I-restricted CD8<sup>+</sup> CTLs mediated this protection [72,73]. In contrast to the durable resistance associated with G and F, the CTL-mediated resistance induced by vac-N and vac-M2 was transient and waned completely by 45

days after immunization. These observations suggest that RSV-specific CTL can play a role in restricting reinfection in the short term, but antigens that induce neutralizing antibodies (i.e., F and G) are the more important ones to include in a vectored vaccine.

Although the initial evaluation of vac-RSV recombinants in rodents and monkeys was encouraging [72,74], intradermal immunization of seronegative chimpanzees with vac-F and vac-G provided only low to moderate levels of serum neutralizing antibodies, inconsistent resistance in the lower respiratory tract, and no resistance in the upper respiratory tract [75,76]. More recently, the MVA strain of vaccinia virus was used to construct recombinants expressing the RSV F, G, or both glycoproteins [77]. The MVA strain is highly defective in producing infectious virus in most mammalian cells and undergoes only a single cycle of replication in human cells. Thus it is a much safer vector than replication-competent vaccinia virus strains and offers the possibility of topical administration. MVA-RSV recombinants were highly immunogenic when inoculated intranasally into RSV-naïve mice and were effective in boosting immunity conferred by previous intranasal infection with an attenuated strain of RSV. However, evaluation in rhesus monkeys of comparable MVA-PIV3 recombinants expressing the HN or F glycoproteins showed that the recombinants were much more sensitive to immunosuppression by passively administered serum antibodies compared to a live-attenuated PIV3 virus [78]. Because infants and young children characteristically possess maternally derived PIV3- and RSV-specific serum antibodies, the MVA-based recombinants likely would be insufficiently immunogenic as pediatric vaccines.

Adenovirus has also been evaluated as a vector for expressing RSV antigens. Initial studies in rodents, ferrets, and dogs demonstrated that topical administration of adenovirus (ad)-RSV recombinant viruses was immunogenic and protective in both the upper and the lower respiratory tracts [79–81]. However, the ad-RSV did not appear to be immunogenic in a seronegative chimpanzee, despite three sequential immunizations with ad-4, ad-5, and ad-7 RSV F recombinant viruses [81]. Thus construction of a recombinant vector that expressed high levels of RSV antigen *in vitro* was not sufficient to provide an effective RSV vaccine.

More recently, an attenuated version of PIV3 was evaluated as a vector for RSV antigens. The specific vector was a cDNA-derived human PIV3 (HPIV3) vaccine candidate called rB/HPIV3 [82]. This virus was a chimera consisting of a bovine PIV3 (BPIV3) backbone in which the BPIV3 HN and F genes were replaced by their counterparts from HPIV3 (see Section III.B.2). Thus rB/HPIV3 combines the F and HN major protective antigen genes of HPIV3 with the BPIV3 backbone, which is attenuated in primates due to a natural host-range restriction. The RSV G or F glycoproteins were inserted singly or together into the promoter-proximal position of rB/HPIV3, and recombinants were made representing both RSV antigenic subgroups [83,84]. The chimeric rB/HPIV3-RSV viruses efficiently replicated *in vitro* and expressed high levels of the RSV G and F glycoproteins. When inoculated into the respiratory tract of rhesus monkeys, the rB/HPIV3-RSV chimeras were some-

what more attenuated than their rB/HPIV3 parent, presumably due to the presence of the insert, but nonetheless were highly immunogenic against both RSV and HPIV3. Thus these rB/HPIV3-RSV viruses have properties that make them attractive candidates as a bivalent pediatric vaccine against RSV and HPIV3. This strategy has the advantage that the vector itself is a needed vaccine rather than simply being a carrier. The attenuation phenotype conferred by the BPIV3 backbone is very stable (see Section III.B.2). Coimmunization against RSV and PIV3 is appropriate and desirable because they cause disease in the same age group, and the natural tropism of PIV3 for the respiratory tract makes it well suited for use as a vector/vaccine for intranasal administration. In addition, the vectored vaccine is free of infectious RSV.

Recombinant vesicular stomatitis virus (VSV) also has been evaluated as a vector to express the RSV G and F glycoprotein genes, each added singly as an additional gene (VSV-RSV-G and VSV-RSV-F viruses) or in place of the VSV G gene (VSV $\Delta$ G-RSV-G and VSV $\Delta$ G-RSV-F viruses) [85]. The VSV $\Delta$ G-RSV viruses were infectious only when grown in the presence of VSV G expressed in *trans*, and thus represent a replication-defective vector that can undergo only a single round of infection *in vivo*. When evaluated as a live vaccine intranasally administered to mice, each of the viruses induced resistance to RSV challenge. However, the levels of RSV-specific serum antibodies that were induced were low, particularly for the VSV $\Delta$ G-RSV viruses, and immunogenicity and efficacy studies in primates will be needed to determine whether these new vectors constitute an advance over vaccinia virus and adenovirus vectors. Vesicular stomatitis virus is a virus to which the young infant is not normally exposed, and it does not represent a needed pediatric vaccine. These considerations, together with the lack of experience with the administration of VSV to humans, pose obstacles to its development as a pediatric vaccine vector.

## 2. Live Attenuated Respiratory Syncytial Virus Vaccines

Live-attenuated RSV vaccines are attractive candidates for use as a pediatric RSV vaccine for a number of reasons. First, a live, topical RSV vaccine likely would stimulate an immune response similar to that of wild-type RSV infection, including the induction of serum and mucosal antibodies and the stimulation of cellular and innate immunity that are important as antiviral effectors [86–88]. Second, topical administration reduces the inhibitory effects of maternally derived serum antibodies on infection and immunogenicity of an RSV vaccine, as has been demonstrated in rodents and chimpanzees [9–11] and in recent clinical studies [62]. Third, while immunization of experimental animals with nonreplicating RSV vaccines such as purified proteins or formalin-inactivated virus can prime for enhanced RSV disease upon subsequent RSV exposure [33], this effect has not been observed with natural RSV infection [62]. Indeed, the balanced, protective immune response associated with live RSV infection supports its use as the first, priming immunization in the young infant.

The host immune response to a single infection with wild-type RSV typically provides incomplete protection against reinfection, particularly in the young infant in whom the immune response is reduced due to immunological immaturity and to the immunosuppressive effect of RSV-specific maternal antibodies on the antibody response to RSV. Therefore it is reasonable to anticipate that the same will be true of a live-attenuated RSV vaccine. It will likely be necessary to administer such a vaccine two or three times during the first year of life, probably as a mixture of viruses representing both RSV subgroups (A and B) and HPIV3. The optimal schedule and dose will need to be determined by experimentation.

Several programs, starting as early as the 1960s, employed conventional approaches to develop a live-attenuated RSV vaccine. Attenuated viruses were sought using techniques such as extensive passage *in vitro* at suboptimal low temperature to select cold-adapted (*ca*) mutants or mutagenizing virus and selecting temperature sensitive (*ts*) mutants [89–92]. The goal was to produce mutants that retain the ability to replicate efficiently in cell culture under permissive conditions (reduced temperature in the case of *ts* and *ca* mutants), thereby permitting efficient vaccine production, but that would be attenuated *in vivo*. These studies were impeded by the difficulty of manipulating RSV due to unstable infectivity and relatively poor growth *in vitro*, the uncontrolled, random nature of the attenuation methods, the lack of a convenient experimental animal for RSV disease, and the complexity involved in the clinical evaluation of a pediatric vaccine.

Recent progress has been obtained in work to generate highly attenuated genetically stable mutant viruses begun at the National Institute of Allergy and Infectious Diseases (NIAID). Initial studies evaluated the level of attenuation, genetic stability, and efficacy in seronegative juvenile chimpanzees of three *ts* mutants of the subgroup A wild-type virus RSV A2, designated *ts*-1, *ts*-1-NG1, and *ts*-4 [76]. These mutants had been prepared previously by one (*ts*-1, *ts*-4) or two (*ts*-1-NG1) rounds of chemical mutagenesis [93]. Each of the *ts* mutants was restricted in replication in the lower respiratory tract of the chimpanzee, but retained the capacity to induce significant rhinorrhea. In addition, each of the three *ts* mutants underwent partial reversion to a non-*ts* phenotype during replication in a minority of the chimpanzees. Data obtained with the *ts*-1, *ts*-1-NG1, and *ts*-4 viruses in chimpanzees [76] were entirely congruent with that from clinical trials with *ts*-1 in seronegative human infants [94], in whom the virus also demonstrated residual reactogenicity and low levels of genetic instability. These studies showed that the seronegative chimpanzee was appropriate to serve as a model for the rapid evaluation of attenuation level and genetic stability of the next generation of live-attenuated RSV vaccines that are more attenuated than *ts*-1, *ts*-1-NG1, and *ts*-4.

A cold-passaged (*cp*) RSV mutant, designated *cp*-RSV, was developed in the 1960s by 52 passages at low temperature in bovine cell culture [95]. The *cp*-RSV virus was not significantly *ca* or *ts*, but was completely attenuated for seropositive adults and children. However, *cp*-RSV retained the capacity to cause upper respiratory disease in seroneg-

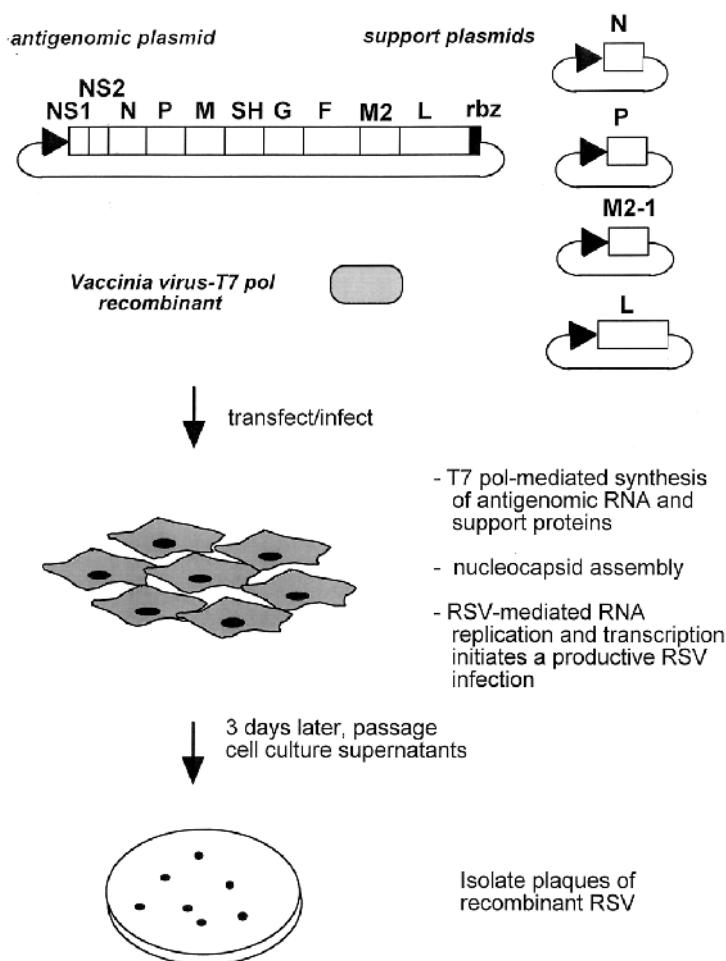

ative infants and thus was insufficiently attenuated. *Cp*-RSV was then subjected to chemical mutagenesis and the resulting virus suspension was screened to identify *ts* derivatives [96]. The two *ts* mutants with the lowest in vitro shutoff temperature (the *cpts*-248 and *cpts*-530 mutants) replicated less efficiently in the chimpanzee nasopharynx and caused less rhinorrhea than their *cp*-RSV parent and were 1000-fold restricted in replication in the trachea compared to wild-type RSV. The *cpts*-248 and *cpts*-530 progeny viruses also exhibited a greater degree of stability of the *ts* phenotype in nude mice and in chimpanzees than the previously studied *ts*-1 virus. The *cpts*-248 and *cpts*-530 viruses were thought likely to be incompletely attenuated for fully susceptible seronegative human infants and young children, based on data from seronegative chimpanzees. Therefore each virus was subjected to a second round of chemical mutagenesis and mutants were selected for increased *ts* phenotype [10,97]. Mutants designated *cpts*-248/955, *cpts*-248/404, *cpts*-530/1009, and *cpts*-530/1030, each with an in vitro shutoff temperature (i.e., the lowest temperature at which  $\geq 100$ -fold reduction in plaquing efficiency is observed) of approximately  $37^{\circ}\text{C}$ , were selected for further evaluation. The *cpts*-248/955 virus was more restricted in replication in chimpanzees than its parental viruses *cp*-RSV and *cpts*-248 (J. Crowe et al, unpublished observations). Clinical trials revealed that *cpts*-248/955 was attenuated in seropositive adults and children but retained virulence for seronegative infants and was transmissible to contacts [98]. Importantly, the *ts* phenotype of this mutant was observed to be stable even when replicating to high titers in seronegative infants. Thus, this virus was the first to demonstrate that a high level of genetic stability of an RSV *ts* mutant in the fully susceptible human infant could be achieved. Subsequent clinical studies in seronegative infants with *cpts*-530/1009 [98] showed that it, too, was phenotypically stable but was insufficiently attenuated, and preclinical data for *cpts*-530/1030 were similar.

The *cpts*-248/404 virus appeared to be somewhat more attenuated in the seronegative chimpanzee and thus suitable for evaluation in 1–2-month-old RSV-naive infants, the target age for an RSV vaccine [62]. This vaccine virus replicated in the nasopharynx to similar levels in older seronegative infants and in the 1–2-month-old infants, who possess substantial titers of maternally derived RSV-specific antibodies. This finding indicated that maternal antibody does not significantly inhibit the replication of the attenuated virus. More than 80% of vaccinees were infected and shed from  $10^3$  to  $10^5$  PFU of vaccine virus per milliliter of nasal wash. This level of virus replication was sufficient for immunization, because the majority of infants were not infected with a second vaccine dose given 1 month later. In addition, more than 80% of vaccinees had a significant rise in RSV-specific IgA. Interestingly, the antibody response to the G protein was more frequent and of greater magnitude than that to the F protein. Thus although there is speculation that G has antigenic properties when administered in the absence of other RSV antigens that contribute to priming for immune-enhanced RSV disease in rodents [99], it probably would be ill advised to delete this antigen from a pediatric vaccine. More than 70% of vaccinees experienced brief nasal congestion

that interfered with sleep and feeding following the initial immunization and that appeared coincident with the peak of virus shedding, indicating that the virus needs to be further attenuated. In addition, virus recovered on several days from a single vaccinee exhibited a partial loss of the *ts* and attenuation phenotypes. Although this revertant virus did not become a predominant species and remained significantly attenuated, it would be desirable to achieve a greater level of phenotypic stability.

Given the difficulty in obtaining an appropriately attenuated, phenotypically stable vaccine virus by conventional biological methods, the studies shifted to using recombinantly derived RSV as the substrate for producing a live-attenuated vaccine. Recombinant wild-type RSV strain A2 can be produced entirely from cDNA by the intracellular coexpression of a complete positive-sense copy of RSV genomic RNA and the RSV N, P, L, and M2-1 proteins from transfected plasmids (Fig. 1) [100]. This recombinant wild-type virus was confirmed to be virulent in seronegative chimpanzees and thus was an appropriate substrate for the development of attenuated derivatives.

To identify attenuating mutations for insertion into recombinant RSV, the biologically-derived *cp*-RSV and *cpts*-RSV mutants described above were sequenced in their entirety, and the contribution of the mutations identified to the *ts* and attenuation phenotypes was evaluated by introduction into the wild-type recombinant virus. Sequence analysis showed that the *cp*-RSV mutant had five nucleotide substitutions in the N, F, and L genes that each gave rise to an amino acid change, and the introduction of all five mutations into wild-type recombinant RSV reconstituted the attenuation phenotype [101,102]. Sequence analysis of the *cpts*-248, *cpts*-530, *cpts*-248/404, *cpts*-530/1009, and *cpts*-530/1030 viruses showed that the singly and doubly mutagenized viruses each contained one and two point mutations, respectively, that independently conferred *ts* and attenuation phenotypes [103–107]. Each of the mutations involved an amino acid substitution in the L polymerase protein with the exception of one of the mutations in *cpts*-248/404, which involved a single nucleotide change in the transcription gene-start signal of the M2 gene. Biologically derived viruses such as *cpts*-248/404 and *cpts*-530/1009 were then reconstructed in recombinant form, which reconstituted the authentic *ts* and attenuation phenotypes and confirmed that the attenuating mutations had been correctly and completely identified. The recombinant version of the *cpts*-248/404 virus was then modified by the introduction of one of the attenuating mutations from the *cpts*-530/1030 virus, resulting in a recombinant virus called *cp*248/404/1030 that was more *ts* and more attenuated than *cpts*-248/404. This recombinant virus represents a promising new RSV vaccine candidate [108]. This work demonstrated that the recombinant recovery method (also called “reverse genetics”) can indeed be used to place predetermined changes into infectious virus to obtain new combinations of attenuating mutations and to obtain incremental increases in the *ts* and attenuation phenotypes. It also is noteworthy that, while each of the amino acid changes in the biologically derived mutants was due to a single nucleotide change and thus could revert to the wild-type assign-

**Figure 1** Production of infectious recombinant RSV from cloned cDNAs. The antigenomic plasmid contains a cloned cDNA of the complete RSV genome, with the viral genes shown as boxes. This cDNA is flanked on the upstream, left side by the promoter for T7 RNA polymerase (filled triangle) and on the downstream, right side by sequence encoding a self-cleaving ribozyme (rbz, filled box). Transcription by T7 RNA polymerase yields the positive sense replicative intermediate RNA, the antigenome: the strategy of synthesizing the antigenome rather than the negative-sense genome is to avoid hybridization with the positive-sense RNAs produced by the support plasmids. The four support plasmids contain cDNAs encoding the RSV N, P, M2-1, and L proteins under the control of T7 RNA polymerase. The antigenomic and support plasmids are transfected into cultured cells that are also infected with a vaccinia virus recombinant expressing T7 RNA polymerase. Co-expression of the antigenomic RNA and the N, P, M2-1, and L proteins results in the assembly of a viral nucleocapsid, which includes the RSV polymerase and is the minimum unit of infectivity. This nucleocapsid is replicated and transcribed by the RSV polymerase, thereby producing progeny genome and antigenome as well as expressing all of the genes. This launches a productive infection that results in the production of infectious recombinant virus. Following a three-day incubation, the clarified cell culture supernatant fluid is passed onto a fresh monolayer and viral plaques are isolated and propagated. Production of recombinant PIV, such as PIV3, follows the same strategy except that only three support plasmids are required, namely N, P, and L: the PIVs lack an equivalent to the RSV M2-1 protein.

ment in a single step, in many cases it was possible to introduce the attenuating amino acid assignments into recombinant virus using two nucleotide differences per codon relative to wild type. This modification might greatly reduce the frequency of reversion and thus provide greater genetic stability.

Another source of attenuating RSV mutations has been the deletion of nonessential genes. Surprisingly, five RSV genes can be deleted or silenced individually and in certain combinations without the loss of infectivity in vitro [109–115]. For example, the genes encoding the NS1 and NS2

nonstructural proteins can be deleted individually or together, resulting in viruses that replicate only slightly less efficiently than wild-type RSV in Vero cell culture. Recent work suggests that the function of NS1 and NS2 is to coordinately antagonize the interferon type I-mediated antiviral state [116]. Deletion of the gene encoding the small hydrophobic SH surface protein, whose function is unknown, results in a virus that replicates as efficiently in vitro as wild-type. Remarkably, the G glycoprotein gene also can be deleted without much effect on the ability of the virus to replicate in Vero cell culture [115], although this particular

deletion mutant likely would not be useful for vaccine purposes because G is one of the major protective antigens. Finally, deletion or silencing of the M2-2 open reading frame (ORF), which is the second, downstream ORF of the M2 mRNA, resulted in a virus in which the balance between transcription versus RNA replication appeared to be shifted, such that transcription is increased and RNA replication is decreased. This provided the novel phenotype of increased antigen expression concomitant with attenuation, a phenotype that might be highly desirable for vaccine purposes. When evaluated in chimpanzees and compared to the *cpts*-248/404 virus, the order of increasing attenuation of these gene-deletion viruses was:  $\Delta$ SH <  $\Delta$ NS2 < *cpts*-248/404 <  $\Delta$ NS1 <  $\Delta$ M2-2 [117,118]. Thus these gene deletions represent promising attenuating mutations for vaccine purposes, either on their own or in combination with point mutations previously described. For example, a virus consisting of the *cpts*-248/404/1030 backbone mentioned above together with the deletion of the SH gene was more attenuated and resulted in a lower level of virus shedding in seronegative children compared to *cpts*-248/404, and represents a promising vaccine candidate (R. Karron, unpublished data). An advantage of a gene deletion is that it is likely to be phenotypically highly stable.

Another method of attenuation is based on the naturally occurring host range restriction of bovine RSV (BRSV) in primates. Bovine RSV and human RSV (HRSV) are closely related viruses that share considerable antigenic cross-reactivity as measured with pooled human antibodies or HRSV F-specific monoclonal antibodies [119]. Bovine RSV has been considered for use as a live vaccine against human RSV (HRSV). Immunization of cotton rats with BRSV provided partial resistance to HRSV challenge [120]. However, BRSV strain A51908 did not replicate to a detectable level in seronegative chimpanzees and failed to induce resistance to challenge with HRSV [121], indicating that BRSV was overattenuated in primates. To reduce the host range restriction and improve antigenic cross-reactivity with HRSV, a recombinant version of BRSV was modified so that the HRSV counterparts replaced the BRSV G and F genes. This chimeric rBRSV/A2 virus replicated to very low levels in chimpanzees and did not induce significant protection against HRSV challenge [121]. This finding indicated that the introduction of the HRSV glycoproteins provided some improvement in growth, but that the rBRSV/A2 chimeric virus remained overattenuated. The next step will be to replace additional BRSV genes in rBRSV/A2 with the HRSV counterparts to improve the growth of the chimeric virus and achieve a satisfactory level of immunogenicity.

A successful live-attenuated RSV vaccine should induce protection against viruses of either antigenic subgroup A or B. Attempts to produce a satisfactorily attenuated subgroup B vaccine candidate by conventional methods have not been successful so far [113,122,123], and a reverse genetics system for subgroup B has not yet been developed. Therefore the existing subgroup A strain A2 recombinant virus was modified so that its G and F glycoprotein genes were replaced by those of the subgroup B strain B1 virus [24]. The resulting AB virus, bearing the major antigenic determinants of subgroup B in the A2 backbone, replicated like a wild-type

virus in cell culture and chimpanzees. Because nearly all of the available attenuating mutations identified for the A2 strain lie outside the G and F genes, they can be directly inserted into the A2 backbone of the A/B chimeric virus. The glycoprotein swap had very little effect on virus growth; therefore it is likely that the same attenuated backbone can be used for the subgroup A and B vaccine viruses. For example, an AB chimeric virus that was constructed with the backbone of the *cpts*-248/404/1030 vaccine candidate described above possessed the same shut-off temperature as *cpts*-248/404/1030 and exhibited a similar, high degree of attenuation in chimpanzees [124]. A second approach to making a subgroup B vaccine is to express the G protein of subgroup B as a supernumerary gene inserted into the subgroup A strain A2 genome [125]. Because G is highly divergent between the subgroups, whereas F is relatively well conserved, this single chimeric virus expressing the G proteins of both subgroups and the F protein of subgroup A alone could serve as a bivalent vaccine against both subgroups.

### 3. Future Directions

The ability to introduce predetermined changes into infectious RSV via a cloned DNA intermediate provides the means to produce novel, improved vaccine candidates and to fine-tune their level of attenuation. A critical feature of this strategy was to develop a menu of mutations that attenuate *in vivo* but have little or minimal effect on virus growth *in vitro*. The present menu, including non-*ts* point mutations, *ts* point mutations, gene deletions, and host range determinants, has been used to produce a number of promising recombinantly derived vaccine candidates that are in clinical trials or in preparation. Other methods of attenuation also are available, such as inserting additional sequence or genes into the genome, which has the effect of reducing the efficiency of virus growth [126], or rearrangement of the viral genome so that the expression of the various proteins is suboptimal and growth efficiency is reduced [127]. However, these methods appear to reduce growth *in vitro* as well as *in vivo*, and hence might interfere with vaccine production to an unacceptable level.

The ability of reverse genetics to derive viruses that are more attenuated than *cpts*-248/404 suggests that it will be possible to produce vaccine candidates that are sufficiently attenuated for use as pediatric vaccines. It remains to be seen whether such viruses will be able to induce a satisfactory level of protective immunity in the very young infant. The ability of *cpts*-248/404 to confer a high degree of resistance to a second vaccine dose suggests that effective immunity can be achieved in the young infant, at least for the short term [62]. Additional immunizations or restricted natural infection in the context of the maturing immune response might result in increased, longer-lived protection.

It might also be possible to produce an RSV vaccine that is "better than nature" with regard to the balance between immunogenicity and attenuation. The  $\Delta$ M2-2 virus is one example because it has a higher intrinsic level of transcription per genome compared to wild-type RSV and thus provides a higher level of antigen expression. Another way

to increase the level of expression of the protective antigens would be to move their genes to be promoter-proximal [128] or to manipulate the encoded mRNAs to be more efficiently translated. The expression of cytokines or chemokines from one or more genes inserted into RSV offers another way to attenuate virus replication and to boost and alter the immune response [129,130] although additional care might be needed to demonstrate the safety of such a vaccine. It might also be possible to improve vaccine virus by eliminating features that have been suggested to enhance pathogenesis or interfere with the host immune response. For example, deletion of the NS1 and NS2 interferon antagonists might improve the immune response. In addition, the G glycoprotein is expressed in part as a secreted form that might mimic a protein vaccine in priming for enhanced immunopathology [131], and G contains a CX3C-like domain that might function as a chemokine antagonist [132]. Either of these features could be removed from vaccine virus by reverse genetics. In addition, we still do fully not understand why RSV can infect young infants despite the presence of moderate titers of RSV-neutralizing serum antibody, nor why the immune response to RSV is relatively inefficient in blocking reinfection. Hopefully, answers will be obtained in future work and used to improve RSV immunoprophylaxis.

Respiratory syncytial virus is a significant cause of respiratory tract disease in adults and, in particular, the elderly, where its impact approaches that of nonpandemic influenza virus [133]. A vaccine virus that is appropriately attenuated for young infants likely will be overattenuated for adults, based on an evaluation of the above-mentioned *cpts*-248/404 virus in both age groups [43,62]. Therefore it also is important to define a second group of live-attenuated vaccine candidates, such as  $\Delta$ NS2, that are somewhat less attenuated than *cpts*-248/404 and are appropriate for evaluation in the elderly.

### III. VACCINE DEVELOPMENT FOR HPIV1, HPIV2, AND HPIV3

#### A. General Considerations

HPIV1, HPIV2, and HPIV3 cause severe respiratory tract disease that leads to hospitalization of infants and young children [134]. HPIV1, HPIV2, and HPIV3 are distinct serotypes, and significant cross-neutralization or cross-protection is not seen following primary infection. In a long-term study in infants and children over a 20-year period, HPIV1, HPIV2, and HPIV3 were identified as etiologic agents responsible for 6.0%, 3.2%, and 11.5%, respectively, of hospitalizations for respiratory tract disease [134], accounting in total for slightly less than that caused by RSV. Respiratory syncytial virus and PIV3 cause significant illness within the first 4 months of life whereas most of the illness caused by HPIV1 and HPIV2 occurs after 6 months of age. A likely immunization sequence employing live-attenuated RSV and HPIV vaccines would be administration of RSV and HPIV3 vaccines together as a combined vaccine that would be given two or more times, with the first dose administered at or before 1 month of age, followed by a bi-

valent HPIV1 and HPIV2 vaccine at 4 and 6 months of age. The protective antigens of the PIVs are the hemagglutinin-neuraminidase (HN) glycoprotein (the attachment protein) and the fusion (F) glycoprotein, both of which induce neutralizing antibodies [134]. Because the PIVs, like RSV, cause repeat infection of humans, resistance against these viruses in humans may be best achieved by the induction of an immune response consisting of antibodies, both serum and mucosal, and cell-mediated immunity [134,135].

The PIV gene order is 3' leader-N-P-M-F-HN-L-5' trailer [134]. The 3' end of genomic RNA and its full-length positive-sense replicative intermediate antigenomic RNA contains promoter elements that direct RNA synthesis. The genes are bordered by short conserved gene-start and gene-end signals that guide the polymerase during sequential transcription. The nucleocapsid-associated proteins are composed of the nucleocapsid protein (N), the phosphoprotein (P), and the large polymerase (L). The internal matrix protein (M) and the major protective antigens, the F and HN, are the envelope-associated proteins. The PIV P gene gives rise to additional, accessory proteins (designated C, C', Y1, Y2, V, D, and X) that vary in occurrence among the different PIVs [134].

Previously tested, inactivated PIV vaccines were not sufficiently immunogenic to be protective in humans [136], but disease potentiation was not observed in these clinical studies as it had been for RSV. However, disease potentiation has recently been observed following wild-type PIV3 challenge of rodents previously immunized with either formalin- or UV-inactivated PIV3 vaccines [137]. Therefore as is the case for RSV and measles virus, there are concerns that nonreplicating vaccines such as purified proteins might be associated with immune-mediated disease potentiation. Other factors impede the development of PIV subunit vaccines including the weak immunogenicity of purified proteins in immunologically naive subjects and the need for the codevelopment of a safe adjuvant that is effective in humans, including the young infant [138]. There have been few recent studies on inactivated or subunit vaccines [139], and this summary of new vaccines will focus on the live or vectored PIV vaccine candidates under active study. The extensive safety record of live-attenuated measles and mumps virus vaccines, together with the experience with experimental live RSV vaccines, suggests that it is unlikely that immunization with a live-attenuated HPIV vaccine would be followed by disease potentiation.

#### B. Live Virus Vaccines

##### 1. Vaccines Whose Attenuation Is Based on Host Range

Bovine PIV3 (BPIV3) was chosen as a candidate live-attenuated virus vaccine to protect against infection with HPIV3 for several reasons. First, antigenic analysis using monoclonal antibodies and postinfection sera from rodents and primates indicated that the surface glycoproteins of the BPIV3 and HPIV3 are about 25% related by reciprocal cross-neutralization [140]. The majority of the antigenic sites recognized by humans undergoing infection with HPIV3

also were recognized by sera of monkeys and chimpanzees following infection with BPIV3 [141]. This high degree of relatedness revealed by antigenic analysis is consistent with the relatively high degree of sequence relatedness between the HN and F glycoproteins of BPIV3 and HPIV3 (77% and 80% identity, respectively) [142]. Second, infection of cotton rats or monkeys with BPIV3 induced resistance to subsequent challenge infection with HPIV3 [140]. The replication of the two different strains of BPIV3 that were tested was restricted 100- to 1000-fold in rhesus monkeys or chimpanzees, but was sufficient to induce moderate levels of serum neutralizing antibodies to HPIV3 [140]. It seems likely that many of the sequence differences between BPIV3 and HPIV3 are a result of evolution and adaptation in their respective hosts. This principle forms the basis for natural host range restriction. This mechanism of attenuation based on host range is analogous to that of vaccinia virus (the vaccine virus for prevention of smallpox), which was much less virulent in humans than smallpox virus but, nonetheless, provided excellent protection against smallpox. This approach to immunization against viral pathogens has been termed the “Jennerian” approach. The combined properties of restriction of replication and induction of a protective immune response to HPIV3 in nonhuman primates made the BPIV3 a promising candidate for use as a live virus vaccine.

BPIV3 was restricted in replication, poorly infectious, and avirulent in both seropositive children and adults [143,144]. However, BPIV3 was highly infectious for seronegative vaccinees when administered at a dose of  $10^{4.0}$  or  $10^{5.0}$  TCID<sub>50</sub> and was nonreactogenic at these doses. BPIV3 infected 92% of HPIV3-seronegative children; 92% developed a serum hemagglutination inhibiting (HAI) antibody response to BPIV3 and 61% to HPIV3. Additional studies indicated that the live BPIV3 vaccine is attenuated, infectious, immunogenic, poorly transmissible, and phenotypically stable, and it is continuing to be evaluated as a candidate vaccine in infants and children [145].

An investigation has been initiated into the genetic basis of attenuation of BPIV3 using reverse genetics. A chimeric recombinant human–bovine parainfluenza virus type 3 (PIV3) virus (rHPIV3-N<sub>B</sub>) was constructed in which the nucleoprotein (N) ORF of HPIV3 was replaced by its counterpart from BPIV3 [82]. rHPIV3-N<sub>B</sub> was restricted in replication in rhesus monkeys to a similar extent as its BPIV3 parent, showing that the BPIV3 N protein is a determinant of the host range restriction of replication, i.e., the attenuation phenotype, of BPIV3 in primates [146]. There are 79 differences out of a total of 515 amino acids between the N proteins of human PIV3 and BPIV3 [147]. Many of these 79 amino acid differences likely contribute to the host range attenuation phenotype of rHPIV3-N<sub>B</sub>. Because of this, it is anticipated that the attenuation phenotype of rHPIV3-N<sub>B</sub> will be stable following prolonged replication in vivo, and preliminary findings indicate that this is so [144]. The HN and F genes of BPIV3 also have been shown to contribute to its attenuation for primates [82]. Because BPIV3 is only 25% antigenically related to HPIV3 [141], its immunogenicity against HPIV3 would be improved if it could be modified to express the protective F and HN antigens of HPIV3.

rHPIV3-N<sub>B</sub>, which combines the antigenic determinants of HPIV3 with the host range restriction and attenuation phenotype of BPIV3, represents such a virus. In nonhuman primates, it induced a level of resistance to HPIV3 challenge that was indistinguishable from that conferred by immunization with HPIV3. Thus in the process of analyzing the genetic basis of attenuation of BPIV3 for primates, a promising vaccine candidate, rHPIV3-N<sub>B</sub>, was generated, and this analysis identified chimerization of human and bovine PIV3 viruses as a novel method to produce an attenuated HPIV3 vaccine.

A second vaccine candidate based on the host range attenuation of BPIV3 for primates was constructed. rBPIV3 was recovered from cDNA and was used to construct a BPIV3/HPIV3 chimeric virus, designated rB/HPIV3, in which the F and HN genes of BPIV3 were replaced with their HPIV3 counterparts [82,148]. The F and HN genes were exchanged as pairs because of the known requirement for the presence of homologous F and HN proteins of parainfluenza viruses for full functional activity [149–151] and because the two proteins together constitute the PIV3 neutralization antigens. rB/HPIV3 replicated in vitro as efficiently as its parental viruses, and it replicated in the upper respiratory tract of rhesus monkeys to the same level as that of its BPIV3 parent [82,83]. Thus introduction of the HPIV3 F and HN genes into the BPIV3 backbone was insufficient alone to alter its attenuation phenotype. Immunization of rhesus monkeys with rB/HPIV3 induced a higher level of antibody to HPIV3 than did immunization with BPIV3, consistent with the presence of the homologous HPIV3 glycoproteins in rB/HPIV3. Furthermore, rB/HPIV3 conferred a level of protection against replication of HPIV3 challenge in the upper and lower respiratory tract that was statistically indistinguishable from that conferred by previous infection with wild-type HPIV3. Thus rB/HPIV3 and rHPIV3-N<sub>B</sub> represent promising new PIV3 vaccine candidates, and studies with them are planned in humans. A possible advantage of rB/HPIV3 over rHPIV3-N<sub>B</sub> is that it possesses all of the BPIV3 genes other than HN and F, so that if more than one BPIV3 gene is involved in the host range restriction of replication of BPIV3 for primates, rB/HPIV3 should be even more phenotypically stable than rHPIV3-N<sub>B</sub>. Conversely, a potential advantage of rHPIV3-N<sub>B</sub> over rB/HPIV3 is that it possesses all of the HPIV3 antigens except N, and thus might induce a cell-mediated response that would more closely resemble that of HPIV3. Studies of safety (attenuation), immunogenicity, and protective efficacy in humans will be needed to resolve these issues.

The close antigenic relatedness between Sendai virus and HPIV1 suggested that Sendai virus could be used as a Jennerian vaccine to protect against HPIV1. Mice immunized with HPIV1 were partially protected against a lethal dose of Sendai virus [152]. Similarly, African green monkeys immunized with Sendai virus were protected against experimental challenge with HPIV1 infection [153]. However, these studies did not evaluate the level of replication of Sendai virus and HPIV1 in the upper and lower respiratory tract of the primates, and it was unclear whether Sendai virus would be satisfactorily attenuated for primates. A subse-

quent study showed that Sendai virus is not significantly restricted in its replication in the upper and lower respiratory tract of African green monkeys and chimpanzees compared to HPIV1 [154], suggesting that it is an unlikely vaccine candidate for use in humans.

## 2. Live-Attenuated Human Parainfluenza Virus Vaccines

Live-attenuated mutants of HPIV3 are also being developed. A wild-type strain of HPIV3, designated strain JS, was cultivated in primary monkey kidney tissue culture at low temperatures for 45 passages and mutants were selected after 12, 18, or 45 passages and designated HPIV3cp12, HPIV3cp18, or HPIV3cp45, according to their cold-passage level [155]. Three phenotypic markers were acquired during the process of low temperature passage: cold-adaptation (*ca*), i.e., the ability to replicate efficiently at 25 °C; temperature sensitivity (*ts*), i.e., restriction of growth at 40 °C in tissue culture; and attenuation (*att*), restricted replication in hamsters [155,156]. The HPIV3 *cp*PIV3 mutants protected hamsters against HPIV3 challenge [157], and each of the three *cp* mutant viruses was attenuated in seronegative rhesus monkeys [158]. The level of temperature-sensitivity of the *cp* mutants directly correlated with the degree of attenuation in monkeys, with the HPIV3cp12 being the least *ts* and the least attenuated, whereas the HPIV3cp45 mutant was the most *ts* and the most attenuated. Data derived from the evaluation of the HPIV3cp12, HPIV3cp18, and HPIV3cp45 viruses in rhesus monkeys indicated that HPIV3cp45 was the most promising of the three *cp* mutants because it was the most restricted in replication in the lower respiratory tract and its *ts* phenotype was the most stable following replication *in vivo*. The HPIV3cp45 mutant was also the only one of the three cold-passaged viruses that possessed both *ts* and non-*ts* mutations contributing to the attenuation phenotype in rhesus monkeys, suggesting that the HPIV3cp45 virus had acquired a greater number of attenuating mutations compared to the HPIV3cp12 and HPIV3cp18 mutants [159].

The HPIV3cp45 virus was highly restricted in replication in both the upper and lower respiratory tract of the chimpanzee compared to the JS wild-type parent virus and the animals were highly resistant to wild-type HPIV3 challenge [160]. The HPIV3cp45 virus present in the respiratory tract secretions of chimpanzees retained the *ts* phenotype, but some decrease in the level of temperature sensitivity was observed in the virus isolated in tissue culture (referred to as isolates). In other words, the input HPIV3cp45 vaccine virus was more restricted in plaque formation at 38°C than the HPIV3cp45 isolates, but all the isolates were *ts* at 40°C. Stability of the attenuation phenotype was demonstrated by the administration of an isolate of HPIV3cp45 (*ts* at 39°C), obtained after 10 days of replication in a chimpanzee, to two additional chimpanzees. This chimpanzee-passaged HPIV3cp45 virus was attenuated in both the upper and lower respiratory tracts, indicating that the attenuation phenotype of the HPIV3cp45 virus was stable following replication in chimpanzees, despite the decrease in temperature sensitivity. These results provided the basis on which to proceed to clinical trials in humans.

The HPIV3cp45 mutant was evaluated in a randomized, placebo-controlled, double-blind trial in 114 children 6 months to 10 years of age [161]. The *cp*45 vaccine was well tolerated when given intranasally to HPIV3 seropositive or seronegative children. A *cp*45 vaccine dose of 10<sup>4</sup> or 10<sup>5</sup> TCID<sub>50</sub> infected 86% of seronegative vaccinees, 83% of whom shed virus at a mean peak titer of 10<sup>2.2</sup> pfu/mL. Virus present in the respiratory specimens retained the *ts* phenotype, and each of 86 *cp*45 isolates tested retained both the *ts* and *ca* phenotypes. A single dose of 10<sup>5</sup> TCID<sub>50</sub> induced a serum HAI antibody response in 81% of vaccinees; the geometric mean titer achieved was 1:32. These studies indicate that the HPIV3cp45 vaccine is satisfactorily attenuated, infectious, immunogenic, and phenotypically stable. Further evaluation of this promising vaccine candidate is underway.

To characterize the genetic basis for the *ts*, *ca*, and *att* phenotypes of this promising vaccine candidate, a recombinant HPIV3cp45 (rHPIV3cp45) virus was constructed that contained all fifteen HPIV3cp45-specific mutations identified by sequence analysis [159,162]. rHPIV3cp45 was indistinguishable from the biologically derived HPIV3cp45 on the basis of plaque size, level of temperature sensitivity, cold-adaptation, level of replication in the upper and lower respiratory tract of hamsters, and ability to protect hamsters from subsequent wild-type HPIV3 challenge. A series of recombinant viruses was constructed containing individual HPIV3cp45 mutations or combinations of several mutations. Analysis of these recombinant viruses revealed that multiple HPIV3cp45 mutations distributed throughout the genome contribute to the *ts*, *ca*, and *att* phenotypes [162]. Each of the three amino acid substitutions in the L polymerase protein of HPIV3cp45 independently confers the *ts* and *att* phenotypes, but not the *ca* phenotype [163]. In addition to the mutations in the L gene, at least one other mutation in the 3'-N region (i.e., including mutations in the leader, in the gene start *cis*-acting sequence of N, and in the N coding region) contributes to the *ts* phenotype. A recombinant virus containing all the HPIV3cp45 mutations except those in L was more *ts* than HPIV3cp45, illustrating the complex nature of this phenotype. The *ca* phenotype of HPIV3cp45 also is a complex composite phenotype reflecting contributions of at least three separate genetic elements, namely mutations within the 3'N region, the L protein, and the CMFHN region. The *att* phenotype, which is the most relevant for vaccine purposes, was found to be a composite phenotype due to both *ts* and non-*ts* mutations. Attenuating *ts* mutations are in L, and non-*ts* attenuating mutations are located in C and F. The presence of multiple *ts* and non-*ts* attenuating mutations in *cp*45 likely contributes to the high level of attenuation and phenotypic stability of this promising vaccine candidate.

A live-attenuated HPIV1 vaccine candidate was generated by modification of the extensively studied HPIV3cp45 vaccine candidate using the techniques of reverse genetics [164,165]. Promising vaccine candidates had not been developed for HPIV1, and a reverse genetics system was not available for HPIV1 until very recently [166]. It was found that the HN and F glycoproteins of HPIV3 could be replaced with those from HPIV1, and an rHPIV3-1 chimeric

virus was recovered that possesses a wild-type phenotype for replication in vitro and in vivo [167]. Next, the HN and F glycoproteins of the HPIV3cp45 candidate vaccine virus were replaced with those of HPIV1. This created a live-attenuated HPIV1 vaccine candidate, termed rHPIV3-1cp45, which contained the attenuated background of the rHPIV3cp45 vaccine virus together with the HN and F protective antigens of HPIV1. The chimeric rHPIV3-1cp45 virus was more restricted in replication in hamsters than HPIV3cp45, indicating that the introduction of the heterologous HPIV1 HN and F proteins into HPIV3 had an attenuating effect (i.e., attenuation due to chimerization) that was additive to that conferred by the 12 HPIV3cp45 mutations present in rHPIV3-1cp45. rHPIV3-1cp45 was immunogenic and protective against challenge with wild-type HPIV1 in hamsters. This virus shows sufficient promise that it should be evaluated further as a candidate live-attenuated vaccine strain for the prevention of severe lower respiratory tract disease caused by HPIV1 in infants and young children.

The same strategy as described above for the rHPIV3-1 chimeric virus was used to develop a live-attenuated HPIV2 vaccine virus, but a recombinant chimeric HPIV3–HPIV2 virus carrying the full-length HPIV2 glycoproteins in a wild-type HPIV3 backbone could not be recovered [167]. This difficulty was presumably due to incompatibility between the HPIV2 glycoproteins and the HPIV3 internal proteins, and might reflect the more distant relatedness between HPIV3 and HPIV2 than between HPIV1 and HPIV3 [134]. However, viable HPIV3-HPIV2 chimeric viruses were recovered when chimeric HN and F ORFs rather than complete HPIV2 F and HN ORFs were used to construct the full-length cDNA. One recovered virus, designated rHPIV3-2CT, in which the HPIV2 F and HN ectodomains and transmembrane domains were fused to their HPIV3 counterpart F and HN cytoplasmic domains, replicated efficiently in vitro. Thus it appears that only the cytoplasmic tail of the HN or F glycoprotein or both of HPIV3 were required for successful recovery of HPIV3-HPIV2 chimeric viruses. Although rHPIV3-2CT replicated efficiently in vitro, it was moderately to highly attenuated for replication in the respiratory tract of hamsters, African green monkeys (AGMs), and chimpanzees. This unexpected finding indicated that chimerization of the HN and F proteins of HPIV2 and HPIV3 itself specified a strong attenuation phenotype in vivo. Despite this attenuation, these viruses were highly immunogenic and protective against challenge with HPIV2 wild-type virus in hamsters and AGMs, and they represent promising candidates for clinical evaluation as a vaccine against HPIV2.

Although antigenic chimeric viruses provide a strategy for the rapid generation of new vaccine candidates, there might be a price to pay for their use. As indicated above, the epidemiology of RSV and HPIV1, HPIV2, and HPIV3 suggests that it would be optimal to administer vaccines in a sequential schedule with RSV and HPIV3 vaccines given before HPIV1 or HPIV2 vaccines. Should cross-protection between an HPIV3 and an HPIV3-1 vaccine occur, this would complicate a scheme of sequential immunization with a HPIV3 vaccine followed by an HPIV3-1 vaccine. We found that prior infection with HPIV3 moderately decreased the

replication, immunogenicity, and efficacy of an rHPIV3-1 vaccine candidate [135]. This resistance to replication of HPIV3-1 likely was mediated by T cells directed against the shared internal PIV3 proteins of the two viruses, and in hamsters the resistance had waned within 4 months. The magnitude and duration of cell-mediated immunity to HPIV3 in primates and in young human vaccines is unknown. Thus a sequential immunization protocol using HPIV3-1 and HPIV3-2 antigenic chimeric vaccines in HPIV3 immune persons might pose potential problems for the infectivity and immunogenicity of these vaccines. A successful vaccine against HPIV1 and HPIV2 might require the development of attenuated human HPIV1 and HPIV2 vaccine viruses using the recently described reverse genetics systems for each of these viruses [166,168,172].

### 3. Use of Human Parainfluenza Viruses as Vectors

The limitations of the use of vaccinia or MVA viruses as vectors for RSV protective antigens was discussed above, as was the usefulness of attenuated HPIV3 viruses as vectors for the RSV F and G protective antigens. Human PIV3-based vectors, either based on attenuation specified by mutations present in HPIV3cp45 or host range sequences present in BPIV3, have also been used as vectors to express the HA protective antigen of measles virus, resulting in a bivalent vaccine virus against HPIV3 and measles viruses [169,170]. The HPIV3/HPIV1 antigenic chimeric virus described above, designated rHPIV3-1, in which the HN and F proteins of wild-type HPIV3 were replaced by their HPIV1 counterparts, was used as a vector to express the HN protein of HPIV2 to generate a single virus capable of inducing immunity to both HPIV1 and HPIV2 [171]. The HPIV2 HN ORF was expressed from an extra gene cassette, under the control of HPIV3 *cis*-acting transcription signals, inserted between the F and HN genes of rHPIV3-1. The recombinant derivative, designated rPIV3-1.2HN, was readily recovered and exhibited a level of in vitro growth similar to that of its parental virus. The rPIV3-1.2HN virus was restricted in replication in both the upper and lower respiratory tract of hamsters compared to rPIV3-1, identifying an in vivo attenuating effect of the HPIV2 HN insert. In hamsters, rPIV3-1.2HN elicited serum antibodies to both HPIV1 and HPIV2 and induced resistance against challenge with wild-type HPIV1 or HPIV2. Thus rPIV3-1.2HN, a virus solely attenuated by the insertion of the HPIV2 HN gene, functioned as a live-attenuated bivalent vaccine candidate against both HPIV1 and HPIV2.

## Developing a Vaccine Against Epstein–Barr Virus

Denis Moss and Mandvi Bharadwaj

*University of Queensland, Herston, Queensland, Australia*

### I. INTRODUCTION

There is a strong scientific and commercial focus on developing vaccines and immunotherapeutic strategies for the treatment of Epstein–Barr virus (EBV)-associated diseases. This increased interest is due to a deeper understanding of the immune variables that control EBV infection and an appreciation of the biology of this potentially oncogenic virus [1,2]. Epstein–Barr virus, discovered in 1964 by Epstein and colleagues, is a human gamma herpesvirus that infects over 90% of the world's population. It is a double-stranded DNA virus encoding approximately 100 proteins [3]. Primary infection most commonly occurs during childhood and is generally asymptomatic, resulting in a lifelong viral latency in B cells. In developed countries, primary infection is sometimes delayed until adolescence and then results in clinical infectious mononucleosis (IM) (commonly called as "glandular fever"). This clinical manifestation occurs in about 50% of adolescents experiencing primary EBV infection (typically following kissing) and is characterized by fatigue, pharyngitis, fever, cervical lymphadenopathy, and splenomegaly. The major target of EBV infection is apparently the B lymphocyte, although a role for squamous epithelial cells cannot be unequivocally discounted. During primary infection (Figure 1), colonization of the lymphoid system occurs through virus-driven expansion of infected B cells that selectively express six latent EBV nuclear antigens (EBNAs 1–4, 6, -LP) and latent membrane proteins (LMPs 1, 2A, and 2B) [4,5]. These latently infected B cells maintain a lifelong virus carrier state and constitute the reservoir on which viral persistence depends. Viral shedding into the oropharynx is another feature of primary EBV infection and arises from expression of the "lytic switch" protein BZLF1 [6], which launches the productive cycle cascade. Lytic and structural proteins gp85, BMLF1, BMRF1, BHFR1, and gp350 are also a feature of virus replication [7].

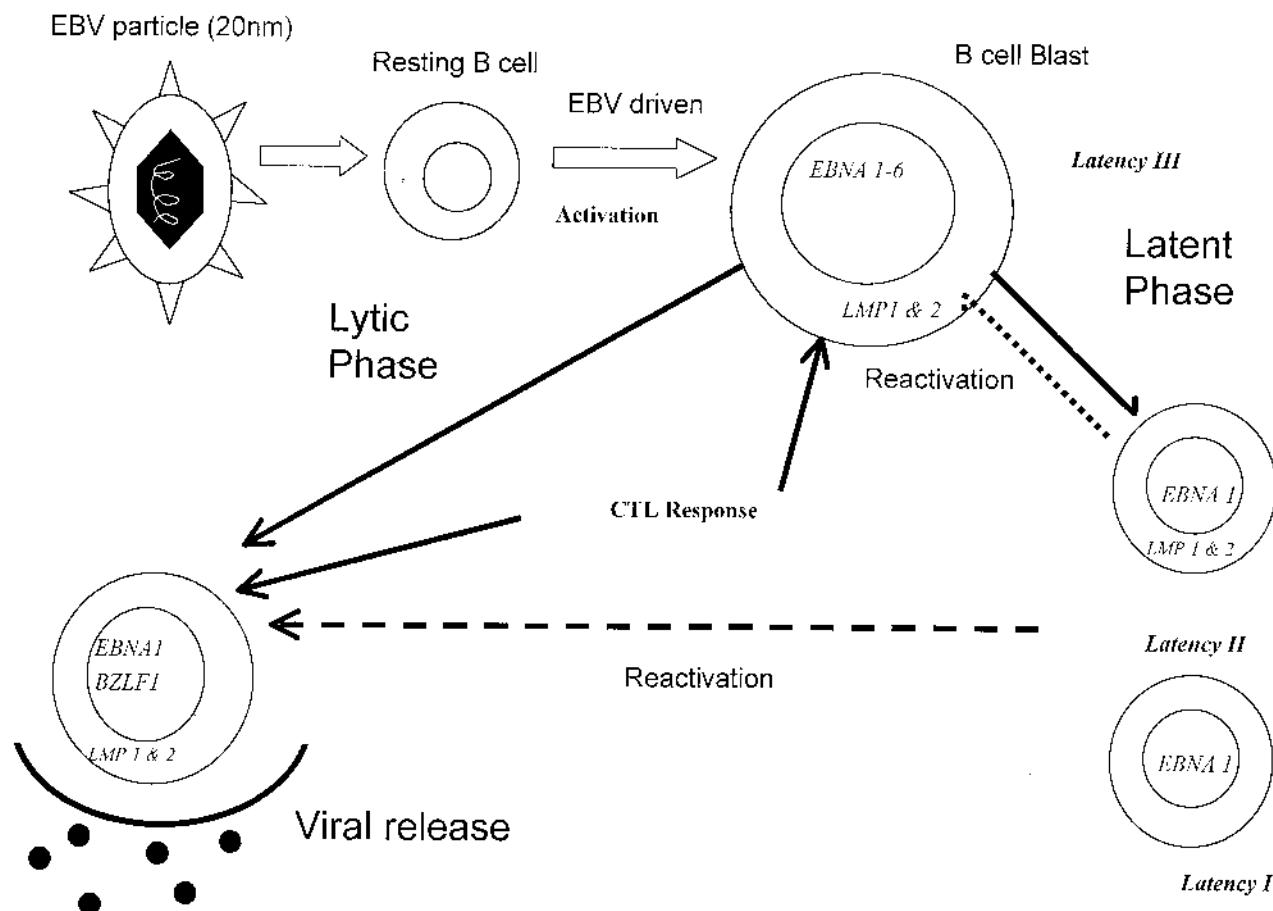

### II. EPSTEIN–BARR VIRUS-ASSOCIATED CANCERS

Epstein–Barr virus is presently the most prolific viral contributor to the development of human lymphomas [8]. It is strongly linked to several human malignancies including Burkitt's lymphoma (BL), a common form of childhood cancer in areas of Africa and Papua New Guinea, nasopharyngeal carcinoma (NPC), a tumor of epidermoid origin most prevalent in southern China, posttransplant lymphoproliferative disease (PTLD) in transplant recipients, and certain types of Hodgkin's disease (HD) common in western countries and characterized by the presence of mononuclear Hodgkin and multinuclear Reed–Sternberg (RS) cells. Recent evidence also suggests that some T-cell lymphomas [9], gastric carcinomas [10], oral hairy leukoplakia [11], and breast cancer [12] may also be linked to EBV.

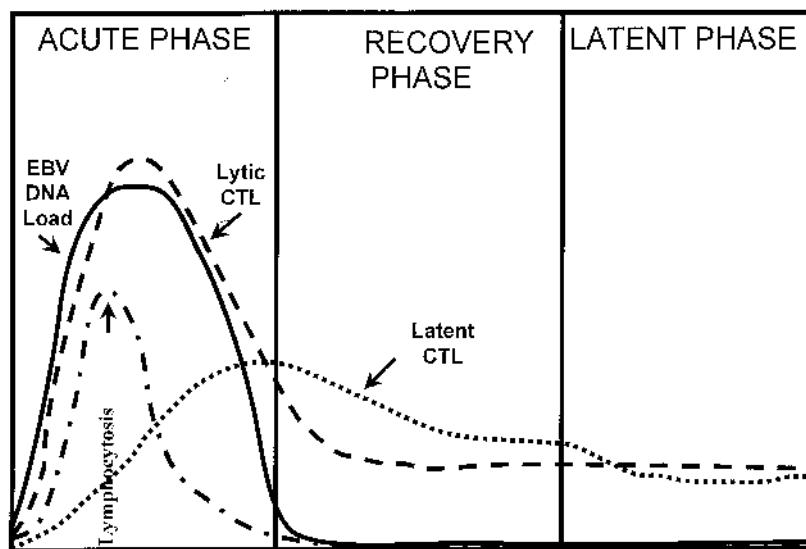

Epstein–Barr virus-associated diseases are best classified by the degree of latent EBV antigen expression in vivo (Figure 1). Latency III diseases (IM and PTLD) are characterized by the expression of the full array of EBV latent antigens (EBNAs 1–6 and LMP1, LMP2A, and LMP2B). In NPC and HD, which are classified as latency II diseases, the latent gene expression is limited to EBNA 1, LMP1, and/or LMP2A/B. and in some cases of NPC the lytic protein, BARF1 may also be expressed [13]. Endemic BL biopsies exhibit the classical features of latency I with the expression of a single EBV protein, EBNA 1.

### III. IMMUNE RESPONSE TO EBV

Although many details of the cell–virus relationship that occur during primary infection remain obscure, there is now convincing evidence that EBV-specific cytotoxic T cells (CTLs) are of prime importance in controlling the expansion

**Figure 1** A model of EBV and B cell interactions depicting the different levels of viral antigen expression in infected B cells associated with the different latency phenotypes in EBV-associated diseases and stages of immunological intervention by CTLs.

**Figure 2** The figure represents the CTL response to the latent and lytic epitopes in the different phases of EBV infection and its relation to the viral load and lymphocytosis in healthy virus carriers.

of latently infected B cells and reducing viral load by targeting peptide epitopes (processed antigens) expressed on infected B cells (Figure 2). During acute infection this response is directed toward peptide epitopes encoded within the EBV latent (EBNA 2–6, LMP1 and 2) and lytic/structural (BZLF, BARF1, BMLF, gp350/340) proteins presented in association with molecules of the major histocompatibility complex (MHC) on infected B cells. This T-cell response is generally virus-specific, class I-restricted ( $CD8^+ \alpha/\beta$  CTL) although  $CD4^+$ , class II-restricted CTLs have also been described [5]. A higher number of precursor CTLs are generally found to epitopes during acute infection compared to the latent infection in healthy virus carriers.

Analysis of CTL responses in a large panel of healthy virus carriers screened for reactivity to latent antigens revealed a marked predominance of reactivity toward epitopes within EBNA 3, 4, and 6 [14–16], while CTL responses to other latent proteins (LMP1 and 2 and EBNA 2) were less frequently detected. An interesting feature of EBV-specific CTL responses in healthy virus carriers is that certain class I alleles (predominantly the B alleles) such as HLA-B7, -B8, -B27, -B35, and -B44 commonly present immunogenic peptide epitopes encoded within the EBV latent proteins, whereas weaker activity is observed through other alleles such as HLA A1, A3, and A24. It is also relevant that there is no class I processing of EBNA 1 due to a glycine–alanine (GAR) repeat that has an inhibitory effect on the endogenous processing of this antigen [17].

#### IV. LESSONS FROM ANIMAL MODELS

##### A. Murine Models

Murine models present a potentially important tool to study the efficacy of EBV immunotherapeutics. First, combined immunodeficient (SCID) mice that lack mature B and T cells provided an *in vivo* model that demonstrated the efficacy of adoptive transfer of CTLs to control EBV-associated lymphoma [18–20] paving the path for clinical trials of adoptive immunotherapy using  $CD8^+$  CTL in PTLD patients [21]. Second, transgenic mice expressing chimeric human and murine class I domains are a useful and convenient method of quantifying and optimizing CTL responses to epitopes restricted by diverse HLA alleles [16,22]. Third, MHV-68 is a naturally occurring herpes virus of wild rodents and represents a potential model of both latent and lytic EBV infection. The virus offers an opportunity to study the acute lytic phase of a gamma herpesvirus infection as it readily replicates in epithelial cells both *in vivo* and *in vitro* [23].

##### B. Primate Models

It is unfortunate that there is no model of EBV infection in animals that entirely reproduces the cell–virus relationships seen in symptomatic primary infection in humans and on which vaccine-formulation decisions could be based. However, a potential model for testing vaccine formulations might involve primates infected with either EBV or closely related viruses. Three species of new-world monkeys that can be experimentally infected have been studied. Cotton top

tamarins (*Saguinus oedipus oedipus*) inoculated with high-titered EBV develop multiple B-cell lymphomas. Several studies using this model have demonstrated that purified or recombinant gp350 formulated with various adjuvants or delivered by live vectors induce virus-neutralizing gp350 antibodies and in some cases have shown protection from tumor development after high-dose EBV challenge [24,25]. However, there is some doubt about the relevance of this result because immunoblotting and immunochemical studies have suggested that latent rather than replicative antigens are expressed in these tumors [26], thus indicating a cell-mediated rather than antibody-mediated mechanism of protection. Other primate models include the common marmoset (*Callithrix jacchus*), which presents a rather ill defined IM-like syndrome, and the owl monkey (*Aotus trivirgatus*), which is susceptible to EBV-induced lymphomas [27,28].

However, none of these models are ideal as there is no demonstrable asymptomatic virus persistence and/or replication in these primate models. Furthermore, the route of experimental challenge in these models is generally intraperitoneal and the virus–cell relationships established in human mucosal surfaces might be quite different. Moreover, although the lymphomas in this model have some features in common to those of PTLD, symptoms associated with acute primary EBV infection are not seen.

Perhaps the best primate model is that based on infection of rhesus monkeys with the rhesus lymphocryptovirus (LCV). This virus, which shares significant sequence homology with EBV, reproduces many of the key events associated with primary EBV infection when these primates are infected orally. Moreover, this model appears to be relevant to vaccine formulation because resistance to a second challenge following primary infection is observed [29]. Although, this model is likely to prove expensive when used to screen potential formulations, it may provide an excellent system for demonstrating final confirmation of the efficacy of a formulation before human trials.

#### V. STRATEGIES FOR EBV VACCINE DEVELOPMENT

The latency phenotypes have determined to a large extent the available strategies in developing vaccines to EBV-associated diseases. Thus, in the case of the latency III diseases (IM and PTLD) there are available the complete array of latent antigens as potential targets (EBNAs 1–6 and LMP1, LMP2A, and LMP2B). In contrast, fewer available targets are expressed in latency II (NPC and HD) or latency I diseases (BL).

##### A. Development of a Vaccine to Latency III Diseases

Commercial considerations have meant that the focus of attention in developing a vaccine to EBV has been dominated by IM. However, it should be pointed out that a successful vaccine to IM would be effective in reducing the incidence of disease in individuals most at risk of developing

PTLD (EBV seronegative graft recipients). Infectious mononucleosis affects an estimated 250,000 young adults in the United States and Europe annually. Approximately 90% of adults in the United States have been infected with EBV and between 35% and 50% of young adults will develop IM when exposed to EBV for the first time [30].

### 1. Potential for an Attenuated EBV Vaccine

One of the earliest and most successful methods of creating vaccines has been the use of live, attenuated forms of the pathogen. This approach evokes both humoral and cellular immunity because the full repertoire of viral proteins is presented in the same quantity and context as in the virulent form. This method has proven successful in developing the chickenpox vaccine, currently the only herpesvirus vaccine licensed by the FDA. However, in the case of EBV, the potential oncogenicity of the virus precludes its use particularly in the case of the IM. Another obstacle toward developing such an attenuated vaccine is the absence of an efficient in vitro culture system capable of yielding the quantities of virus required for a commercially viable vaccine [31].

### 2. Potential of Recombinant-Based EBV Vaccine

The membrane proteins of EBV have been targeted as potential vaccine candidates for IM. Three glycoproteins with similar antigenic determinants have been found: gp340/350 (of molecular weight 340,000–350,000 Da), gp220 (220,000–270,000 Da), and gp85 (85,000 Da). Most attention has focused on gp340/350, because it includes the main neutralizing determinants of the virus [31,32]. Various formulations of gp340/350, either presented as a subunit protein or expressed from recombinant viral vectors, have shown protection against challenge in the tamarin model of EBV infection [33]. The mechanism of protection in this primate model is not yet clear, but it seems likely that it is mediated either by antibody- and/or cell-mediated responses [34]. The importance of the cell-mediated response has gained further support by the observation of CTL epitopes within gp340/350 [35].

### 3. Cytotoxic T-Cell Epitope-Based Vaccines

An alternative approach to vaccine development is based on formulations that exploit defined CTL epitopes. Here the aim is not to prevent primary infection *per se* but to limit those events occurring immediately postinfection, namely, virus replication in the oropharynx and/or the expansion of virus-transformed B cells within the lymphoid pool. There is circumstantial evidence that establishment of such a CTL response against the EBV nuclear antigens (EBNA 2–6) may prevent symptoms of IM [36] and PTLD [manuscript in preparation]. As a first step to developing a CTL-epitope-based vaccine, we have conducted a Phase I clinical trial based on a single epitope. Healthy EBV seronegative HLA B8 volunteers were vaccinated with a formulation consisting of the synthetic peptide FLRGRAYGL from EBNA 3 with tetanus toxoid and emulsified in the water-in-oil adjuvant, Montanide ISA 720. To date this vaccine preparation has been well tolerated and no serious adverse events have been

recorded. Furthermore, although not specifically designed to yield any statistically relevant data in regard to protection, it is interesting that all vaccinated individuals recorded a detectable CTL response and no individuals experienced a clinical seroconversion [Bharadwaj, Elliott, Lawrence, Suhrbier, and Moss, manuscript in preparation].

An EBV vaccine based on CTL epitopes will need to incorporate protective determinants restricted by a range of class I MHC to provide cover for all human populations. In considering this selection, it should also be borne in mind that the response seen during natural primary infection may be different from the immunogenic potential of CTL epitopes delivered in an effective formulation. For example, a hierarchy of HLA-A2-restricted CTL responses was established in acute IM and in healthy seropositive individuals and the relative immunogenicity of these epitopes assessed in HLA-A2 transgenic mice. When analyzed using the ELI-SPOT assay of interferon- $\gamma$  release there was no obvious correlation between the strength of the response seen to individual epitopes in transgenic mice and that seen in healthy seropositive individuals or during acute IM. This is an important observation and serves to highlight the difference in responses seen as a result of natural infection and that deliverable by a formulation in which all of the epitopes are presented to the immune system at the same concentration and at the same site. It might thus be possible to boost protective responses to individual epitopes in a vaccine preparation to levels not seen in naturally infected individuals [16]. Since the virus encodes 100 latent and lytic proteins, it may be necessary to restrict the choice of proteins to those for which there is a priori evidence of immune-mediated protection from the clinical consequences of primary EBV infection by dominant CTL epitopes. Indeed, independent evidence suggests a limited role for epitopes within lytic antigens [36].

As with any subunit vaccine, critical decisions need to be reached not only on the choice of immunogen but on the means of delivering a comparatively large number of CTL epitopes that might be needed to span the MHC diversity seen in man. Although formally this requirement might be satisfied by mixing peptide epitopes, technical and regulatory considerations are likely to restrict the use of this approach. An alternative approach under active consideration is to make use of a technical advance [37] in which minimal EBV CTL epitopes are encoded in a recombinant or synthetic polyepitope protein. The constituent epitopes are processed and presented on the cell surface and can efficiently activate CTL responses [37,38]. Thus, for example, it might be possible to link an array of dominant CTL epitopes from EBV latent proteins as a polyepitope, either formulated in an adjuvant capable of inducing a CTL response or injected directly as purified DNA.

## B. Vaccine Strategies for Latency I and II Diseases

Epstein–Barr virus vaccines directed against BL, NPC, and HD are conceptually different from latency III diseases because the malignant cells do not express the immunodo-

minant latent antigens. Moreover, in the case of BL, escape mechanisms enable them to evade CTL recognition by (1) downregulating the processing of proteins and adhesion molecules [39] and (2) the observation that the only protein expressed, EBNA 1, is devoid of class I CTL epitopes [17]. Protection from the long-term consequences of these tumors would ideally require a vaccine that either conferred sterile immunity, thereby preventing establishment of the long-term latent EBV infection, or a therapeutic vaccine based on tumor antigens. Thus, an effective vaccine against BL appears to have limited chance of success and it may be necessary to either target non-EBV tumor antigens or to use an approach that shifted the phenotype of BL to either latency II or III.

Both NPC and HD share certain features that offer some hope that a successful therapeutic vaccine might be developed. A number of studies have shown that most NPCs retain detectable EBV-specific T-cell surveillance, indicating that CTL dysfunction is an unlikely reason for the outgrowth of this tumor [40]. Furthermore, immunohistochemical analysis of fresh biopsies and laboratory-established tumor lines indicate that malignant cells in both NPC and HD express normal levels of HLA class I and TAP-1 and TAP-2 [41,42]. Because NPC and HD may express both LMP1 and 2, conceptually a polytope vaccine including these epitopes may be the preferred strategy. However, it should be borne in mind that although NPC is classified as a latency II disease, there has been no unequivocal evidence of LMP2 expression in this malignancy. Furthermore, the recent observation that NPC cells express BARF1 should provide impetus to the definition of CTL epitopes within this protein and to incorporation of these epitopes within a polytope formulation [13].

## VI. EPSTEIN-BARR VIRUS VACCINE TRIALS

There have been three EBV Phase I vaccine trials to date. The first was conducted in China in 1995 using a recombinant vaccinia vector gp220/350 [43] in three distinct human populations: EBV-positive adults preexposed to vaccinia virus, EBV-positive children not preexposed to vaccinia virus, and EBV-negative infants not exposed to the vaccinia virus. The vaccination resulted in (1) no significant impact on the level of EBV antibody in the adults, (2) an increase in the level of EBV-neutralizing antibody titers in the vaccinated children, while antibodies to the viral capsid antigen remained the same, (3) development of membrane antigen antibodies with neutralizing properties *in vitro* in all vaccinated infants. The second Phase I clinical trial conducted by Aviron [44] demonstrated safety and immunogenicity for a subunit vaccine containing the gp220/350 surface glycoprotein. The trial was a randomized, double-blind study containing 67 healthy adult participants. The study indicated that the vaccine was tolerated and safe. Evidence of an immune response was shown by laboratory tests from participant sera [32]. A third Phase 1 clinical trial of a peptide vaccine with an EBNA 3 epitope (FLRGRAYGL) was conducted at the Queensland Institute of Medical Research

(QIMR), Australia. As mentioned previously, no adverse reactions to date were noted and CTLs were induced [Bhardwaj, Elliott, Lawrence, Suhrbier, and Moss, unpublished].

## VII. FUTURE TRIALS

Aviron has announced the initiation of a new Phase 2 clinical trial of an EBV vaccine. This randomized, double-blind trial has enrolled 79 individuals aged 18–45 years. The study is being conducted at two universities in Belgium. On the other hand, the EBV unit at QIMR, Australia, is currently working on the development of a CTL-based polytope vaccine in collaboration with CSL Limited.

## VIII. FUTURE DIRECTIONS

Much of the groundwork regarding the immune control of EBV infection has been developed to the point where application to clinical situations has become a reality. However, there remain many intriguing basic scientific questions. Foremost among these are the factors that define the focusing and dominance of the CTL response to certain EBV proteins. The two extremes of this immunodominance are the EBNA 3, 4, and 6 proteins on the one hand and EBNA 1 on the other. Although the definition of the lytic response is still in its relative infancy, there is an early indication that there may also be a focused response to particular lytic cycle proteins. It will be fascinating to determine whether this dominance distribution is a function either of protein concentration or of the kinetics of induction, or is influenced by differences in the efficiency with which different proteins are processed. Of course, in the case of EBNA 1, there is likely to be keen interest in defining the mechanism(s) whereby this protein evades HLA class I processing. It remains something of an enigma how EBNA 1-specific CTLs can be activated and whether they perform any useful function. A full definition of the mechanism of the GAr-mediated inhibitory effect may lead to strategies to inhibit its function, and this in turn could find application in the control of EBV-associated malignancies. Now that it is possible to quantitatively define CTL responses using tetramer and ELISPOT technology [16,45,46], it will be possible to consider the relative importance of individual CTL responses in the control of EBV infection. As with antibody responses, it is likely that all CTL responses may not be protective, nor should we assume that the quantitatively abundant responses serve any useful role *in vivo*. One early approach to unraveling this problem may be to define the induction and decay of CTL responses in various EBV-associated diseases as has been done in the case of IM. For example, there is still no clear view of the distribution of responses seen in NPC and HD patients before and after treatment. Indeed, there is still a degree of uncertainty regarding the magnitude of the response to epitopes within the LMP proteins in both these groups of patients compared with normal healthy individuals.

Furthermore, it will be most important to define the response in those individuals who undergo a clinically silent

seroconversion. It is not clear, for instance, whether such individuals experience a relatively early protective response or whether their response is more or less focused than those undergoing an acute infection. It is possible that a subclinical infection might be characterized by a broad response to multiple T-cell epitopes compared with the more focused response seen in acute infection [36].

### I. INTRODUCTION

The human cytomegalovirus (HCMV) causes the most prevalent maternal infection transmitted to the fetus, often with adverse consequences for the unborn child. Those consequences may be severe or mild, starkly evident at birth or becoming manifest later in life. Because of those sometimes subtle late effects in infancy and childhood, one of us has called HCMV the “changeling demon” [1].

In general, postnatal HCMV infection is quite common throughout the world, with seroprevalence rates of 50–90%. Seroprevalence is inversely related to socioeconomic level, but directly related to the intensity of contact between toddlers, who acquire HCMV in day care. Most HCMV infections produce few, if any, symptoms in healthy individuals, but occasionally infection can produce a mononucleosis-like illness. Human cytomegalovirus is also a leading cause of morbidity and occasional mortality in immunocompromised children and adults, particularly HIV-infected individuals and transplant recipients. More recently, there has been concern regarding the possible role of HCMV in atherosclerosis [2] and autoimmune disease [3]. The availability of antivirals and intravenous immunoglobulins has led to a decreased incidence of HCMV diseases in some of these high-risk populations, but such modalities provide incomplete or no protection, depending on the population at risk. In view of the limitation of available measures for preventing HCMV disease, an effective vaccine against HCMV would be highly desirable.

### II. CLINICAL MANIFESTATIONS

#### A. Congenital Infection

Severe congenital infections with HCMV were first recognized in the early 1900s when they were termed cytomegalic

inclusion disease (CID). Human cytomegalovirus is the most common congenital infection with 0.2–2.5% of newborns infected in utero ( $\approx 40,000$  infants in the United States), and the most common infectious cause of congenital abnormalities. Severe disease is seen in about 10% of congenitally infected infants and is characterized by intrauterine growth retardation, hepatosplenomegaly, jaundice, a rash often described as “blueberry muffin”-like, and severe central nervous system involvement including microcephaly, intracranial calcifications, and chorioretinitis. Laboratory abnormalities include thrombocytopenia, elevated liver function levels, and hemolytic anemia. Most infants severely affected at birth develop significant neurologic sequelae with a mortality of 4–37%. The most common sequelae of congenital HCMV is progressive sensorineural hearing disease which can be seen in both infants who are symptomatic or asymptomatic at birth [4,5]. The precise number of affected infants born annually in the United States is unknown, but the estimate by Fowler et al. [6], is about 8000 infants. Cost-benefit analysis have suggested that an estimated \$834 million would be saved annually by immunization, assuming complete immunization of all women ages 15–24 years with a moderately priced vaccine [7].

Important distinctions have been drawn between congenital infection which follows a primary maternal infection and that which results from an infection in a previously infected mother [6,8–16,16a]. Transmission to the fetus occurs in about 30–50% of pregnancies complicated by a primary HCMV infection during pregnancy compared to about 1% following recurrent infection. Initial reports suggested that severe sequelae were almost exclusively seen following pregnancies complicated by primary HCMV infection [6,9]. For example, Fowler et al. [6] found that sequelae occurred in 25% of 125 infants with congenital infection following primary CMV infection during pregnancy but in only 8% of 64 infants with congenital infection

born to mothers who were HCMV seropositive prior to pregnancy. More importantly, none of the infected infants born to seropositive mothers developed severe sequelae; defined as bilateral hearing loss or mental retardation (an I.Q. of <70). These sequelae occurred only among infants born to mothers who had a primary infection during pregnancy. Such observations suggest that maternal immunity to HCMV prior to pregnancy prevents the majority of severe sequelae associated with congenital infection and form an important argument for the feasibility of developing HCMV vaccines to prevent congenital HCMV disease.

Other reports [12–15] and, especially recent observations [16–18], suggest that symptomatic congenital infection and permanent neurologic sequelae are not as rare in infants of women with preconceptional immunity as previously thought. For example, Boppana et al. [17] recently reported that 8 out of 47 infants with symptomatic congenital HCMV infections were born to mothers with a confirmed nonprimary or recurrent HCMV infection. They caution, however, that the type of maternal infection could only be categorized in 43% of the 47 pregnancies evaluated. Clearly symptomatic congenital infection can occur after nonprimary or recurrent maternal infections but the extent of the risk is not clear. Determining whether these infections are due to reactivated virus in the mother or reinfections has significant implications for the development of vaccines. Recent evidence based on the antibody response to the amino terminal region of glycoprotein H suggests that reinfection may account for a substantial portion of symptomatic congenitally infected infants born to women with preconceptional immunity [19].

### B. HCMV Infections in Immunocompromised Individuals

Bone marrow and solid organ transplant patients are both at risk to develop HCMV disease [20–23]. Depending on the serostatus of the donor and recipient and the level of immunosuppression, the onset of most active HCMV infections is from 2 weeks up to several months after transplantation. The mortality rate remains at about 5% even with available therapies. Besides the direct effects of infection, HCMV also increases immunosuppression, elevating the risk for fungal and other infections, and increases the risk for organ rejection, and/or organ dysfunction [23]. The risk of HCMV disease is least in kidney, followed by heart and liver transplants (8–35%), while the highest risk is in pancreas (50%) and lung or lung–heart transplants (50–80%) [21]. The most common clinical manifestations include fever, pneumonitis, hepatitis, leukopenia, gastroenteritis, and encephalitis. Bone marrow transplant recipients who are seropositive or who are seronegative and receive bone marrow from a seropositive donor are at equal risk to develop HCMV disease. In contrast, among patients receiving solid organ transplants, the risk of developing HCMV disease is highest among those who are seronegative prior to transplant and receive an organ from a seropositive donor. However, HCMV disease also occurs among recipients who are seropositive prior to transplant. In such patients, HCMV infection may occur as a result of reactivation of the patient's own virus or reinfection with HCMV strains introduced via the transplanted organ.

Recent improvements in diagnostic assays including polymerase chain reaction, and antigen (pp65) detection, and the availability of prophylactic (ganciclovir, acyclovir, and hyperimmune HCMV serum) and therapeutic drugs (ganciclovir, cidofovir, and foscarnet) have dramatically changed the way HCMV infections are approached in transplant recipients [22].

Human cytomegalovirus is also an important cause of opportunistic infection in HIV-infected individuals [24–26]. In this population, HCMV retinitis is the most common disease manifestation, but gastrointestinal manifestations including oral ulcers, esophagitis, colitis and cholecystitis, pulmonary involvement, and central nervous system involvement are also seen. The advent of highly active antiretroviral therapy has decreased the incidence of HCMV disease by decreasing the profound immunosuppression that leads to HCMV reactivation and disease but continued attention to this important pathogen is required [25].

### III. MICROBIOLOGY

Cytomegaloviruses are the principal members of the betaherpesvirus subgroup of the Herpesviridae family. Cytomegalovirus is an enveloped virus with a large icosohedral capsid surrounded by a tegument. The double-stranded DNA genome of HCMV is approximately 235 kb in size. The unique long sequence, U<sub>L</sub>, and the unique short sequence, U<sub>S</sub>, of HCMV are flanked by repetitive sequences that are inverted relative to each other allowing for the presence of four isomeric forms. The replication of CMV is slow, at least 24 hr, and replication is highly species-specific. In vitro, human fibroblasts show the greatest susceptibility to infection while in vivo fibroblasts, epithelial cells, macrophages, smooth muscle, and endothelial cells can support replication [27]. The macrophage is the probable major site of latency, together with other cells of myeloid derivation [28–30].

The purified virus contains 30–40 polypeptides including seven capsid proteins, perhaps as many as 60 glycoproteins (8 major), and 25 proteins making up the tegument or matrix [27,31,32]. The most prominent glycoproteins are found as complexes. gB, encoded by UL 55, is the major envelope glycoprotein and appears as a heterodimer of two cleaved products, 93 and 55 kDa in size [31,32]. It plays a critical role in virus entry and is the most important target for neutralizing antibody. The gH, gL, and gO complex, UL75, UL115, and UL 74, respectively, also play an important role in virus entry. Recently, four distinct gB and two distinct gH genotypes have been observed which are useful in epidemiologic studies [33–39].

### IV. IMMUNOLOGY

Protection from CMV infections is multifactorial. Innate, humoral, and cell-mediated immunity all contribute to protection. Initial studies suggesting a role for innate immunity came from mouse experiments showing that animals deficient in functional natural killer (NK) cells were more susceptible to CMV. Later, *Cmv-1*, the gene that controls the initial splenic replication of murine CMV (MCMV) was identified and linked to NK cell activity [40]. Most recently,

the definitive evidence linking NK cell activity to protection from MCMV infections was provided when the NK cell subset and receptor, Kira8, that confers susceptibility was identified [41–43]. The MCMV-susceptible mouse strains were found to lack Kira8 while all resistant strains carried it [42].

Evidence linking protection to antibody comes from several sources. Mouse studies have found that passive transfer of antibody can provide protection from a lethal infection [44–45]. Furthermore, by using the guinea pig model of congenital infection two groups have showed that passive transfer of antibody can protect the fetus from a lethal infection [46,47]. Further support for a role of antibody in protection comes from neonatal transfusion studies [48,49]. These studies showed that premature newborns born of HCMV seronegative mothers developed symptomatic CMV infections following transfusion, but that the premature newborns born to HCMV seropositive mothers remained asymptomatic after receiving the same blood products. These observations indicate that maternal antibody modulates HCMV infection. The role of antibody in protection following organ transplantation is less clear except for kidney transplants where passive immunization does not protect against infection but decreases the severity of disease in seronegative recipients of kidneys from seropositive donors [50]. For review of the many studies evaluating HCMV immune globulin, immune serum globulin, antivirals, and combinations of these strategies, the reader is referred to the comprehensive review by King [51].

The proteins that appear to induce the most consistent antibody response include glycoproteins gB(UL55), and gH(UL75), the tegument proteins pp150 (UL32), the matrix protein pp65 (UL83), and the nonstructural DNA binding phosphoprotein pp52 (UL44) [52]. Neutralizing antibody is primarily induced by gB, 60–70%, followed by gH [1,53,54].

The critical role of cell-mediated immunity and protection from CMV is documented by animal and human studies. Perhaps, the best evidence is the fact that the depletion of T-cell responses following HIV infections or transplants leads to severe HCMV disease. Early mouse studies demonstrated that suppression of T cell function lead to reactivation and dissemination of MCMV [55,56], while adoptive transfer studies confirmed a role for CD8<sup>+</sup> cytotoxic T-lymphocyte (CTL) in protection [57,58]. Similarly, in transplant patients, a correlation between recovery of the cytotoxic T cell response and recovery from HCMV infections has been identified [59,60], while adoptive transfer of CD8<sup>+</sup> cytotoxic T clones were able to reconstitute the cellular immune response to HCMV and possibly provide protection [61]. A role for CD4<sup>+</sup> T cells has also been proposed [62,63].

In humans, several targets for the CD8<sup>+</sup> CTL response to HCMV have been identified. The predominate target is p65 (UL83), although responses to IE1 (UL123), pp150 (UL32), and gB (UL55) have been identified [64–67].

## V. ANIMAL MODELS

The lack of an animal model in which HCMV replicates has hindered the development of an HCMV vaccine. Thus most animal models utilize species-specific CMV strains that are

similar, but not identical, to HCMV. More recently, HCMV has been utilized in SCID and nude mouse models [68–69] but thus far, these have little relevance to vaccine evaluation. Animal models of CMV include mouse, guinea pig, rat, and rhesus monkey [70–73]. Murine CMV models have provided important insights into the immunology and pathogenesis of CMV, but differences in placental structure severely limit its use for evaluating congenital CMV. Primate models would be of interest for studying congenital CMV, but the cost and ubiquity of natural simian CMV infection makes these studies difficult. Thus the guinea pig has become the model of choice for initial investigation of vaccines for congenital infection because the placental structure of the guinea pig is similar to that of humans [74], and the cost of study is reasonable.

Guinea pig CMV (gpCMV) infection of the pregnant guinea pig produces a maternal infection that can be lethal or cross the placenta to induce fetal resorption, fetal death, or fetal growth retardation, depending on the challenge dose and time of virus challenge in relation to pregnancy [71]. The primary infection of a pregnant animal typically produces a vertical transmission rate of 40–80%, similar to that in women following a primary HCMV infection. Several groups have used this model to explore the protection provided by live virus, killed and subunit vaccines [75–77].

This model was also used to examine the protective effect of gpCMV antibody alone, because it is not clear if a CMV vaccine will need to induce cell-mediated immune responses or whether the antibody alone would provide protection by neutralization or other mechanisms. Thus these studies have significant implications for the choice of proteins to include in a subunit or vectored vaccine. In two recent studies, passive transfer of high titered antibody to pregnant CMV challenge dams provided significant protection against pup mortality but results on protection from infection differed [46,47]. From these studies, it appears that a vaccine that primarily induces neutralizing antibody (such as subunit gB) would be an effective vaccine. Whether the addition of other proteins that are more likely to induce CTLs would provide additional benefit is unclear, but can be tested in this model [78].

Two recent vaccine evaluations using the guinea pig model of congenital infection provide further evidence for

**Table 1** Effect of gpCMV Immunization on Pregnancy Outcome in Guinea Pigs Following gpCMV Challenge

the utility of a subunit gB vaccine (Table 1). In one study, the purified homolog of HCMV gB was used to immunize guinea pigs [76], while in the other, purified gpCMV glycoprotein consisting mostly of gB was used [77]. Both studies combined gB with complete Freund's adjuvant, followed by incomplete Freund's adjuvant. Vaccination decreased pup mortality, shortened maternal viremia, and decreased infection rates in pups.

## VI. VACCINES

The main public health objective of an HCMV vaccine is to prevent symptomatic congenital HCMV disease. This can be accomplished by preventing HCMV infection of pregnant women, by modifying the infection so that virus is not passed to the fetus, or by modifying the fetal infection so that it does not induce disease. A secondary objective is to provide HCMV immunity and limit the number of HCMV infected individuals prior to a time when they might become immunosuppressed as a result of transplantation, HIV infection, etc.

The neurological consequences of congenital HCMV are at least equal to several other pathogens for which vaccines are available, including rubella, H. flu meningitis, and pneumococcal meningitis. Thus there is an unmet need that has been recognized for many years [79,80]. Delays in vaccine development are attributed to the difficulty and cost of evaluating HCMV vaccine efficacy, the lack of a correlate of protection, and the concern regarding persistence of live virus, and possible reactivation of live vaccine virus, as well as the lack of priority given to HCMV vaccines by vaccine companies. Approaches to HCMV vaccines have included primarily live attenuated vaccines, subunit and killed vaccines, DNA vaccines, and vectored vaccines.

### A. Subunit Vaccines

Much of the interest in subunit HCMV vaccines has centered on glycoprotein B (gB) because gB (UL55) is the major target of neutralizing antibodies [53,81–83]. Antibodies to gB are thought to represent 60–70% of the HCMV-specific neutralizing antibody response [53], with the majority of this response directed to the AD1 region of the protein (residues 560–635), also known as the principal neutralizing domain [82]. In addition to neutralizing antibody response, several laboratories have reported that gB can elicit major histocompatibility complex (MHC)-restricted, CD8<sup>+</sup> cytotoxic lymphocyte responses, and proliferative CD4<sup>+</sup> T cell responses following natural infection [84]. However, as discussed in Section 4, the dominant CTL target for HCMV is the pp65 phosphoprotein (UL83 gene product) [85].

Most recently, results of two large human trials evaluating a subunit gB vaccine developed by Chiron Corporation (Emeryville, CA) and combined with an oil-in-water-based adjuvant, MF59 have been reported [86,87]. The HCMV gB vaccine is derived from Chinese hamster ovary cells that have been stably transfected with the coding sequence of HCMV Towne strain gB, except that the membrane spanning domain was deleted to facilitate secretion of HCMV gB and the

single protease cleavage site was mutagenized [88]. The resulting uncleaved protein is 807 aa in length with 19 putative N-linked glycosylation sites. The adjuvant, MF59, is a squalene in water emulsion that induces higher antibody titers than alum alone [86,87], which is the only approved adjuvant for human vaccines in the United States. MF59 has been used by Chiron in over 7000 individuals, including the recently published trial of their genital herpes subunit glycoprotein D herpes simplex virus vaccine [89].

In the two recent human trials, the HCMV gB vaccine plus 10.75 mg dose of MF59 was shown to be safe and immunogenic. Evaluations included vaccine regimens of 0, 1, and 2 months, 0, 1, and 4 months, and 0, 1, and 6 months; doses of HCMV gB between 5 and 100 µg; and a comparison of alum vs. MF59. Immunization at 0, 1, and 6 months induced the highest level of antibody with neutralizing and gB enzyme-linked immunosorbent assay (ELISA) antibody titers that were higher than natural infection [86,87]. An optimal HCMV gB dose, between 5 and 30 µg, was detected and groups receiving MF59 developed higher titers compared to alum gB recipients.

Subunit gB vaccines remain a viable candidate for further evaluation, either alone or combined with other vaccine strategies, designed to induce CTL responses such as canarypox expressing pp65 (discussed later). Other HCMV glycoproteins, including gH (UL75) and the gM (UL100)/gN (UL73) complex, are also targets for neutralizing antibody [90,91] and may need to be considered more strongly for inclusion in a vaccine, given the recent reports of the heterogeneity of gB and gH [33–39], especially as it pertains to congenital infection [38,39]. Thus if gB and/or gH heterogeneity contribute to reinfection, then inclusion of several other proteins that elicit neutralizing antibody may be necessary.

### B. Live Attenuated

#### 1. Towne

The Towne strain vaccine was developed in the mid-1970s by multiple passages of an isolate from a congenitally infected infant in human fibroblast cells. Towne vaccine remains the most widely evaluated HCMV vaccine [92]. The first clinical trial utilized pass 125 (MRC-5 cells) in healthy male subjects [93]. Infection was not seen following intranasal administration, but following subcutaneous inoculation, all seronegative volunteers seroconverted. Transient local reactions, including erythema and induration, beginning in the second week and lasting about 1 week, occurred in more than half of the recipients. Systemic signs and symptoms, however, were not seen. Subsequent studies supported the safety and immunogenicity of the vaccine when given subcutaneously. Other important aspects of the vaccine include its inability to establish latency [94], inability to be isolated after immunization (including attempts from urine, saliva, and blood), and its ability to induce antibody, lymphoproliferative (CD4<sup>+</sup>) responses, and CD8<sup>+</sup> cytolytic responses.

Studies of Towne vaccine were also performed in renal transplant recipients because of the known risk associated with transplant, especially when an HCMV seronegative recipient receives a kidney from a seropositive donor. Three

**Table 2** Comparative Results of Three Blinded Trials of Towne Vaccine in Seronegative Renal Transplant Patients Who Received Kidneys from Seropositive Donors

Trial	<i>n</i>	Rate of all CMV disease (%)		Rate of severe CMV disease (%)		Reduction of severe disease in vaccinated compared with placebo (%)

Source: Ref. 1.

placebo-controlled, randomized studies revealed that Towne vaccine did not prevent HCMV infection but modified the severity of disease with severe disease reduced by 85% [95–97] (Table 2). A unique challenge study conducted in 1989 [98] provided further evidence for the protection offered by Towne vaccine (Table 3). In this study, healthy HCMV seronegative Catholic priests were either immunized with vaccine, or not immunized and then challenged with a range of doses of the Toledo strain of HCMV, a low passage isolate that retained virulence [99]. Vaccinated subjects were protected from infection compared to unimmunized controls but were not protected as well as those who were naturally immune prior to challenge with Toledo.

In a study of women naturally exposed to HCMV from their infant shedding HCMV in day care, Towne vaccine did not provide protection from infection, whereas those women with prior natural infection were protected from reinfection [100]. However, in this study, one dose of Towne vaccine induced neutralizing antibody titers that were 10- to 20-fold less than after wild-type infection. In a subsequent trial, using a different lot of Towne vaccine, neutralizing titers was comparable to natural infection [101]. As the latest trial did not measure protection, it is unclear if a more potent Towne or other attenuated HCMV vaccine would provide better protection.

Furthermore, evidence for the utility of attenuated live virus vaccines comes from recent studies using a temperature-sensitive, replication-defective MCMV [102] or an attenuated MCMV, RV7, that contains a deletion of 7.7 kb spanning portions of MCMV *HindIII-J* and *-I* [103]. RV7 replication was similar to wild-type MCMV in vitro but RV7 failed to replicate in target organs of immunocompetent BALB/c mice or severe combined immunodeficient mice [103,104]. Following immunization with RV7 protection against a virulent salivary gland, passaged virus was seen following parenteral, as well as mucosal, routes of challenge [104].

## 2. Recombinant Towne/Toledo

An ideal live HCMV vaccine might combine the safety profile of Towne vaccine and the immunogenicity of wild-type HCMV. If the Towne strain is overattenuated because

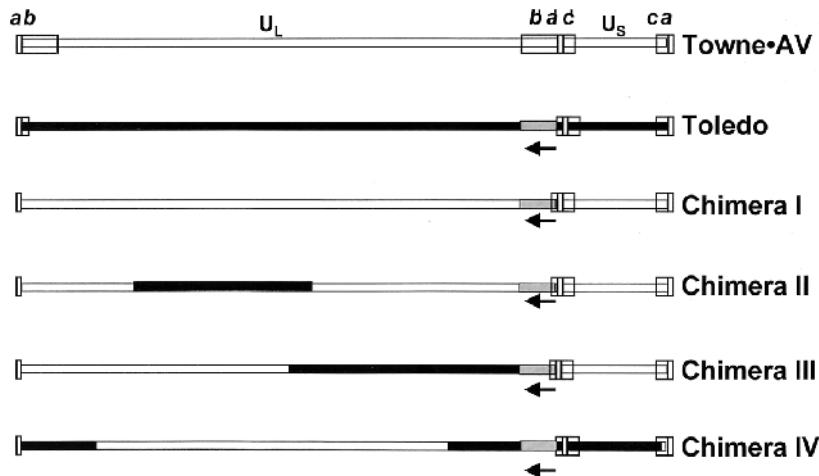

of extensive mutations acquired during the 125 passages, then perhaps, replacing defined regions of the Towne genome with the corresponding region from a wild-type virus could modify this overattenuation. Indeed, researchers at Aviron (Mountain View, CA) have chosen this approach and are using the Toledo strain, a low passage isolate that had been previously characterized and used as the wild-type challenge in studies of Towne vaccine [98,99], as the wild-type virus donor. They initially characterized the genetic differences between Towne and Toledo, and identified deletions in the Towne vaccine strain including the UL/b' sequence, which is at the right edge of the unique long segment of the HCMV genome of Toledo and wild-type isolates [105]. They then constructed a set of four vaccine candidates (Figure 1).

Vaccine candidates were constructed by cotransfection of overlapping cosmid clones so that every region of the

**Table 3** Challenge with Low-Passage Toledo Strain CMV in Seronegative, Seropositive, and Towne-Vaccinated Participants [98,99]

**Figure 1** CMV chimeric strains prepared by recombination of the Towne attenuated virus and the low passage virulent Toledo virus. Open lines represent portions of the Towne genome and solid lines portions of the Toledo genome. The ULb' region is shown as the gray portion at the right edge of the unique long segment. It has been found in all clinical isolates but in the reverse orientation compared to the Toledo strain and the chimeras, thus allowing differentiation between vaccine and clinical isolates.

Towne genome was replaced in at least one candidate vaccine [106]. For safety reasons, the genome of each cosmid is primarily derived from the genome of the Towne strain ( $\approx 70\%$ ) and each still contains at least one of the defined Towne deletions. In order to increase the immunogenicity, each construct also contains a Toledo replacement for at least one of the defined Towne deletions and in addition the UL/b' region of Toledo. Gene products of UL/b' are targets of the humoral immune response. Because the UL/b' of Toledo is in reverse orientation to wild-type HCMV, this can also serve as a marker, allowing differentiation between vaccine and wild-type HCMV.

Phase I clinical trials of these four vaccine candidates have begun in HCMV seropositive adults. Only subsequent clinical trials in seronegatives can determine whether the right balance between safety and immunogenicity has been achieved in any of the four candidates.

### C. Canarypox Recombinants

Canarypox virus is considered to be a good candidate vector for recombinant vaccines. Canarypox can accommodate large amounts of foreign DNA, which can be expressed in infected mammalian cells [107]. Canarypox and other fowlpox viruses productively infect avian cells but do not produce infectious virus in mammalian cells, providing a safety factor not seen in vaccinia virus. The canarypox infection of mammalian cells results in transcription and translation of early genes including genes that are inserted downstream of early promoters, thus inducing both humoral cell-mediated immune response to the inserted gene product.

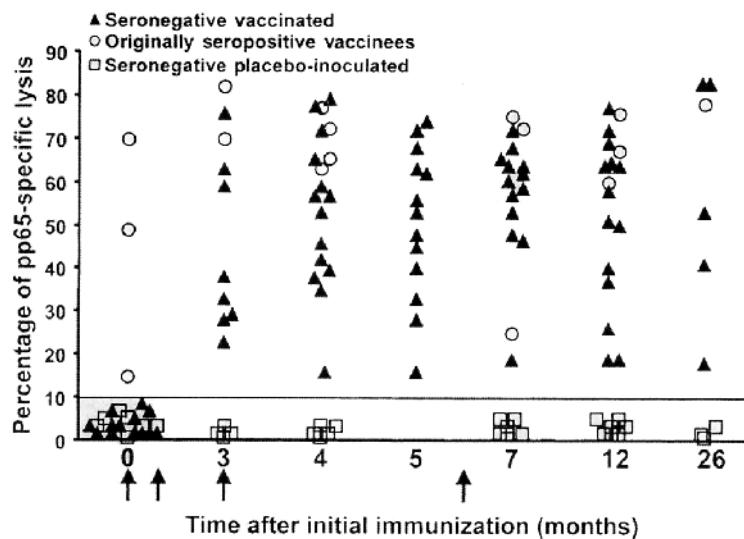

Recombinant canarypox expressing the glycoprotein B of HCMV Towne strain was initially evaluated in mice and guinea pigs. Immunization appeared to be safe and induced neutralizing antibodies and CD8<sup>+</sup> CTL responses [108]. Vaccination of HCMV seronegative humans with this vac-

cine, however, failed to induce significant gB ELISA or neutralizing antibody [109]. In later experiments, this gB expressing vector was shown to prime for the induction of a booster response following subsequent Towne vaccination as discussed below [109].

Because one of the main advantages to vectored vaccines is the induction of CTLs, there is still interest in using canarypox as a vector for expressing major CTL targets such as pp65. Indeed, recent evaluations of canarypox expressing pp65 showed that it induced HCMV-specific CD8<sup>+</sup> CTL, helper T lymphocyte, and antibodies [110]. The CTLs were elicited after only two vaccinations and were still detectable 12 and 26 months after vaccination (Figure 2).

### D. Prime Boost

The rationale for evaluating prime boost strategies with canarypox was largely developed by HIV researchers in the hope of achieving antibody and cell-mediated immune responses that were higher than with either vaccine alone [111]. In the initial report evaluating HCMV prime boost strategies, Adler et al. [109] showed that priming with two doses of canarypox expressing HCMV gB induced only a weak response but primed for a subsequent boost by live attenuated Towne CMV vaccine. Subjects primed with the canarypox HCMVgB developed higher neutralization and gB ELISA titers that developed sooner and lasted longer than in Towne recipients who had first received a canarypox expressing a rabies protein. In a subsequent trial [112], the effect of priming with two doses of canarypox HCMVgB followed by two doses of the subunit HCMVgB vaccine with the adjuvant MF59 or the combination of canarypox HCMVgB plus simultaneous HCMVgB/MF59 did not have an advantage over immunization with three doses of gB/MF59. Neutralization and ELISA gB titers, lymphoproliferative, and  $\gamma$  interferon response were all equivalent after

**Figure 2** Kinetics of phosphoprotein 65 (pp65)-specific cytotoxic T cell activity of 25 subjects after initial immunization with canarypox–cytomegalovirus pp65. Pp65-specific lysis at an effector-to-target ratio of 25:1 (E:T of 30:1 for subjects 9, 27, 32, 33, and 38 at month 5). pp65-specific lysis was considered to be significant at 10%. (Reprinted with permission from *The Journal of Infectious Diseases*. From Ref. 110.)

the final dose of vaccine. Thus it appears that the potent combination of gB and MF59 induces substantial levels of antibody and cell-mediated immune responses to HCMV gB that were not enhanced by previous or simultaneous canarypox HCMVgB immunizations.

#### E. DNA and Other Vaccine Approaches

Several approaches to creating an HCMV vaccine have not yet reached clinical trials, to our knowledge. DNA vaccines, or genetic immunization, has become a popular concept but initial optimism stemming from small animal evaluations have been tempered by the poorer immunogenicity seen in larger mammals including man. Several studies have reported both cell-mediated and humoral responses to DNA immunization with either CMV gB or pp65 plasmids in mice and guinea pigs [113–116]. In one study, immunization with a plasmid expressing the MCMV immediate early gene (IE1), the major CD8 CTL target provided some but incomplete protection against a lethal MCMV infection and more consistent protection against a sublethal MCMV challenge [116]. In another report, the same group evaluated plasmids encoding MCMV homologs of HCMV, including the tegument (M32, M48, M56, M82, M83, M69, and M99), capsid (M85 and M86), and nonstructural antigens IE1-pp89 and M84. Only pp89 and M84, a nonstructured protein that shows homology with HCMV UL83-pp65, provided protection [117].

Several vectors, including adenovirus and vaccinia, were also used to deliver CMV genes [118–120]. A recombinant adenovirus gene expressing gB was found to be immunogenic when given intranasally [119] and vaccinia expressing the dominant CTL target of mice, pp89, protected animals from a lethal challenge through a CD8<sup>+</sup> T lymphocyte response [120]. Using synthetic peptides spanning the IE1 epitope of pp89, other investigators were also able to elicit protective

CD8<sup>+</sup> T cell responses [121]. The use of plant expression systems has paved the way for the delivery of oral vaccines through edible transgenic plants. Recently, a research group expressed the HCMVgB in tobacco plants as a model system [122]. They found that transformed plants produced antigenic gB at levels of 70–146 mg/mL extracted protein.

Because of the probable importance of CTL induction to protection from CMV disease, the use of CMV peptide vaccination with CTL epitopes of pp65 is also being explored [123,124]. Lipid modification at the amino terminal of one peptide produced a vaccine that did not require the use of adjuvant [123]. More recently, using a new approach, positional scanning synthetic combinatorial libraries, researchers were able to modify the HLA-A\* 0201 pp65 (495–503) epitope to enhance activity [124]. The fusion of a promiscuous tetanus Th epitope to the pp65 CTL epitope produced an even more robust response [125]. Peptide vaccines are limited because of the requirement of HLA allele-specific peptide motifs; however, estimates made by using epitopes from two CMV proteins suggested that this approach is feasible, even for a diverse, multiethnic populations [126].

Another intriguing approach for CMV immunization is the use of dense bodies, defective noninfectious enveloped particles as vaccine candidates. Pepperl et al. [127] recently reported that immunization with dense bodies without adjuvant, induced both humoral and CTL responses. Titers of neutralizing antibody were similar to those seen in convalescent human sera.

## VII. CONCLUSIONS

The major obstacle to the development of a vaccine against HCMV is the lack of a defined correlate of protection. The available evidence points in two directions: i.e., both anti-

body and cellular immunity play a role. Fortunately, experimental vaccines have been developed that stimulate either humoral or cellular responses, and both prior natural infection and live virus vaccination have been shown to protect against CMV disease to some degree. Future clinical trials will determine which immune responses, and accordingly, which vaccines offer the best protection against fetal disease or disease acquired after immunosuppression. It may be that prevention of viremia will be easier to accomplish than prevention of infection. In that regard, it should be noted that we have little information concerning mucosal immune responses to CMV.

## Herpes Simplex Vaccines

**Richard J. Whitley**

*University of Alabama at Birmingham, Birmingham, Alabama, U.S.A.*

### I. INTRODUCTION

Our knowledge of the pathogenesis, natural history, treatment, and molecular biology of herpes simplex virus (HSV) and its resultant infections has increased dramatically over the past decade. These advances, in part, paralleled the development of antiviral drugs that are selective and specific inhibitors of viral replication. The unequivocal establishment of the value of antiviral therapy has had a major impact on altering the severity of human disease and has major implications for long-range control of HSV infections. Nevertheless, no studies have indicated that therapy interrupts transmission of infection. Furthermore, some clinical diseases (e.g., herpes simplex encephalitis and neonatal HSV infections) are still associated with significant mortality and morbidity despite antiviral therapy. Even with the rapidly evolving knowledge of the molecular biology of HSV, the development of a successful vaccine—either subunit or live attenuated—has eluded the biomedical investigator. The past decade has witnessed increasing insight into viral gene structure and function, particularly those genes responsible for latency, virulence, and host immune responses. Such advances have been recently summarized [1]. Our current level of biomedical knowledge sets a stage for the application of molecular biology to the evaluation of human disease, the development of genetically engineered vaccines, and the potential for the development of antiviral therapeutics predicated upon newly identified site-specific molecular targets [2,3].

The development of an HSV vaccine has attracted the interest of investigators for the better part of the 20th century. The goal of producing a vaccine that protects against HSV disease has not been fully realized, as compared to other vaccines described in this book. In large part, the unique properties of HSV—especially its ability to become latent and reactivate—and its human biology make the potential success of a vaccine more difficult to achieve than with many other viral pathogens. This chapter will review the unique problems of HSV infections and consider approaches that have been developed historically. Further,

initial success with subunit vaccines, albeit limited, and the application of genetically engineered HSV to treatment of human disease will be described.

### II. HISTORY

Herpes simplex virus infections of humans have been documented since ancient Greek times [4–6]. Records of human HSV infections began with descriptions of cutaneous spreading lesions thought to be of herpetic etiology, particularly in the writings of Hippocrates, as reviewed [6,7]. Scholars of Greek civilization defined the word “herpes” to mean creep or crawl in reference to the spreading nature of the skin lesions [4,5]. The Roman scholar Herodotus associated mouth ulcers and lip vesicles with fever and defined this association as “herpes febrilis” [8]. Likely, many of these original observations reiterated Galen’s deduction that the appearance of such lesions was an attempt by the body to rid itself of evil humors, and, perhaps, led to the name of “herpes excretins” [4]. However, these original descriptions of skin lesions probably bare little resemblance to later reports of the 19th and 20th century [8].

As noted by Wildy [4], Shakespeare described recurrent labial lesions. As he wrote in *Romeo and Juliet*, Queen Mab, the midwife of the fairies, stated: “O'er ladies lips, who straight on kisses dream, which oft the angry Mab with blisters plagues, because their breaths with sweetmeats tainted are.”

In the 18th century, Astruc, physician to the King of France, drew the appropriate correlation between herpetic lesions and genital infection [9]. By the early 19th century, the vesicular nature of lesions associated with herpetic infections was well ascertained. However, it was not until 1893 that Vidal specifically recognized human transmission of HSV infections [4].

Observations from the early 20th century brought an end to the early imprecise descriptive era of HSV infections. First, histopathologic studies described the multinucleated giant cells associated with herpesvirus infections [10]. Sec-

ond, the unequivocal infectious nature of HSV was recognized by Lowenstein in 1919 [11]. He experimentally demonstrated that virus retrieved from the lesions of humans with HSV keratitis or the vesicles of patients with HSV labialis produced lesions on the rabbit cornea. These corneal lesions were similar to that encountered in humans with HSV eye infection. Furthermore, the vesicle fluid from patients with herpes zoster failed to reproduce similar dendritic lesions in the rabbit eye model. In fact, these observations were actually attributed to earlier investigations by Grüter who performed virtually identical experiments around 1910 but did not report them until much later [12].

Reports between 1920 and the early 1960s focused on the biologic manifestations of these viruses as well as the natural history of human disease. During these four decades, the host range of HSV infections was expanded to include a variety of laboratory animals, chick embryos, and, ultimately, *in vitro* cell culture systems. Expanded animal studies demonstrated that transmission of human virus to the rabbit resulted not only in corneal disease but also could lead to infections of either the skin or central nervous system [13], as reviewed [7,14–16].

Host immune responses to HSV were reported initially in the early 1930s. The first studies were performed by Andrews and Carmichael who defined the presence of HSV neutralizing antibodies in the serum of previously infected adults [17]. Subsequently, some of these patients developed recurrent labial lesions, albeit less severe than those associated with the initial episode. This observation led to the recognition of a unique biologic property of HSV, namely, the ability of these viruses to recur in the presence of humoral immunity—a characteristic known as reactivation of latent infection. Only individuals with neutralizing antibodies developed these recurrent vesicular lesions, a paradoxical finding given the classical lessons of such infectious diseases as measles and rubella whereby antibodies were normally associated with protection from subsequent episodes of disease. By the late 1930s it was well recognized that infants with severe stomatitis, who shed a virus thought to be HSV [18], subsequently developed neutralizing antibodies during the convalescent period [19]. Later in life, some of these children had recurrent lesions of the lip.

The medical literature of the 1940s and 1950s was replete with descriptions of disease entities such as primary and recurrent infections of mucous membranes and skin (e.g., gingivostomatitis, herpes labialis and genitalis, herpetic whitlow or eczema herpeticum) [20], keratoconjunctivitis [21], neonatal HSV infection, visceral HSV infections of the immunocompromised host, and HSV encephalitis [22]. The clinical spectrum of HSV infections subsequently was expanded to include Kaposi's varicella-like eruption and severe and prolonged recurrent infections of the immunocompromised host.

Significant laboratory advances have provided a foundation for the application of molecular biology to the study of human disease and, no less, vaccine development. These advances include, among others, 1) detection of antigenic differences between HSV-1 and -2 [6,23–25]; 2) proven antiviral therapy for virtually all manifestations of HSV disease [26–36]; 3) application of restriction endonuclease

technology to HSV strains in order to show epidemiologic relatedness [37]; 4) definition of type-specific antigens allowing the development of serologic assays that distinguish HSV-1 from HSV-2 [38,39]; 5) the characterization of the replication of HSV, its resultant gene products, and the biologic properties of some of these products [1]; and 6) the attenuation of HSV through genetic engineering and the subsequent expression of foreign genes, providing technology for the development of new vaccines [40].

### III. THE INFECTIOUS AGENT

Herpes simplex virus, types 1 and 2, are members of a family of large DNA viruses that contain centrally located, linear, double-stranded DNA. All of the herpesviruses consist of similar structural elements arranged in concentric layers [1,41,42]. Other members of the human herpesvirus family include cytomegalovirus, varicella-zoster virus, Epstein-Barr virus, human herpes virus 6, 7, and 8. Human herpesvirus 8 is also known as Kaposi Sarcoma virus. The DNA of HSV has a molecular weight of approximately 100 million and encodes for about 80 polypeptides, an increasing number of which have biologic functions that are understood. The genome consists of two components, a unique long and unique short region which can invert upon themselves, allowing for the coexistence of four isomers in virus suspensions [1,42,43]. The genomic arrangement of HSV-1 and -2 indicates that a number of genes are collinear with reasonable, but not identical, matching of base pairs.

Viral DNA is packaged inside a protein structure known as the capsid, which confers icosapentahedral symmetry to the virus. The capsid consists of 162 capsomeres and is surrounded by a tightly adherent membrane known as the tegument [44]. An envelope loosely surrounds the capsid and tegument, consisting of glycoproteins, lipids, and polyamines. The envelope glycoproteins are primarily responsible for the induction of humoral immune responses.

The replication of HSV is characterized by the expression of three gene classes: alpha (immediate early), beta (early), and gamma (late) genes, respectively, although there is some overlap between each of these classes. These genes are expressed temporally and in a cascade fashion [1,45,46]. Several observations are relevant as it relates to the replication of HSV for vaccine development. First, although herpesvirus genes carry transcriptional and translational signals similar to those of other DNA viruses, the mRNAs arising from the vast majority of genes are not spliced [47,48]. Second, the information density is lower than that encoded in the genes of smaller viruses [1,48], permitting insertion and deletion of genes into the HSV genome without significant alteration of the genomic structure. This property provides an opportunity to genetically engineer HSV as either a vaccine or a vector for the delivery of foreign antigens [40]. In this later circumstance, expression of foreign genes in HSV could provide an endogenous adjuvant or be useful for gene therapy. Finally, replication requires the expression of a viral coded protein,  $\alpha$ -transinducing factor, a potentially unique target for antivirals or antigen for vaccines [1]. The replication of HSV appears under the control of alpha genes of

which there are five. The beta gene products include the enzymes necessary for viral replication, such as HSV thymidine kinase, as well as the regulatory proteins. These genes require functional alpha gene products for expression. The onset of expression of beta genes products coincides with the decline in the rate of expression of alpha genes and an irreversible shut-off of host cellular macromolecular protein synthesis [45,49]. This latter event equates with cell death. Structural proteins are usually of the gamma gene class [45, 50]. The gamma gene products are heterogeneous and are differentiated from beta genes solely by the requirement for viral DNA for maximum expression of their genes.

Assembly of virus begins in the nucleus with formation of empty capsids, insertion of DNA, and acquisition of the envelope as the capsid buds through the inner lamella of the nuclear membrane. Further maturation of envelope glycoproteins occurs in the endoplasmic reticulum. Eleven glycoproteins have been described; these are gB, gC, gD, gE, gG, gH, gI, gJ, gK, gL, and gM [1,51]. The biologic properties of some of these glycoproteins have been identified [15,49]. For example, gD is related to viral infectivity and is the most potent inducer of neutralizing antibodies. Glycoprotein B (gB) is required for infectivity. These two glycoproteins have been utilized extensively in subunit vaccines which have been developed for human experimentation. Glycoprotein C (gC) binds to the C3b component of complement while gE binds to the Fc portion of IgG. In addition, it appears as though a deletion in gC enhances viral pathogenicity [52]. Glycoprotein G (gG) provides antigenic specificity to HSV and, therefore, results in an antibody response which allows for the distinction between HSV-1 and -2 [38]. Glycoprotein I interacts with gE at the Fc receptor [53,54]. The importance of these glycoproteins for vaccine development cannot be overemphasized. Considerable antigenic cross-reactivity exists between HSV-1 and -2.

#### IV. HOST VIRUS INTERACTION

In considering the development of vaccines directed against HSV, some understanding of the induced pathology and its implications on the modulation of the biology of human disease is relevant. The pathogenesis of HSV infections can best be understood through knowledge of the events of replication and establishment of latency in both animal models and humans. Infection is initiated by contact of the virus with mucosal surfaces or abraded skin. The fundamental principle of the pathogenesis of human infections is that transmission occurs by intimate personal contact, resulting in viral replication at the mucosal surfaces of initial infection. With viral replication at the site of infection, either an intact virion or, more simply, the naked capsid enters the nerve termini and is carried by retrograde axonal flow to the dorsal root ganglia where, after several cycles of viral replication, latency is established [55]. These events have been demonstrated in a variety of animal models, as reviewed [56]. After latency is established, reactivation can occur with a proper provocative stimulus (i.e., stress, menstruation, fever, exposure to ultraviolet light, etc.), and virus is transported anterograde down the axon to replicate at

mucocutaneous sites, appearing as skin vesicles or mucosal ulcers.

Viral replication can lead to systemic disease such as disseminated neonatal HSV infection with multi-organ involvement, or, very rarely, multi-organ disease of pregnancy and, infrequently, dissemination in severely immunosuppressed patients. Presumably, widespread organ involvement is the consequence of viremia in a host not capable of limiting replication to mucosal surfaces. It is unlikely that an HSV vaccine will prevent infection; however, disease, particularly multisystem disease, must be prevented or ameliorated for a vaccine to be considered successful. Recently completed vaccine trials support this concept.

Infection with HSV-1 is commonly transmitted to the oropharynx by direct contact of a susceptible individual with infected secretions (such as virus contained in labial vesicular fluid) [57–59]. Thus initial replication of virus occurs in the oropharyngeal mucosa; the trigeminal ganglion becomes colonized and harbors latent virus. Acquisition of HSV-2 infection is usually the consequence of transmission via genital routes. Under these circumstances, virus replicates in the vaginal tract or on penile skin sites with colonization of the sacral ganglia. For uncertain reasons, HSV-1 infection, when symptomatic, recurs more frequently in the oropharyngeal area, and HSV-2, when symptomatic, recurs more frequently in the genital area [60].

Operative definitions for the type of infection are of relevance. For individuals susceptible to HSV infections, namely, those without pre-existing antibodies, first exposure to either HSV-1 or -2 results in primary infection. The epidemiology and clinical characteristics of primary infection are distinctly different than that associated with recurrent infection. This subject has been reviewed extensively [7,14,15,61,62]. During primary infection of the genital tract or oropharynx, viral replication persists for nearly 2 weeks and disease for 3 weeks. After the establishment of latency, reactivation of HSV is known as recurrent infection. During recurrent symptomatic infection, viral replication persists for 24–48 hr and total disease lasts 7 to 10 days. Reactivation of infection leads to recurrent skin vesicular lesions such as HSV labialis or recurrent HSV genitalis. Individuals with pre-existing antibodies to one type of HSV can experience a first infection with the opposite virus type at the same or different site. This occurrence is known as an initial infection rather than primary. An example of an initial infection would be those individuals who have pre-existing HSV-1 antibodies, acquired after HSV gingivostomatitis, who, then, acquire a genital HSV-2 infection. The natural history of an initial infection more closely resembles recurrent infection. Pre-existing antibodies to HSV-1 appear to have an ameliorative effect on disease associated with HSV-2 infection [63]. Both initial and primary infections have also been named first-episode infection. Importantly, shedding of virus can be either symptomatic or asymptomatic. Indeed, transmission occurs more frequently during periods of asymptomatic shedding. Reinfection with the same strain of HSV can occur, albeit exceedingly uncommon [64,65]. This occurrence is defined as exogenous reinfection.

Ideally, vaccines directed against HSV should prevent infection as well as disease. However, it is unlikely that such a

vaccine will uniformly confer protection from infection, as discussed below in the context of a recently completely clinical trial. Thus a vaccine should significantly alter the clinical manifestations of primary disease and, perhaps, the frequency and severity recurrent infection. In so doing, it is anticipated that transmission of infection will be decreased.

## V. ANIMAL MODELS OF HSV VACCINE DEVELOPMENT

Numerous animal models have been used to study the pathogenesis of HSV infections, especially latency, antiviral therapeutics, and vaccines. Potential HSV vaccines have been evaluated in rodents (mice, guinea pigs, rabbits, etc.) and subhuman primates. Selection of the animal model system for vaccine evaluation is relevant. The animal species, virus type, route of infection, state of immune competence, and specific viral challenge strain all influence disease pathogenesis and, synonymously, the evaluation of a vaccine. Disease progression alone can be selectively modulated by the specific strain of the animal selected. The route and site of inoculation of virus become especially important in distinguishing one disease state from another and its prevention.

When HSV-1 is inoculated by the ocular route, encephalitis (virulence) and/or latency ensue, as reviewed [66]. The eye route of infection has been best utilized to study latency. Endpoints of virulence and latency, however, have distinct differences for predicting human disease. Following ocular inoculation after corneal scarification, replication of virus in the eye peaks within 48 hr and declines over the next 6 days. Virus appears in the trigeminal ganglia approximately 1 day after inoculation with peak replication occurring between 4 and 6 days. Subsequently, if the inoculum of virus is large enough and/or a virulent strain of virus is used, brain infection follows invasion of the trigeminal ganglia. Fortunately, while the trigeminal ganglion is routinely infected following human eye infection [67,68], subsequent invasive brain infection is an exceedingly uncommon event, if ever having occurred.

Mice, particularly the hairless mouse [69], rabbits and guinea pigs with abraded or punctured skin have been used to study virus replication and pathogenesis of HSV-1, and to evaluate both antiviral therapies and vaccines. While in each model the nature of the lesions, their duration, and histopathology parallel human infection, there are notable differences, particularly the lack of recurrent lesions similar to those seen in people.

Type 2 genital infections have been studied best in the guinea pig model. Intravaginal inoculation of HSV into female Hartley guinea pigs appears the most predictive of all the animal models for human disease [70]. Reasons for these inconsistencies include endogenous host defenses, the artificial nature of infection, and viral strain differences. Moreover, these animals tend to suffer from continual recurrences of lesions; however, retrieval of HSV from these lesions is most variable. Models of life-threatening disease have been developed for both HSV-1 and -2. Intranasal inoculation of HSV-1 or -2 in young (3 weeks of age) Balb/c mice leads to central nervous system and visceral (usually

lung) disease which may be predictive for neonatal HSV infection. However, inoculation of older mice with similar quantities of either virus may lead to no evidence of disease or, if so, encephalitis but certainly not overwhelming multi-organ disease. Direct intracerebral inoculation of virus is an unnatural route of infection even for the study of either antiviral therapeutics or vaccine efficacy.

Accurate and predictive models of human HSV encephalitis have been described in a rabbit model [71–73]. Virus is inoculated directly into the olfactory bulb or upon abraded nasal epithelium over nerves from the olfactory bulb; it can be traced along the olfactory tract to the anterior-frontal region of the rabbit brain where it causes focal infection, as compared to the diffuse pancortical infection which follows infection by the murine ocular route. The region of the rabbit brain involved correlates with the temporal lobe of humans. Immunosuppression following subclinical infection can result in focal reactivation [73].

Primate models have been utilized to study vaccines. These animals have been thought to more closely approximate that which is encountered in humans; however, the disease pathogenesis varies for each primate species. Specifically, the Aotus monkey (*Aotus trivirgatus* or *nancymanni*) is exquisitely sensitive to HSV and, therefore, serves as a useful model for assessment of attenuated live vaccines but is, perhaps, less amenable to protection studies. The demonstration of safety in the Aotus model provides confidence of safety before introducing such a vaccine into humans [74]. In contrast, the owl monkey is far less susceptible to HSV and, therefore, may more closely resemble humans.

## VI. HOST IMMUNE RESPONSES

### A. Primary HSV Infection

Local control mechanisms of viral spread aim to neutralize the infectious agent and lead to viral clearance. Following primary HSV infection, the initial, local immunological responses involve both nonspecific defense mechanisms, namely, interferons (IFNs) alpha and beta, activated natural killer (NK) cells, and macrophages, as well as HSV-specific responses, such as cytotoxic T cells [75].

In response to a viral infection, the initial cellular response is synthesis and secretion of type I IFNs (alpha and beta). Interferons induce an antiviral state in infected and surrounding cells. The antiviral activity is modulated in part by IFN-mediated activation of cellular enzymes such as 2'-5' oligoadenylate synthetase (2'-5' AS) and double-stranded RNA-dependent protein kinase, as well as intracellular signaling molecules by activation of the JAK/STAT kinase pathway. More specific to HSV infection, IFN- $\alpha$  appears to inhibit immediate-early (IE) gene expression [76]. Thus the antiviral mechanism directly affects transactivation of the IE responsive element necessary for synthesis of viral proteins.

In addition to antiviral activity, IFNs are potent immunomodulators. As such, they mediate macrophage and NK cell activation, activate cytotoxic T cells (CTLs), induce MHC class I (in the case of IFN- $\alpha$  and IFN- $\beta$ ) or MHC class II (in the case of IFN- $\gamma$ ) antigens, stimulate cytokine

secretion, and induce local inflammation. IFN- $\gamma$  may aid the control of HSV infection. Evidence that  $\gamma\delta$  T cells, NK cells, CD4 $^{+}$  T cells, and possibly neurons produce IFN- $\gamma$  and TNF in response to HSV infection in the nervous system has been reported. IFN- $\gamma$  down regulates proliferation of CD4 $^{+}$  Th2 cells, responsible for inducing Ig isotype B-cell switching from IgA to IgG, thereby exerting a major effect on humoral immune responses [77].

NK cells lyse pathogen-infected cells before virus-specific T-cell immunity is generated and constitute a first line of defense against infection. In vitro and in vivo experiments have demonstrated that NK cells protect from HSV challenge in a murine model [78]. Severe herpetic disease has correlated with low in vitro NK activity in newborns, as well as in a patient lacking NK cells [79]. NK cell involvement is also supported by direct evidence of resolution of herpetic disease in humans. Other mononuclear cells, such as macrophages, are recruited to the site of infection and, upon activation, release immune cell mediators such as IFN- $\gamma$  and interleukins. Macrophages play a major role in mediating antibody-dependent cellular toxicity for viral clearance and antigen presentation [80].

An important aspect of immune responses to HSV infections is the maturation of dendritic cells (DCs) at the site of infection. Mucosal immunity is generated by DCs, such as Langerhans cells (LCs), which contribute to disease resolution because of their antigen-presenting capacity to CTLs [81]. Langerhans cells migrate to the site of infection, where they process viral antigens for presentation to both naïve and primed T cells [82]. Langerhans cells produce IFNs and other cytokines, express MHC class II antigens, and interact closely with CTLs in genital mucosa.

As infection progresses, virus-specific immune responses are detected. On days 4 and 5 post infection, HSV-specific CD4 $^{+}$  Th1 lymphocytes are detected in genital lymph nodes and in smaller numbers in peripheral blood; they can subsequently be found in the genital mucosa [83].

Humoral immune responses rapidly follow initial HSV infection. The predominant mucosal antibodies are of the IgA isotype, being secreted by plasma cells. These antibodies can be detected as early as day 3 following infection, peaking within the first 6 weeks after disease onset, and are followed by the appearance of IgG1 and IgG3 subclasses of antibodies, which are typically found following viral infections. HSV-specific IgA antibodies are present for at least 6 weeks, gradually decreasing to undetectable levels. IgM-secreting B cells have also been detected in secretions of the female genital mucosa [84]. Shorter periods of viral shedding in women with primary genital herpes have been positively correlated with the presence of secretory IgA in vaginal secretions [78].

## B. Recurrent HSV Infection

Although immunosuppression enhances the frequency of reactivation, there is no proof that the immune system exerts any influence on reactivation at the level of the ganglia [85]. Repeated subclinical episodes of HSV excretion may be a source of antigenic stimulation leading to long-term HSV-specific immune memory [80]. In recurrent HSV-2 infections,

NK and HSV-specific CD4 $^{+}$  cells are detected earlier than CD8 $^{+}$  cells in genital lesions [77]. CD4 $^{+}$  T cells, and more recently, CD8 $^{+}$  T cells have been highlighted as major mediators of viral clearance from mucocutaneous lesions in recurrent episodes [75,86,87]. Low IFN- $\gamma$  titers in vesicle fluid have been associated with a shorter time to the next recurrence in patients with frequent recurrences. T-cell proliferation is decreased in these patients in comparison to patients with less frequent recurrences [80].

Inasmuch as the involvement of cytokines has been studied, IFN- $\gamma$  has been reported to have a role in viral clearance from mucocutaneous sites, whereas altered cytokine production appears to correlate with recurrence [88].

As with primary HSV infection, a shorter duration of viral shedding occurs in women with recurrent genital herpes who have detectable secretory IgA in vaginal secretions [78]. IgA, IgG1, and IgG3 antibodies have been found in the sera of all patients with recurrent HSV-2 episodes, while IgM and IgG4 antibodies were detected in 70–80% of these patients. However, there does not appear to be a clear correlation between humoral immune responses and disease prognosis [89].

Table 1 summarizes the immune responses to primary versus recurrent herpes infection.

## C. Persistence of Immune Responses

The host's immune responses persist and partially control HSV disease; recurrent episodes are generally less severe and of shorter duration over the years, perhaps due to progressive enhancement of long-term immunity [90]. Furthermore, some degree of cross-protection exists between HSV-1 and HSV-2. Additionally, newborns are partially protected by maternal antibodies [91]. Finally, HSV-specific T-cell infiltrates are detected in herpetic lesions during early disease resolution [75].

Studies indicate that persistent cell-mediated immune responses are more important than humoral immune responses in the resolution of HSV disease [92]. NK cells, macrophages, and T lymphocytes as well as cytokines such as IFN- $\alpha$  and IFN- $\gamma$ , IL-2, and IL-12 all have central roles in resolving HSV disease [93]. HSV-specific CD4 $^{+}$  and CD8 $^{+}$  cells are detected in lesions from recurrent episodes, indicating their potential role in controlling HSV disease [75,86]. By contrast, agammaglobulinemic patients do not experience more severe or more frequent herpetic recurrences than the general population [94]. Furthermore, several vaccine trials have demonstrated that the presence of neutralizing antibodies to HSV glycoproteins does not provide protection against HSV infection or disease.

## D. Correlation of Immune Response with Disease

Vaccine development, in general, requires the correlation of disease with host immune responses. The development of a vaccine to prevent HSV infections is no exception. Nevertheless, efforts to precisely incriminate that arm of the host response responsible for disease have remained elusive. Humoral immunity to HSV infection has been evaluated

**Table 1**

## Primary infection

*Local response*

Early nonspecific response interferon (IFN)- $\alpha$  and IFN- $\beta$ , natural killer (NK) cells, macrophages (3 to 4 hr after infection, appearance of viral glycoproteins as targets for ADCC). Mucosal dendritic cells are MHC class II antigen presenting cells, acting as antigen-presenting cells. Herpes simplex virus (HSV) infection induces maturation of these cells that produce high levels of type I IFN. From days 4 to 5: HSV-specific CD4 $^{+}$  Th1 appear in genital lymph nodes, then in the genital mucosa. Cervical immunoglobulin A (IgA) antibodies to several HSV-2 glycoproteins and IgG responses follow.

*Systemic response*

From 2 weeks: detection of IgG to HSV glycoproteins in primary HSV-2 infected patients. IgA and IgG types of HSV-specific antibodies are maintained for at least 6 weeks. IgG responses increase in the first year after primary infection and are detected in all genital herpes patients.

## Recurrent infection

*Local response*

Twelve to 24 hr after appearance of recurrent lesions: HSV-specific CD4 $^{+}$  and CD8 $^{+}$  cells, as well as macrophages are detected, with predominance of CD4 $^{+}$  cells.

*Systemic response*

Frequent subclinical reactivations may maintain relatively high frequencies of HSV-specificity memory T cells. CD8 $^{+}$  cells have been recently proposed as being a critical component in recurrent disease resolution.

*Source:* From Ref. 275.

exhaustively in disease pathogenesis. Polyclonal antibodies have been used to alter disease lethality, particularly in the newborn mouse or to limit progression of both neurologic and ocular disease [95–99]. Monoclonal antibodies to selected specific infected cell polypeptides, especially the envelope glycoproteins gB and gD, confer protection from lethality [100–102]. Importantly, gD2 is a known target of neutralizing antibodies, antibody-dependent cell-mediated cytotoxicity, and CD4 and CD8 T-cell-mediated responses [103–106]. As a consequence, this antigen has been a prime component of subunit vaccines.

Efforts to correlate the frequency recurrences with immune responses have failed to identify any specific humoral response to specified polypeptides [92,107,108]. Thus further efforts focused, in large part, on cell-mediated immune responses. As noted, lymphocyte blastogenetic responses are demonstrable within 4 to 6 weeks after the onset of infection and sometimes as early as 2 weeks [109–116]. With recurrences, boosts in blastogenic responses occur; however, these responses, as after primary infection, decrease with time. Nonspecific blastogenic responses do not correlate with a history of recurrences. HSV-1 and -2 are cross-reactive in these assays.

Lymphokine production has been incriminated in the pathogenesis of frequently recurrent genital and labial HSV infection. Notably, several investigators have recognized a decrease in both gamma interferon production and natural killer cells during disease prodrome [117–119]. Nevertheless, there are no reproducible data from selected populations to confirm these observations. The relevance of lymphokine expression in vaccine development can be assessed only in prospective field trials.

Host response of the newborn to HSV must be defined separately from that of older individuals. Immaturity of host

defense mechanisms is a cause of the increased severity of some infectious agents in the fetus and the newborn. Factors that must be considered in defining the host response of the newborn include also the mode of transmission of the agent (viremia versus mucocutaneous infection without blood-borne spread), time of acquisition of infection, and the potential of increased virulence of certain strains, although this last point remains purely speculative. Two broad issues are of relevance; these are protection of the fetus by transplacental antibodies and definition of host responses of the newborn. Transplacentally acquired neutralizing antibodies either prevent or ameliorate infection in exposed newborns as do antibody-dependent cell-mediated cytotoxicity [120–122]. Importantly, pre-existing antibodies, indicative of prior infection, significantly decrease the transmission of infection from pregnant women to their offspring [123]. This observation provides a strong rationale for the development of an HSV vaccine.

Humoral IgG and IgM responses have been well characterized. Infected newborns produce IgM antibodies specific for HSV, as detected by immunofluorescence, within the first 3 weeks of infection. These antibodies increase rapidly in titer during the first 2 to 3 months, and they may be detectable for as long as 1 year after infection. The most reactive immunodeterminants are the surface viral glycoproteins, particularly gD. Humoral antibody responses have been studied using contemporary immunoblot technology and the patterns of response are similar to those encountered in adults with primary infection [116,124]. The quantity of neutralizing antibodies is lower in babies with disseminated infection [116,121].

Cellular immunity has been considered to be important in the host response of the newborn. The T-lymphocyte proliferative response to HSV infections is delayed in

newborns compared to older individuals [116]. Most infants studied in a recent evaluation had no detectable T-lymphocyte responses to HSV 2 to 4 weeks after the onset of clinical symptoms [111,116,125]. The correlation between these delayed responses may be of significance in evaluating the outcome to neonatal HSV infection. Specifically, if the response to T-lymphocyte antigens in children who have disease localized to the skin, eye, or mouth at the onset of disease is significantly delayed, disease progression may occur at a much higher frequency than babies with a more appropriate response [116,126].

Infected newborns have decreased production of IFN- $\alpha$  in response to HSV when compared to adults with primary HSV infection [116]. The importance of the IFN generation on the maturation of host responses, particularly the elicitation of NK-cell responses, remains to be defined [127,128]. Lymphocytes from infected babies have decreased responses to IFN- $\gamma$  during the first month of life [116,128,129]. These data taken together would indicate that the newborn has a poorer immune response than older children and adults. Antibodies plus complement and antibodies mixed with killer lymphocytes, monocytes, macrophages, or polymorphonuclear leukocytes will lyse HSV-infected cells *in vitro* [130]. Antibody-dependent cell-mediated cytotoxicity has been demonstrated to be an important component of the development of host immunity to infection [131]. However, the total population of killer lymphocytes of the newborn seems to be lower than that found in older individuals, and monocytes and macrophages of newborns are not as active as those of adults [132–137]. These findings are supported by animal model data.

## VII. CRITERIA FOR EVALUATION OF HUMAN HERPESVIRUS VACCINES

The development of an efficacious HSV vaccine is very much needed as best defined by disease burden. In the United States alone, over 100 million individuals are infected by HSV-1 and at least 40 to 60 million individuals have been infected by HSV-2. Annually, a minimum of 2500 cases of neonatal herpes and 3000 cases of herpes simplex encephalitis results in significant morbidity and mortality despite efficacious anti-viral therapy. Furthermore, because HSV results in genital ulcerative disease, the risk of acquisition of human immunodeficiency virus (HIV) is significantly increased [138].

An ideal vaccine should induce immune responses adequate to prevent infection. If primary infection was prevented, the colonization of the sensory ganglia would not occur and, therefore, no source of virus for either subsequent recurrences or transmission would exist. No one knows today if such ideal objectives can be met. In fact, it is open to discussion whether the criteria of success for candidate vaccines should be one or any combination of the following effects: abrogation or mitigation of primary clinical episodes, prevention of the colonization of the ganglia, suppression or reduction of the frequency and/or of the severity of recurrences, reduction of the shedding (duration and/or quantity) of the virus during primary, recurrent episodes, reduction of asymptomatic shedding (frequency, duration,

quantity), and/or prevention of person-to-person transmission (either vertical or horizontal). These issues must be weighed in the context of the age of the target population, the duration of the desired results. Arguably, fundamental to a successful vaccine is the last point—namely, its ability to prevent person-to-person transmission in order to interrupt the ongoing HSV epidemic. To illustrate the difficulty of achieving such an end, overt clinical recurrences may only be apparent in approximately 20% of HSV-infected individuals, resulting in a large reservoir of unknowingly infected individuals who may intermittently excrete virus in the absence of symptoms and transmit it to intimate partners. Further complicating the issue, HSV DNA has been detected by polymerase chain reaction (PCR) in the genital secretions of women without either lesions or evidence of infectious virus [139], usually threefold more frequently than infectious virus. Subsequent person-to-person transmission has been documented from infected mothers to their newborns. The persistent detection of HSV DNA implies that HSV is a more chronic infection than previously thought and a more difficult vaccine target.

Prospective clinical trials, a time consuming and expensive exercise, will be required to appropriately define the true utility of an HSV vaccine. For these reasons, it is of the utmost importance to determine which factors are protective against HSV infection (humoral versus cell-mediated immunity, local immunity versus systemic immunity, antibody-dependent cell-mediated cytotoxicity versus cytotoxic T cells) such that markers can be developed to expedite the evaluation of vaccines in humans [74].

The rationale for an HSV vaccine is threefold. First, exogenous re-infection is exceedingly uncommon in the immune competent host. Second, many more individuals are infected by HSV than experience either clinical recurrences or shed virus. Finally, transplacental antibodies significantly decrease the risk of infection in the newborn exposed to HSV at the time of delivery. Taken together, these facts strongly suggest that a properly designed vaccine could be efficacious.

## VIII. HERPES SIMPLEX VIRUS VACCINE DEVELOPMENT

Two of the more promising HSV vaccines represent entirely different theoretical approaches. The first is based on either microorganisms or cell lines producing gB or gD2 for use as subunit vaccines in combination with an adjuvant. The second is a genetically engineered live, attenuated vaccine from which putative neurovirulence sequences have been removed. Each of these approaches has been evaluated extensively in animal model studies and to varying extents in human investigations. While these vaccines are exciting, much prior effort has been devoted to vaccine development. These latter studies will be reviewed first.

Extrapolating protection from animal model systems to humans has not been possible because there are no markers of protection comparable to neutralizing antibodies for other viral diseases [140–147]. While initial HSV vaccine efforts were oriented toward the prevention of recurrent

infections and, therefore, were considered therapeutic vaccines, more recent efforts have been devoted to the prevention of infection following exposure to an infected partner.

The approaches to HSV vaccine development include the utilization of 1) wild-type virus; 2) inactivated or killed virus; 3) subunit vaccines; and 4) genetically engineered vaccines.

### A. Wild-Type Virus

Numerous clinicians attempted to alter the pattern of recurrences by inoculation of autologous virus, of virus from another infected individual or, in one set of experiments, of virus recovered from an experimentally infected rabbit [148–150]. The consequences were obvious with lesions appearing at the site of inoculation in as many as 40% to 80% of volunteers [151–153]. Despite the appearance of lesions and the evaluation of only a very limited number of patients, the efficacy of such an approach was reported in the literature. Furthermore, these studies failed to utilize controls [153–155]. In some cases, inoculation led to recurrences [149,150, 156,157]. In large part, live viruses were abandoned on the grounds that many patients did not develop lesions at the site of inoculation and, therefore, it was not perceived that the patient had an “adequate take” [158–160]. At the present time, inoculation of either autologous or heterologous virus is unacceptable.

### B. Inactivated (or Killed) Virus

Killed virus vaccines have been studied in a variety of animal model systems, often with good results, as reviewed [161–163]. Unfortunately, when these vaccines were administered to HSV-infected individuals to alleviate recurrences, most studies failed to include an appropriate control group. Under such circumstances, significant bias was introduced because patients may experience 30% to 70% decrease in the frequency of recurrences as well as improvement in severity, simply from having received placebo [164–169].

The initial inactivated vaccines were derived from phenol-treated infected animal tissues [158–160]. Because of the possibility that administration of animal proteins might lead to demyelination, these vaccines did not attract much biomedical attention. Instead, ultraviolet light inactivation of purified virus derived from tissue culture replaced phenol inactivation. Over the past two decades, numerous reports in the literature suggested either the success or failure of these approaches. As reviewed [162], viral antigen obtained from amniotic or allantoic fluid, chorioallantoic membranes, chick cell cultures, sheep kidney cells, rabbit kidney cells and inactivated either by formalin, ultraviolet light, or heat led to a series of vaccine studies in thousands of patients [164, 170–193]. With one exception [170], each of these studies reported significant improvement in as many as 60% to 80% of patients [184–186,192].

As these studies progressed several important observations were made. First, despite repeated inoculations, antibody titers (as measured by neutralization or complement fixation) remained unchanged in the majority of patients [173,180,194] or only demonstrated slight increases [171,

191]. Second, while these efforts reported few side effects, some authors noted concern that, in patients with keratitis, autoimmune phenomena might make the herpetic disease worse [181,189,195–197]. Placebo-controlled studies utilizing inactivated vaccines were few, as reviewed [168,197–199]. The results were widely discrepant, even when the same vaccine was utilized, a finding most discouraging. A conclusion from these investigations was that there may be some initial benefit for patients with recurrent infection; however, long-term benefit could not be established. The only prospective study of prevention of HSV infections by vaccination was performed by Anderson et al. in children of an orphanage [199]. In this study 10 children received vaccine and 10 the placebo; yet, HSV stomatitis developed in an equal number of patients on long-term follow-up.

### C. Subunit Vaccines

Subunit vaccines evolved out of attempts to remove viral DNA and eliminate the potential for cellular transformation, to enhance antigenic concentration and induce a stronger immunity, and, finally, to exclude any possibility of residual live virus contamination [200]. Available subunit vaccines have been prepared from a variety of methods combining antigen extraction from infected cell lysates by detergent and subsequent purification. The immunogenicity of vaccines derived from all of the envelope glycoproteins, free of viral DNA, has been demonstrated in animals [62, 201–203]. The results of studies in humans are conflicting. While one vaccine was reported to decrease recurrences in infected patients, the study design did not employ a placebo control [204]; thus no conclusions of efficacy can be drawn. Vaccination with envelope glycoproteins does not protect uninfected sexual partners of individuals with genital HSV infection [205,206].

More recently, specific subunit vaccines have arisen out of the cloning of specific glycoproteins in either yeast or Chinese hamster ovary cell systems [166,207,208], as well as by other methods [209–211].

Subunit vaccines have been studied in a variety of animal model systems including mice [212–218], guinea pigs [219–224], and rabbits [225]. Neutralizing antibodies can be detected in these systems in varying amounts, and in some systems ELISA antibodies as well [226]. In these systems the quantity of neutralizing antibody correlated with the degree of protection upon challenge. Challenge in the experimental systems has been studied in mice [212–215,218,226–228], rabbits [225,229–231], and guinea pigs [219,221,222,231]. Each of these systems utilized a variety of different routes of challenge as well as dosages. Challenge included skin, lip abrasion, intravaginal inoculation, intradermal ear pinna inoculation, intradermal injection, foot pad challenge, intraperitoneal, ocular, or subcutaneous. Thus interpretation of these results is extremely difficult. While there are many conflicting animal model studies, in general, the subunit vaccines elicited a degree of protection as evidenced by amelioration of morbidity and reduction in mortality in the immunized animals. Nevertheless, several injections were required to induce protection and must include adjuvant as well. The necessity for an appropriate adjuvant has been

recently emphasized [232,233]. Protection in the rodent is significantly easier than in higher primate species. This may be especially the case as the HSV is not indigenous to rodent species and, thus, protection studies may be totally irrelevant when evaluating human responses.

Vaccination of primates, specifically rhesus monkeys [225], chimpanzee [201,225], and cebus monkeys [228] can induce neutralizing antibodies, leading to an amnestic response following subsequent injection months later. The significance of the protection in these animals remains unclear for human experimentation.

Subunit vaccines have been evaluated in humans. Both HSV-1 and -2 antigens have been prepared in human diploid cells, Chinese hamster ovary cells, and chicken embryo fibroblasts for vaccine purposes. Several studies have reported evidence of improvement [204,234,235]. Other studies suggested very little benefit [201,205,206].

Several human subunit vaccine trials have now been completed. One of the earliest human vaccine experiences was with an early Merck Sharpe and Dohme [228] glycoprotein envelope subunit vaccine [205,206,236]. This vaccine was produced by purification of the envelope glycoproteins. In a Phase IIA study, carried out in sexual partners of patients known to have genital herpes, the number of individuals developing herpetic infection was nearly equal between placebo and vaccine recipients; thus vaccination failed to provide any benefit at all.

More recently, a series of clinical trials have evaluated the Chiron Corporation gB2 and gD2 and SmithKline Beecham gD2 subunit vaccines in humans. Both vaccines incorporated either a single glycoprotein or both in combination with adjuvants unique to each company. From a developmental perspective, important lessons were learned. Extensive rodent experiments, utilizing the guinea pig and murine genital herpes models demonstrated that either combined gB and gD or gD-2, with a Freund's adjuvant, completely protected against both primary and spontaneous recurrent disease following intravaginal viral inoculation [221]. However, complete Freund's adjuvant is not acceptable for human administration. Thus alternative adjuvants were explored, including Chiron Corporation MF59 and a proprietary SmithKline Beecham adjuvant. Both afforded a high level of protection from HSV disease [208,232]. An important finding from these preclinical studies was that the quantity of neutralizing antibody elicited by immunization and the total HSV antibody titer (as measured by ELISA) were higher after vaccination than following natural infection and, furthermore, that these antibody titers correlated with protection from disease [221,237].

Data from the largest series of vaccinated individuals with the Chiron Corporation construct failed to demonstrate significant long-term prevention of infection in susceptible sexual partners, although initial benefit was apparent for the first 5 months [238]. In this trial, there was a 50% reduction in the rate of infection among HSV seronegative women during this short window. The overall efficacy of the vaccine for 1 year following a 6-month vaccination period was 9%. The vaccine had no *apparent* effect on the frequency of recurrences [239]. No further vaccine studies are planned for this construct. Of note, the

adjuvant for these studies was MF59, a potent inducer of Th-2 responses.

Another series of clinical trials utilizing gD2 [SmithKline Beecham (now Glaxo SmithKline)] have been reported. Here, the adjuvant was alum plus monophosphoryl lipid A, a potent inducer of Th-1 responses. In these studies, women who were seronegative for both HSV-1 and -2 were protected from both disease (72% efficacy) and infection (43% efficacy). However, in individuals seropositive for HSV-1, irrespective of sex, and seronegative men, no significant clinical benefit could be demonstrated. Thus the two Phase III efficacy studies suggest that the GSK candidate genital herpes vaccine (gD/Alum/MPL) may be effective in preventing HSV-1 or -2 genital herpes disease in a subset of volunteers, i.e., women who were HSV-1 and -2 seronegative (HSV1/-2-) prior to vaccination. However, these studies were neither designed nor powered to assess efficacy in HSV1/-2- exclusively in women and therefore did not meet their primary endpoints of overall efficacy. Consequently, a double-blind, randomized, controlled Phase III study is currently planned to assess the prophylactic efficacy of gD/Alum/MPL vaccine in the prevention of genital herpes disease in young HSV1/-2- sexually active women.

## D. Live Vaccines

Live vaccines, in general, are considered preferable to killed or subunit vaccines because they are more likely to induce a broad range of immune responses to the expressed gene products and, therefore, provide a high level of protection as has been the case with numerous viral pathogens such as measles, mumps, and rubella. Furthermore, as these vaccines replicate in the recipient, the resulting immunity should be longer lasting. Moreover, they usually require smaller doses of antigen and, therefore, should be more economical. Several approaches to live virus vaccines have been attempted. These include HSV mutants, heterologous herpesviruses, antigens expressed in non-HSV viral vectors, and genetically engineered viruses.

### 1. Herpes Simplex Virus Mutants

It was recognized very early in biologic laboratory investigations that virulence varied significantly among wild-type HSV isolates. Conceivably, one could use the least virulent wild-type HSV as a vaccine, but reversion from nonpathogenic to pathogenic strains easily occurs following serial passages either in cell culture or animal hosts. This lack of genetic stability is unacceptable for potential human vaccines [237,240].

### 2. Heterologous Herpesvirus Vaccines

While considered for other herpesvirus infections, such as Marek's disease, the utilization of heterologous herpesvirus for humans is considered untenable medically or ethically.

### 3. Antigens Expressed in Live, Non-HSV Vectors

Vaccinia virus has been proposed as a vector for delivering antigens to animals or humans [241]. The principle of inserting foreign genes into a vaccinia vector has been

exploited for the expression of the gD and gB genes of HSV [242–248]. Significant concern has been raised over the utilization of vaccinia as a vector for delivering foreign antigens. In large part this concern stems from the occurrence of vaccinia gangrenosum and disseminated vaccinia in individuals who were vaccinated to prevent smallpox. As such, this major concern for adverse effects has led to decreased interest in utilizing vaccinia as a vector in the prevention of HSV, although this virus has become of increased importance with the threat of bioterrorism. Furthermore, immune memory in individuals who have previously received vaccinia may prevent recognition of any foreign gene insert. Likely, the use of canary pox as a vector will be attempted.

Adenoviruses have also been proposed as expression vectors, on the grounds that they might be safer than vaccinia [249].

#### 4. Genetically Engineered Herpes Simplex Viruses

Molecular biology makes it possible to modify, almost at will, the genome of large DNA viruses and construct genetically engineered attenuated live viruses [40]. Utilizing the technology developed by Post and Roizman [250,251], recombinant HSVs were constructed as a prototype of HSV vaccines [252]. These vaccines were engineered with the objective that they should be attenuated, whether for primary inoculation or potential reactivation of latent virus; protect against HSV-1 or HSV-2 infections; provide serological markers of immunization distinct from wild-type infections; and serve as vectors to express immunogens of other human pathogens.

The construction of these viruses was based on the use of an HSV-1 [HSV-1(F)] as a backbone. The genome was deleted in the domain of the viral thymidine kinase (TK) gene and in the junction region between the unique long and short sequences in order to excise some of the genetic loci responsible for neurovirulence and to create convenient sites and space within the genome for insertion of other genes. Last, an HSV-2 DNA fragment encoding the HSV-2 glycoproteins D, G, and I was inserted in place of the internal inverted repeat. The purpose of type 2 genes was to broaden the spectrum of the immune response and to create a chimeric pattern of antibody specificities as a serological marker of vaccination. The resulting recombinant, designated as R7017, had no TK activity and, therefore, would be resistant to acyclovir. Therefore another recombinant was created, designated R7020, by insertion of the TK gene next to the HSV-2 DNA fragment. As this virus expresses TK, it is susceptible to antiviral chemotherapy with acyclovir. When analyzed by restriction enzyme digestion, the DNA of the recombinants shows typical patterns which enable their unambiguous identification.

When evaluated in rodent models, the two constructs appeared considerably attenuated in their pathogenicity and ability to establish latency and were capable of inducing protective immunity. The recombinants did not regain virulence, nor did they change DNA restriction enzyme cleavage patterns when subjected serial passages in the mouse brain [252]. It is remarkable that the TK deleted virus R7017 behaved similarly to the TK expressing virus R7020, be-

cause the deletion of this gene was thought to attenuate the virus.

These results were corroborated by studies in owl monkeys (*Aotus trivirgatus*) [253]. While 100 PFU of wild-type viruses administered by peripheral routes was fatal to the monkeys, recombinants given by various routes in amounts at least  $10^5$ -fold greater were innocuous or produced mild infections, even in the presence of immunosuppression by total lymphoid irradiation [252].

Unfortunately, human studies with this vaccine were disappointing. The maximum dose of vaccine administered was  $10^5$  PFU which elicited only mild immunogenicity even with the administration of two doses [253]. In many respects, the R7020 construct was overly attenuated. However, as noted below, this virus is now being studied for gene therapy of adenocarcinoma metastases from the colon to the liver. Regardless, these same principles of genetic engineering have been applied to newer generation of newer constructs. The recent identification of a neurovirulence gene, identified as  $\gamma_{134.5}$ , provided a marker for genetic engineering [254]. The deletion of the two copies of this gene and genes UL 55 and 56, genes associated with nuclear associated proteins, results in an attenuated candidate vaccine that is currently undergoing evaluation in animal models. Importantly, engineered viruses have been evaluated for gene therapy of malignancy and, therefore, can also be assessed for the ability to induce host immune responses.

An alternative strategy for attenuation is under investigation by Knipe and colleagues.

#### 5. Genetically Engineered Replication Attenuated HSV

**Background.** Genetically engineered HSV have mainly been assessed for the treatment of human glioblastoma multiforme. These constructs have included mutations in the viral genes thymidine kinase, DNA polymerase, ribonucleotide reductase, and  $\gamma_{134.5}$  [255–261]. Each of these studies sought to optimize the therapeutic index in the treatment of gliomas by exploring therapies with different types of genetically engineered HSV constructs. While virtually any alteration of HSV ameliorates neurovirulence, only the deletions in the  $\gamma_{134.5}$  gene consistently demonstrate safety and efficacy in animal models. Tumoricidal effects in vitro and in vivo in multiple glioma models (mouse, rat, and human glioma cell lines, human glioma explants) are demonstrable. In vivo models include tumor reduction in subrenal capsule and flank subcutaneous implants but, more importantly, increased survival and some tumor cures in intracranial implant models. These effects are reproducible in vivo for both immune deficient animals (nude, *scid* mice) [255,256,260,261] as well as immune competent models (rats and mice) [258,259,262–264].

**Animal Model Studies.** Studies in animal models of gliomas of various constructs of HSV (engineered viruses deleted in  $\gamma_{134.5}$ ) have been performed. These studies demonstrate the following principles: 1) the time course of infection (quantitative virology and PCR) represents impaired replication with limited spread of virus across the brain using marker genes (*lacZ* under an ICP6 promoter)

with HSV antibody staining [258,259,263,265]; 2) two selected mutations appear to avoid second-site mutations with reversion to wild-type phenotype ( $\gamma_134.5$  and ribonucleotide reductase deletions) [266]; 3) the retention of the native HSV TK allows for acyclovir susceptibility [261]; 4) the safety of these constructs was established in susceptible primates (*Aotus*) [266]; and 5) HSV could be used in successful vector genes [264,267,268], as reviewed [269].

Indeed, one construct, namely, G207 [255], demonstrated an adequate safety profile in both cell culture as well as in animal models [270,271] and was efficacious in several tumor models *in vivo* [255–261]. This candidate therapeutic is deleted in both copies of the  $\gamma_134.5$  gene as well as ribonucleotide reductase. Sufficient quantities of virus were produced under GMP conditions in a Phase I study in humans with recurrent glioblastomas, as described below.

Numerous other constructs have been developed, including cytokine/chemokine genes, enzymes, and receptors [272]. These constructs will be detailed below in the description of our accomplishments. However, other investigators have taken the approach of altering host recognition of HSV by deleting the  $\alpha-47$  gene and, thereby, avoiding host MHC-I processing. The potential utility of this approach remains to be established.

*Clinical Experience with Intratumoral HSV in Glioma Patients.* The leading genetically engineered HSV candidate for the treatment of glioblastomas is G207, a conditionally replicating HSV mutant, as described above. G207 was evaluated in a Phase I safety trial for patients with recurrent malignant gliomas, failing standard therapy, and with a lesion greater than 1 cm in diameter [273]. A total of 21 patients were recruited and received escalating doses of G207, beginning at  $1 \times 10^6$  and in cohorts of three to a final dose of  $3 \times 10^9$  PFU at five intratumoral sites. While adverse events were noted in several patients, no toxicity or adverse event was unequivocally ascribed to G207 administration. Importantly, no patient developed herpes simplex encephalitis. Host seroconversion to HSV was documented in one of five seronegative volunteers. Two volunteers have survived greater than 3 years with stable Kornofsky scores. These data provide the basis for a Phase I B and II clinical trials, recently approved by the FDA, for further dose escalation after tumor debidement or administration of concomitant radiotherapy.

An HSV deleted in both copies of the  $\gamma_134.5$  gene, mutant 1716, and expressing *lacZ* under the control of the latency associated transcript was studied in Scotland in a similar population. In this trial, a total of nine patients were evaluated at one of three doses of virus, beginning at  $1 \times 10^3$  and escalating by a factor of 10 to  $1 \times 10^5$  [274]. As in the U.S. study, there were no reports of significant adverse events directly attributable to virus administration. Four of the nine patients were alive 14–24 months after injection. Of note, the maximum amount of virus administered in this trial was four logs lower than that of the study performed in the United States. These promising studies have led to Phase II trials in both the United States and the United Kingdom.

Although the two trials utilized different genetically engineered constructs and doses of virus for administration, the demonstration of safety following intratumoral inocula-

tion is truly remarkable and paves the way for the evaluation of genetically engineered HSV in Phase II trials. Importantly, future studies should address the extent and magnitude of viral replication in the tumor as well as the host response in much more detail.

*Follow-Up Investigations.* In studies in Europe and the United States, Phase II investigations of genetically engineered HSV for the treatment of brain tumors are currently in progress. Second-generation constructs that express the cytokine IL-12 will be in human investigations in the immediate future. This later construct will assuredly induce an enhanced effect within the tumor bed. Such studies will provide the groundwork for using a similar construct as a vaccine to prevent HSV infections.

## IX. CONCLUSION

Within the last several years focused efforts on developing vaccines for HSV infections as well as gene therapy have led to creative potential candidates. These vaccines have entered human investigations. These studies should indicate the potential efficacy of these vaccines. We have learned for example that seronegative individuals at high-risk for infection represent ideal candidates for participation in vaccine trials, while individuals with frequent recurrences probably do not offer the opportunity for complete suppression of symptomatic disease. As a consequence, vaccination should be scheduled for a time prior to exposure of the offending pathogen. For a vaccine designed to prevent HSV-2 infections, this would be early in adolescence prior to the onset of sexual activity.

Adequate methodology has not always been applied to previously performed evaluations of HSV vaccines. The current and future studies are to be randomized, double-blind, placebo-controlled, with a sufficient number of volunteers for appropriate statistical analyses to comply with proper trial drugs. Interim analyses predicated on results obtained during the performance of the trial will guarantee the ethical nature of the trial design. After enrollment into a prospective clinical trial, the diversity of clinical HSV diseases, the lack of predictability of patterns of recurrence, will mandate a very careful prospective evaluation for both symptomatic and asymptomatic evidence of infection in vaccine recipients, including the use of PCR. On both clinical and laboratory levels, detailed evaluations will have to determine the presence or absence of subsequent wild-type infection.

Nevertheless, the intellectual and scientific challenges posed by the development of a vaccine to prevent HSV infections are extremely rewarding. Hopefully, within the next several years the results of excellent clinical trials will help establish the value or failure of such an approach.

## ACKNOWLEDGMENT

Studies performed by the author and herein reported were initiated and supported under a contract (NO1-AI-65306, NO1-AI-15113, NO1-AI-62554) with the Development and

Applications Branch of the National Institute of Allergy and Infectious Diseases (NIAID), a Program Project Grant (PO1 AI 24009), by grants from the General Clinical Research Center Program (RR-032) and the State of Alabama.

### I. VACCINES AGAINST HANTAVIRUSES

#### A. Hantaviruses and Hantaviral Diseases

The genus *Hantavirus*, family Bunyaviridae, contains more than 20 viruses, including those causing hemorrhagic fever with renal syndrome (HFRS) or hantavirus pulmonary syndrome (HPS) [1]. Each distinct hantavirus is generally carried by a single rodent host species, although spillover of viruses into other rodents and rare species-jumping events has been observed [2–5]. Genetically closely related rodents carry closely related hantaviruses, reflecting coevolution or cospeciation of hantaviruses and rodents, probably over hundreds of thousands of years [3,6]. Because of this close association of the viruses and hosts, hantaviral diseases are geographically restricted to the range of the rodent carrying a particular virus. For this reason, HFRS, which is caused by hantaviruses carried by Old World rodents, is found in the eastern hemisphere, whereas HPS, which is caused by viruses carried by New World rodents, is found in the western hemisphere. An exception to this generality is Seoul virus, an etiologic agent of HFRS, carried by rats (*Rattus norvegicus* or *Rattus rattus*). Although rats are native to the Old World they, along with Seoul virus, have been distributed worldwide over the past few centuries, mostly as passengers on cargo ships.

Rodents carrying hantaviruses show no detrimental signs of infection, and where studied, the viruses persist in the presence of high levels of neutralizing antibodies [7–10]. The characteristics of and mechanism by which persistence is maintained has not been determined for many hantavirus-

rodent host pairs [11]. Hantavirus transmission usually results from inhalation of virus contained in rodent excreta [12,13]. Biting has also been suggested to be a frequent mode of transmission among rodents [14].

Rodent control is an effective way of preventing HFRS or HPS; however, it is not always possible or practical to avoid exposure to hantavirus-carrying rodents. Highly effective drugs or therapeutics are not available for HFRS or HPS; consequently, vaccines are the most rational approach to controlling hantaviral diseases. HFRS is a much more common disease than HPS. Whereas less than 1000 cases of HPS have been observed in North and South America since the discovery of HPS in 1993 (<http://www.cdc.gov/ncidod/diseases/hanta>), 60,000 to 150,000 cases of HFRS are reported each year [15]. Of these, the majority is found in China, with the rest occurring throughout western Russia, other parts of Europe, and Scandinavia [15].

Four hantaviruses are known to cause HFRS. Hantaan virus (HTNV), carried by *Apodemus agrarius* (striped field mice), and Dobrava virus (DOBV), carried by *Apodemus flavicollis* (yellow-necked mice), cause severe HFRS in Asia and in Europe, respectively, with mortality rates from 4% to 15% [15]. Puumala virus (PUUV), carried by *Clethrionomys glareolus* (bank voles) causes HFRS in Europe, European Russia, and Scandinavia. Puumala virus infection is usually not fatal (1–2% mortality) [16]. Seoul virus (SEOV) is most prevalent in China and Korea, but has also been associated with HFRS found in other parts of the Eurasian continent [16,17]. Although SEOV infections can be fatal, generally, SEOV causes a disease with lower mortality than that associated with HTNV [18].

Four hantaviruses are known to cause HPS in North America: Sin Nombre (SNV), New York, Bayou, and Black Creek Canal viruses. Sin Nombre virus, carried by *Peromyscus maniculatus* (deer mice) was the first pathogenic New World hantavirus described [19] and has caused most of the ~320 known cases of HPS in North America. Hantavirus pulmonary syndrome has been observed in 31 states in the United States with a mortality rate of approximately 37%. In South America and Central America, several hantaviruses have been associated with HPS [20]. Andes virus (ANDV), carried by *Oligoryzomys longicaudatus* (long-tailed pygmy rice rat), was identified in southern Argentina in 1995 and was later shown to be a prevalent cause of HPS in Chile [20]. Andes virus is the only hantavirus shown to be transmitted from person to person, causing secondary HPS [21–23].

### B. Protective Immunity to Hantaviruses

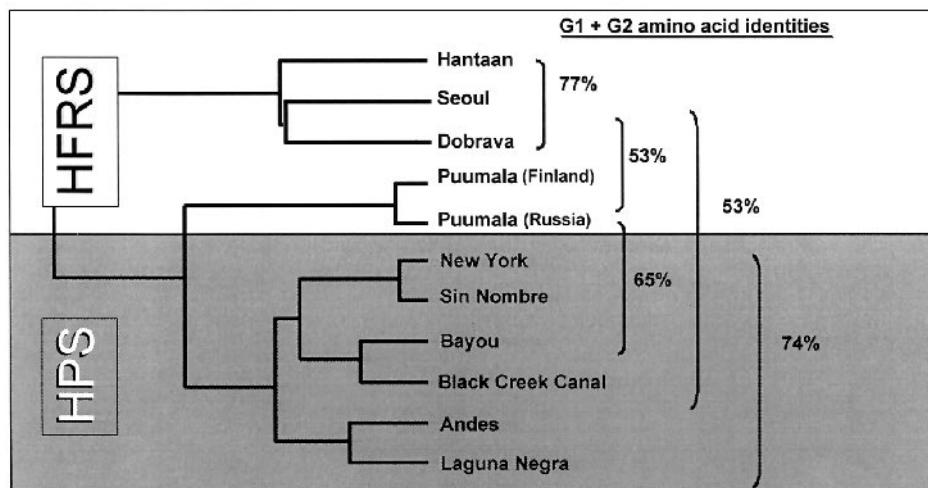

The large number of hantaviruses that are potentially pathogenic for humans, and their genetic and antigenic diversity, pose a challenge for developing a comprehensive vaccine (Figure 1). Assessing cross-protection among hantaviruses has been difficult because, except for ANDV, hantaviruses are not known to be pathogenic for animals. The discovery that ANDV causes a disease in hamsters that is very similar to human HPS [24] provides an opportunity for studying protection from ANDV challenge; however, for other hantaviruses, protective immunity can only be gauged by the ability to prevent infection of a challenge virus. Typically, this is done by measuring viral antigens in target organs after challenge, and/or comparing antibody responses before and after challenge [25–29]. Such studies suggest that it may be possible to generate cross-protective immunity among the more closely related viruses, e.g., HTNV, SEOV, and DOBV viruses, but not against the more distantly related viruses [27,30]. If the hamster studies can be extrapolated to indicate that the ~80% amino acid sequence homologies of HTNV,

SEOV, and DOBV are sufficient to elicit cross-protective immunity, but that the ~65% homologies of PUUV and these other HFRS-causing viruses are insufficient, then none of the HFRS-causing hantaviruses could serve as a basis for an HPS vaccine (Figure 1). The amino acid sequence homologies of the known HPS-causing hantaviruses, however, suggest that a single vaccine component could offer cross-protective immunity to HPS.

Protection from infection is primarily mediated by neutralizing antibodies, as indicated by the ability of passively transferred immune sera to prevent infection by various hantaviruses in laboratory rodents [25,31,32]. In humans, a strong neutralizing antibody response has been linked to a better chance for survival of HPS [33]. Although a neutralizing antibody response alone appears to be sufficient for preventing infection with hantaviruses, cell-mediated responses have also been measured and found to offer cross-protective immunity in mice [34–36]. Cell-mediated immunity in humans has been documented by isolating T-cell clones from the blood of hantavirus-infected individuals [37–39]. The cell-mediated immune response to hantaviral infection is thought to be involved in pathogenesis. Inflammatory responses, particularly those associated with certain cytokines including tumor necrosis factor (TNF- $\alpha$ ) and gamma interferon, are thought to be major contributors to the increased vascular permeability that is characteristic of both syndromes [40–44].

### C. Conventional Vaccine Approaches

Because HPS is so rare, commercial vaccine development has not yet been actively pursued. In contrast, HFRS is a significant infectious disease problem in Asia, and several inactivated-virus vaccines have been developed and tested. A Korean vaccine, Hantavax®, is modeled after the commercially successful Biken vaccine for Japanese encephalitis. This vaccine was originally produced in suckling rats, but now consists of brain preparations from suckling mice

**Figure 1** The phylogenetic basis of antigenic differences among hantaviruses.

infected with Hantaan virus. The vaccine is formulated with aluminum hydroxide adjuvant and is given by intramuscular injection. A clinical study of the original rat brain-derived vaccine demonstrated that 89% of the 456 volunteers who received one dose of vaccine, and 99% of 336 who received two doses of vaccine, seroconverted as determined by indirect fluorescent antibody test (IFAT) on infected, fixed cells. Neutralizing antibodies were not reported. A subsequent study showed that 97% of 64 volunteers given two doses of the mouse-brain-derived vaccine developed antibodies to HTNV detectable by ELISA or IFA and 75% had neutralizing antibodies. At 1 year after vaccination, neutralizing antibodies were no longer detected and a booster vaccination resulted in neutralizing antibodies in only 50% of the volunteers [45]. In another study of Hantavax in 30 volunteers, 76% developed antibodies detectable by ELISA and 33% developed low levels of neutralizing antibodies [46]. Antibody responses to individual HTNV proteins were not reported for these volunteers, but the discordance between ELISA and neutralizing antibodies might reflect a stronger response to the nucleocapsid protein than to the envelope glycoproteins of HTNV. Although controlled efficacy studies of the vaccine have not been reported, the incidence of HFRS in Korea has dropped since the introduction of the vaccine in 1990. Of course, other factors may also have contributed to the decline in cases of HFRS such as rodent population fluctuations or improved living conditions. Thus, proactive studies are still needed to validate the vaccine's effectiveness.

Rodent-brain-derived vaccines have also been developed and given to more than a million people in The People's Democratic Republic of Korea (North Korea). Although few details are available, one such vaccine reportedly consists of brain suspensions (from HTNV-infected suckling rats or hamsters) prepared by heating at 56°C for 30 min and mixing with protamine sulfate and coal powder [47]. Two doses of the vaccine, given to more than 1000 individuals, resulted in antibodies detected by IFA in 75% of recipients.

Both suckling mouse brain (SMB)-derived and cell-culture-derived inactivated vaccines for HFRS have been tested in China. A vaccine for HFRS caused by HTNV is prepared from virus-infected primary Mongolian gerbil (*Meriones unguiculatus*) kidney cells (MGKC). Virus is recovered and concentrated from whole-cell preparations by filtration. Beta-propiolactone (BPL; 0.025%) was chosen for inactivating infectivity because when compared to formalin, BPL treatment resulted in higher levels of hemagglutinating antigen, indicating better preservation of the envelope proteins [48]. Aluminum hydroxide (0.5 mg/mL) is added as an adjuvant. Three doses of vaccine given to two groups of 12 volunteers at intervals of 0, 7, and 28 days or 0, 28, and 60 days resulted in low levels of neutralizing antibodies to HTNV (GMT ~ 50) in all but one of the volunteers [49]. A booster vaccination given at 1 year resulted in a two- to threefold increase in antibodies titers as compared to those measured after the primary series [49].

A vaccine for HFRS caused by SEOV is prepared in primary golden hamster kidney cells (GHKC). Infected cells are harvested 9–10 days after infection and the whole-cell preparations treated with 0.025% formalin to inactivate infectivity. The vaccine is formulated with aluminum hy-

droxide (0.5 mg/mL) adjuvant. Three doses of the vaccine were tested in 10 volunteers and two doses in 2 volunteers with intervals of 0, 1, and 3 weeks. All of the volunteers developed neutralizing antibodies in a focus reduction test, although titers were low, ranging from 1:10 to 1:160 [50].

The HTNV and SEOV cell-culture-derived vaccines and an SMB-derived inactivated vaccine were compared in more than 100,000 individuals in China. Each vaccine was given as a primary series of three intramuscular inoculations according to the specifications of the manufacturer followed by a boost at 1 year. The HTNV-MGKC vaccine was given at 0, 1, and 2 weeks. The SEOV-GHKC vaccine was given at 0, 2, and 4 weeks [51]. Evaluation of antibody responses in some of the recipients after the primary series of vaccinations revealed the SEOV vaccine to more effectively elicit neutralizing antibodies (~80% of volunteers) compared to the other two vaccines (~50–60% of volunteers). Of approximately 40,000 recipients of each vaccine, 4 who received the SEOV vaccine and 7 who received the HTNV vaccine developed HFRS during the 4 years after vaccination. Although this was apparently not a randomized study, and it is not clear how controls were chosen, there were many more cases of HFRS in each control group, with incidence as high as ~150 cases per 100,000 population in the first year after vaccination [51].

Because both of the monovalent vaccines elicited no or low cross-neutralizing antibodies to the heterotypic virus (HTNV or SEOV), efforts to develop a bivalent HTV-SEOV vaccine have been made. Two such vaccines have been tested in humans in China, one prepared in GHKC and one in MGKC. Three inoculations with the MGKC-derived vaccine elicited neutralizing antibodies to HTNV or SEOV in 88% or 96% of 81 volunteers [49].

The MGKC-derived vaccine was further tested in more than 1000 individuals in two regions of China [51,52]. About 10% of the recipients were screened for neutralizing antibodies after the primary series of vaccinations. Approximately 87% had neutralizing antibodies to HTNV and 96% to SEOV; however, the geometric mean titers were less than 15. A similar study with the GHKC-derived vaccine produced nearly the same results [51]. Further studies are in progress to evaluate the protective efficacies of these vaccines.

#### D. Recombinant DNA-Based Vaccine Approaches

None of the vaccines produced in Asia has been licensed for use outside their country of origin, and it is not likely that any will. The inherent problems associated with rodent-brain-derived vaccines, such as concerns about allergic encephalitis and potential prion-mediated diseases, make this approach unattractive. Cell-culture-derived hantavirus vaccines suffer from production problems associated with maintaining certified cells in acceptable substrates, purification, and inactivation of infectious virus, and formulation with adjuvant. In addition, because hantaviruses grow slowly and only to low titer, such vaccines would likely be expensive if produced under conditions mandated in many countries. To avoid these problems, recombinant DNA

approaches have been the preferred method of vaccine development for HFRS outside of Asia.

Several recombinant DNA vaccine approaches have been evaluated in animals. These include the following: baculovirus-derived expression products [25,53], *E. coli*-expression products [28], chimeric and mosaic hepatitis B core antigens [54,55], packaged Sindbis replicons and DNA-launched Sindbis replicons [56], and naked DNA [27,57,58]. A comparison of the protective properties of these vaccine candidates in various models was reviewed recently elsewhere [51]. To date, only one recombinant DNA-based vaccine has been tested in humans. A recombinant vaccinia virus (VACV) was engineered from the Connaught strain of VACV to express both the M and S gene segments of HTNV [26]. The M segment, which encodes the two envelope glycoproteins (G1 and G2), was chosen to elicit neutralizing antibodies. The S segment, which encodes the nucleocapsid (N), was included because of earlier studies that demonstrated that vaccination with baculovirus-derived N elicited protective immunity to infection in hamsters [25]. The vaccine was tested in Phase I and Phase II clinical trials [59]. Neutralizing antibody responses (geometric mean titer, 160) were found in 72% of the 43 VACV-naïve volunteers who received two doses of vaccine by subcutaneous inoculation in the Phase II trial. However, only 26% of the 47 VACV-immune volunteers developed neutralizing antibodies to HTNV after two vaccinations (geometric mean titer 24). Evaluation of lymphocyte proliferative responses to HTNV, SNV, and VACV of Phase I volunteers demonstrated a cross-reactive response with SNV and indicated that VACV-naïve individuals had more vigorous responses than VACV-immune individuals [59]. The outcome of the study indicated that unlike experiments in hamsters [25], in which preexisting immunity to VACV was not an obstacle to successful vaccination, preexisting immunity to VACV in humans interfered with the ability of the vaccine to elicit a neutralizing antibody response.

Of the potential vaccine platforms assessed so far, DNA vaccines appear to be closest to further evaluation in humans. Comparing HTNV and SEOV M segment DNA vaccines delivered by gene gun to the recombinant VACV M+S vaccine in rhesus macaques demonstrated that the DNA vaccines elicited higher amounts of and longer-lasting neutralizing antibody responses than did the VACV vaccine [27]. Unlike results in hamsters, however, only low levels of cross-neutralizing antibodies to heterotypic virus (HTNV or SEOV) were observed. These results are similar to those observed in humans inoculated with the monovalent, cell-culture-derived Chinese vaccines. Further studies are needed to define more fully the minimal complement of hantaviral genes needed for vaccine efficacy in areas where more than one hantavirus causes disease.

## II. TOWARD A HUMAN LASSA FEVER VACCINE

### A. The Public Health Problem of Lassa Fever

Lassa fever is a viral hemorrhagic fever caused by an *Arenavirus*, first described in West Africa in the 1950s, although the virus was not isolated until 1969 [60,61].

*Arenaviruses* produce mostly silent, persistent infection in rodents. The principal risk to humans from Lassa virus is that the natural host, a small African rat, *Mastomys natalensis*, has successfully adapted to a peridomestic life in village houses in West Africa [62]. Exposure to the virus is therefore frequent, and with the human population growth in the endemic area over the last 50 years, the opportunities for human exposure to this virus, and thus risk of disease, have increased. Among the hemorrhagic fevers, Lassa fever affects by far the largest number of people, creating a geographic patchwork of endemic foci encompassing a population of ~180 million from Guinea to eastern Nigeria.

The lymphocytic choriomeningitis virus (LCMV) and Lassa virus (LASV) complex viruses are monophyletic with three distinct lineages, one of which contains Lassa, Mopeia, and Mobala viruses [63]. Mopeia comes from southern Africa and Mobala from central Africa, and both are carried by related *Mastomys* species [64]. Both can infect humans, but are apparently unable to cause significant clinical disease. Experimental infection of nonhuman primates (NHPs) with Mopeia virus is also silent. Mopeia virus has been proposed as a potential live-attenuated Lassa vaccine, and it is effective as such in NHPs.

In some areas of West Africa 50% of domestic rodents may be *Mastomys* [62]. Because Lassa virus is transmitted vertically in these rodents, infection of local populations of rodents tends to cluster. Thus, human infections tend also to be focal with periodic familial or village clusters against a background of single infections that make up the bulk of endemic disease. Over 200,000 Lassa virus infections are estimated to occur annually, with several thousand deaths [62,65–67]. Lassa fever occurs in all age groups and sexes and antibody prevalence increases with age. This is compatible with viral transmission to humans in and around the homes where the *Mastomys* live. Estimates of antibody prevalence range from 4–6% in Guinea to 15–20% in Nigeria, though in some villages in Sierra Leone, as many as 60% of the population have evidence of past infection. Among hospitalized patients, the mortality is 17% if untreated. In endemic areas, Lassa fever may account for 10–16% of all adult medical admissions and about 30% of adult deaths. Lassa fever also affects children, with higher mortality in infants [68,69].

Person-to-person spread of Lassa virus occurs within homes as well as in hospitals where the main problems have been inadequate disinfection and direct contact with infected blood and contaminated needles. The nosocomial epidemics can be devastating, resulting in deaths of patients and health care workers [70,71].

Lassa fever is an increasing threat that now affects West African communities outside of the broad area of rural endemicity. Indeed, urban Lassa fever in West Africa has been increasing in frequency [71]. In early 2000, hospital epidemics occurred in large towns in Nigeria, the most populous country in Africa. Since 1990, severe social disruption from conflicts and terror campaigns in Sierra Leone and Liberia have resulted in displacement of up to 2,000,000 people—25% of the population of the area—with a substantial increase in the already large number of Lassa fever cases and deaths. Lassa fever is the exotic hemorrhagic fever

most likely to infect returning travelers. In the year 2000, four cases imported into Europe [72] died due to delay in diagnosis and in instituting antiviral therapy (ribavirin). Increased cases in non-West Africans have been seen since 2000 among United Nations peacekeeping efforts in Sierra Leone [73].

### B. The Disease

Lassa fever begins insidiously, after an incubation period of 7–18 days, with fever, weakness, malaise, and severe headache—usually frontal—and a painful sore throat [74]. Up to a third of hospitalized Lassa fever patients progress to a prostrating illness 6 to 8 days after onset of fever, usually with persistent vomiting and diarrhea. Bleeding is seen in only 15–20% of patients, limited primarily to the mucosal surfaces or occasionally conjunctival hemorrhages or gastrointestinal or vaginal bleeding. Severe pulmonary edema and adult respiratory distress syndrome is common in fatal cases with gross head and neck edema, pharyngeal stridor, and hypovolemic shock. Case fatality in hospitalized patients is about 16%, albeit higher in some Nigerian outbreaks and in pregnant women in the third trimester (30–70% depending on the quality of obstetric care) [75]. Lassa fever may result in long-term sequelae. For example, nearly 30% of patients with Lassa fever suffer unilateral or bilateral deafness [76]. About half of the patients show a near or complete recovery by 3–4 months after onset, but the other half continue with significant sensorineural deafness, which after about a year will be permanent [76].

### C. Molecular Biology of Lassa Virus

Like all arenaviruses, Lassa virus is an enveloped, pleomorphic, membrane virus with a mean diameter of 110–130 nm [1]. It contains two segments of single-stranded RNA, tightly associated with a nucleocapsid protein of molecular weight 65,000–72,000. The large strand of ambisense RNA, of molecular weight  $(2.0\text{--}3.2)\times 10^6$ , encodes the viral polymerase and a zinc-binding RING protein [77]. The small RNA ambisense single-strand, molecular weight about  $(1.1\text{--}1.6)\times 10^6$ , encodes the glycoprotein precursor (GPC) and the nucleoprotein (N). The genome is enclosed in a membrane bearing two glycosylated proteins of molecular weights of about 34,000–44,000 (G1) and 54,000–72,000 (G2), derived from GPC by posttranslational cleavage. Antigenic cross-reactivity by monoclonal antibodies occurs at least at one epitopic site across all known arenaviruses, but more cross-reactivity occurs between more geographically proximal viruses [78].

### D. The Immunology of Lassa Fever

This rodent virus is handled quite differently by the immune systems of rodents and primates. In rodents, persistent infection ensues with little effect on the rodent. In humans, clearance of Lassa and LCM viruses depends primarily on cytotoxic T cells, while neutralizing antibodies are associated with clearance of viremia due to the South American arenaviruses [79]. There appears to be a brisk B-cell response with a classic primary IgG and IgM antibody response to Lassa

virus early in the illness. Development of antibody, however, does not coincide with viral clearance, and high viremia and high IgG and IgM titers often coexist in both humans and primates [80]. Indeed, virus may persist in the serum and urine of humans for several weeks after infection, and possibly in occult sites, such as renal tubules, for longer.

Neutralizing antibodies to Lassa virus are rarely detected in the serum of patients at the beginning of convalescence, and in most people and in experimentally infected monkeys, they are never detectable by a classical plaque reduction–neutralization assay. In a minority of patients, some low-titer serum neutralizing activity may be observed several months after resolution of the disease, but only by using a fixed-serum varying-virus dilution assay (log neutralization assay) [81]. Passive protection from Lassa virus has been demonstrated in animals given selected antiserum but only at the time or soon after inoculation with virus. While there have been anecdotal reports on the clinical effectiveness of Lassa immune plasma, controlled clinical trials with human convalescent plasma containing high-titer antibodies have shown no protective effect. Thus, the clearance of Lassa virus appears to be independent of antibody formation, and presumably depends on the CMI response.

### E. Prevention of Lassa Fever: Why a Vaccine?

Lassa virus is acquired in the community either from infected rodents or from people. Rodent to human infection is highly associated with indiscriminate food storage, and practices such as catching, cooking, and eating rodents [62]. Person-to-person spread of Lassa virus in households is common, and in villages, risk of infection is associated with direct contact with someone during the acute phases of illness. Preventing rodent/human contact will eliminate the bulk of the primary cases, and if these are prevented, then person-to-person spread will be eliminated. Control could be largely achieved by improving living conditions, food storage, education, and general hygiene in the community.

Direct contact between virus-contaminated articles and surfaces and cuts and scratches on bare hands and feet may be the most important and consistent mode of transmission in endemic areas. The sporadic pattern of human infection in households suggests that aerosol is not a mode of transmission. Rodent control can reduce the risk of Lassa fever considerably, but rodent control on the scale needed in rural West Africa is unlikely [82]. Similarly, economic development that might lead to improvements in housing, food storage, and education is unlikely to ensue soon in conflict ravaged West Africa. On the contrary, Lassa fever cases continue to increase with displacement of large populations throughout the endemic areas in Liberia and Sierra Leone and in parts of Nigeria. An effective vaccine could be a useful control measure, assuming that it could be delivered in face of the social upheaval affecting endemic areas.

### F. Is a Vaccine Feasible?

Data from human observations in the field show that immunity is achievable, as a single infection with Lassa virus provides long-term protective immunity against future dis-

ease. A second clinical attack of Lassa fever has never been documented despite more than 13 years of continuous observation in a single endemic area (J. B. McCormick, unpublished data). People living or working in conditions where repeated exposure could be expected do have periodic rises in Lassa-virus-specific antibody titers, but no disease [62,83].

There is an excellent precedent for Lassa vaccine in Argentina, where a successful vaccine for AHF has now undergone Phase III studies, and is in use in the endemic area of Argentina, where it has all but eliminated the disease [84]. This is a live-attenuated vaccine, designated Candid1.

## G. Options for a Vaccine

### 1. Live-Attenuated Vaccine

Approaches to vaccines to Lassa virus began in the 1980s. Soon after its isolation, it was shown that Mopeia virus provides monkeys with full protection against fatal Lassa virus challenge [85]. However, data on Mopeia virus are limited, and the virus is classified as BSL3, mostly because of “guilt by association.” In many ways it is an ideal “natural” vaccine, but concerns for safety have not yet allowed us to consider Mopeia a valid option and there are currently no other live candidates in sight [86,87].

### 2. Killed Whole Virus Vaccine Candidates

A killed vaccine was tried in nonhuman primates and found to offer no protection at all [88]. Vaccination of primates with inactivated (gamma irradiated) whole Lassa virus resulted in antibody responses to both envelope proteins, and a brisk booster response after challenge, but all animals died with serum viral titers equal to unvaccinated controls (Table 1). This disappointing experience further emphasizes that protection depends on the ability to elicit a robust T-cell response.

### 3. Genetically Engineered Virus Vaccine Candidates

The first genetically engineered vaccines appeared in the early 1980s. S segment sequences of the Lassa virus genome were expressed as a fusion protein in *Escherichia coli* [89]. The Lister strain of vaccinia virus was used to express the nucleocapsid gene of Lassa virus. Guinea pigs vaccinated with the recombinant virus were protected against challenge of  $10^2$  of Lassa virus, whereas control animals died [90]. This recombinant, however, did not protect primates. It was not until the glycoprotein was expressed in vaccinia that both guinea pigs and primates were uniformly protected [91]. The protection resulting from vaccination with the recombinant virus vaccines did not correlate with the levels of prechallenge serum antibodies, suggesting that a CMI response is a critical component of protective immunity to Lassa fever [92,93].

A broader study of protection was performed with a range of recombinant vaccinia viruses expressing NP, GPC, and combinations of these proteins [87,92]. The studies were performed using 44 nonhuman primates: 28 *Macaca mulatta* (rhesus) and 16 *Macaca fascicularis* (cynomolgus). The recombinant vaccinia viruses expressed S-segment Lassa structural proteins derived from the Josiah strain of Lassa virus, namely: (1) the full-length glycoprotein (V-LSG), (2) the nucleoprotein (V-LSN), (3) full-length glycoprotein and nucleoprotein in the same construct (V-LSG/N), and (4) single glycoproteins (V-LSG1, residues 1–296, and V-LSG2, deletion of residues 67–234) [87]. Two animals were “vaccinated” with Mopeia virus, which, as it produces no symptoms in humans or in monkeys, was used as a live-attenuated positive control; both animals “vaccinated” with Mopeia were protected. All animals were challenged subcutaneously with  $10^3$  to  $10^4$  plaque-forming units (PFU) of the Josiah strain of Lassa virus. After Lassa virus challenge, all unvac-

cinated animals died (0% survival) (Table 2), whereas 9 of 10 animals vaccinated with full S segment proteins survived (90% survival). Although no animals that received full-length glycoprotein alone had high-titer antibody before challenge, 8 of 9 survived (89%). In contrast, all animals vaccinated with nucleoprotein developed high-titer antibody but 8 of 11 died (27% survival). No animals vaccinated with single glycoproteins (G1 or G2) survived challenge but all those that received both single glycoproteins (G1 + G2) at separate sites survived, showing that both glycoproteins are independently important in protection [87]. Neither group of survivors had demonstrable antibody after vaccination and before challenge.

These data show that the GPC gene is necessary and sufficient to protect primates against a large parenteral challenge dose. Still, we conclude that antibody, even to the Lassa glycoprotein, plays a minor, if any, role in clearance of infection and protection in nonhuman primates and probably humans [86,87].

#### H. Specificity of the Vaccine

Amino acid sequence comparisons between the nucleoproteins and glycoproteins reveal that the G2 envelope glycoprotein is more conserved among arenaviruses than the internal nucleoprotein [94]. Monoclonal antibody mapping of the glycoproteins of African arenaviruses also show that the G2 is more conserved than G1. Indeed there is a conserved B-cell epitope on G2 across all of the known African arenaviruses including the protective Mopeia virus, and most South American arenaviruses studied [78]. This may not be of as much consequence to vaccine design as it first appears because the variation at the level of the glycoprotein is much less, and we know that it is the antiglycoprotein CTL response that protects. Variation between Mopeia and Lassa viruses in glycoprotein sequences ranges from 20 to 25%; nevertheless, Mopeia protects in nonhuman

primates against Lassa challenge [87]. Fortunately, it may turn out that the protective CTL epitopes are relatively well conserved throughout the continent. Because there is no evolutionary pressure on the virus to evade the primate immune system, we can hope that a single vaccine strain will be adequate for the entire endemic region.

#### I. Candidates for a Human-Use Lassa Vaccine

It is likely that a Lassa fever vaccine could be developed with an acceptable safety and efficacy profile. However, the vaccinia format is no longer tenable because of potential side effects, particularly in Africa, where HIV prevalence is high.

The population to be served is poor, so a Lassa virus vaccine must be cheap, easily and safely administered, and stable. Because we have now clearly shown that a recombinant vaccine bearing the glycoprotein affords protection, the first issue is the delivery format for this protein. There are several options. A nonpathogenic vaccine such as Mopeia should work very well, but safety issues are likely to impede its development. The attraction of the live-attenuated vaccine approach is that a single immunization, as with the 17D yellow fever vaccine, might well provide protection for many years, particularly among persons living in endemic areas who might receive natural boosts to immunity. Given the remoteness and mobility of the target population, this is a highly desirable property for any vaccine candidate.

Candidate-killed vaccines have been ineffective, and without other innovations, are excluded from consideration. Attenuated poxviruses, such as the Canarypox virus [92], an avian virus that does not replicate in mammalian cells, remain a possibility, but the question is whether the immunogenicity will be sufficient, and how many doses might be needed to achieve protection.

A Lassa fever vaccine requires new approaches. DNA vaccines would offer much in the way of low-cost, stable

**Table 2** Results of Lassa Vaccine Experiments in Nonhuman Primates

Virion protein expression	Vaccine	Survivors/Total	Protection (%)	Peak viremia	Median day of death (range)
None	NYBH Vaccinia	0/3	0	6.7	15 (15–19)
	None	0/7			12 (10–15)

vaccines, but several booster doses might be needed. Another approach is to use the 17D strain of yellow fever virus as a vehicle, without losing yellow fever antigenicity, because the population at risk for Lassa fever is also exposed to yellow fever. For the long term, a yellow fever/Lassa fever chimera vaccine for use in EPI in West Africa is a very attractive solution. The cDNA clone of yellow fever virus could also be used as a vehicle for delivering Lassa virus DNA. This chimera might be a very interesting and very practical model for the future of vaccines, particularly for populations in developing countries. Yellow fever chimera vaccines are already undergoing trials for Japanese encephalitis and dengue [95,96]. However, these last two diseases are caused by flaviviruses, and the chimeras replace the yellow fever E proteins with the proteins of the related virus. A yellow fever/Lassa chimera requires a different approach, that of inserting an additional gene. Still another approach, involving a replication-defective alphavirus that carries genes of both Lassa and Ebola, has shown preliminary promise in guinea pigs [97].

#### J. Target Population

The population at risk encompasses most of the population of West Africa to Nigeria, of the order of 200 million or more by the time we have a vaccine in place. The people most at risk are the poorest of the rural inhabitants and health care workers, who should be the first people offered the vaccine. Because the epidemiological profile of Lassa fever is similar to that for yellow fever, long-term objectives should envisage inclusion of a Lassa vaccine in EPI for West Africa. However, decisions such as these will depend largely on the format of the final vaccine, particularly the recommended schedule for booster shots.

Recently, aid workers including UN personnel and NGO employees have been infected in West Africa. Consequently, travelers to the region who expect to venture outside the strict confines of the major cities should be considered targets for vaccination. Finally, laboratory staff in any country likely to receive specimens from Lassa-virus-infected patients, staff caring for sick returning travelers from Lassa endemic regions, or those working with Lassa virus in research capacity, would also benefit from a future licensed vaccine. Indeed, the existence of an effective vaccine should allow the virus to be downgraded to BSL3, because at that point it would not only be treatable but preventable.

#### K. Economics and Clinical Trials

The economic and political obstacles to producing an effective Lassa fever vaccine far outweigh the practical and scientific obstacles. The fear of biological warfare and manipulation of the hemorrhagic fever viruses, including Lassa virus, to produce weapons has spurred some publicly funded research. The fact remains, however, that there is not a credible market for a Lassa fever vaccine, despite the endemic disease burden and risk to travelers and laboratory workers.

Among the viral hemorrhagic fevers, Lassa fever along with hantaviruses afflicts the greatest number of victims and

represents an emerging disease that could threaten larger communities. Although development of an effective and safe vaccine is scientifically feasible, obstacles to Lassa fever vaccine development are more economic than scientific. The challenge is to overcome these obstacles.

### III. VACCINES AGAINST FILOVIRUSES

#### A. Filoviruses and Filovirus Disease

Filoviruses (from the Latin *filum*: thread, as in *filament*) are distinctively pleomorphic, threadlike viral particles, measuring 78–80 nm in diameter with median lengths of ca. 790 nm (Marburg virus) to 970 nm (Ebola virus) [98]. One of the families in the viral order Mononegavirales, filoviruses contain nonsegmented, negative-stranded RNA genomes of about 19 kb. In the most recent taxonomy [1], the constellation of distinct but related viruses known as Marburg virus is considered a single species, and given the abbreviation MARV; Ebola viruses (EBOV) are even more diverse and divided into four species, with corresponding abbreviations for the species called Zaire (ZEBOV), Sudan (SEBOV), Cote d'Ivoire (CIEBOV), and Reston (REBOV). Most remarkable about filoviruses is the high mortality rate of the hemorrhagic fever that ensues upon infection: case fatality rates have been as high as 88% (ZEBOV), 67% (MARV), and 53% (SEBOV). This, together with the demonstrated potential for airborne infection [99,100], and the concern that at least one of these viruses (MARV) was carried to an advanced form of weaponization [101,102], have raised the alarm about their potential uses as weapons of mass casualty and terror, and have underscored the need for antiviral therapies and preventive vaccines [103].

The first documented and characterized filovirus outbreak occurred in 1967 consequent to Ugandan nonhuman primates imported to Marburg, Germany [104]. Ebola virus was recognized in 1976, and subsequent recorded outbreaks of both viruses were sporadic. More recently, whether due to increased incidence or better surveillance, outbreaks of human disease are typically observed almost every year in sub-Saharan Africa [105]. Infections are transmitted through close contact with fluids or tissues from infected patients or monkeys, or by accidental exposure to infected instruments. A reservoir host in which filoviruses reside between outbreaks has not been identified, although small mammals, especially bats, have been incriminated [106].

Among the seven viral genes, the glycoprotein (GP) undergoes abundant N- and O-glycosylation cleavage by furinlike enzymes to two molecules called GP1 (N terminal) and GP2 (C terminal) [107]. Glycoprotein is the only protein known to be present on the surface of viral particles and infected cells, and thus has received attention as the logical candidate for cell receptor interactions and viral tropisms [108–110], antibody mediated protection [111–114], and critical pathways of virus entry and egress [109,110,115]. VP35 has been described as an interferon antagonist, a functional analog of proteins found in such diverse viruses as influenza and vaccinia, and which appear to increase viral virulence in some hosts [116]. NP is a nucleoprotein with observed molecular mass ( $M_r$ ) of ca. 100 kDa, and VP40 is a

matrix protein essential for viral formation and budding [115]. With all species of EBOV but not MARV, the genome encodes and produces in abundance a truncated and partially frame-shifted variant of GP known as soluble GP (sGP); its role in EBOV biology remains an enigma, as does its relevance to immunity [107,117].

## B. Animal Models of Filovirus Infection and Immunity

In terms of experimental infections by any of several routes, the known filoviruses are extraordinarily virulent for NHPs, usually exceeding 90% mortality, though typical manifestations of disease and times to death may vary between NHP species [100,118–121]. In NHPs, lethal doses tend to equate with infectious doses, which in turn are more numerous than the plaque-forming units conventionally measured in cell culture. By comparison, human susceptibility is difficult to judge from fragmented epidemiological data; in general, humans appear only marginally less susceptible than NHP, with the exception of REBOV, which is highly virulent in NHP but has not been associated with human disease. Guinea pigs are typically vulnerable to infection but not to death when infected with primary filovirus isolates, but several Marburg and Ebola viruses have been rendered lethal for guinea pigs by serial passage in this species [104,111,117,119]. Mice are even more refractory to lethal infection, and only ZEBOV has been adapted to lethal infection of immunocompetent mice [122]. From the capacity of several Ebola and Marburg viruses to cause lethal infection in severe combined immunodeficient (SCID) mice, it was inferred that any innate immunity to filoviruses in mice is not absolute, and that resistance to disease and death require adaptive immune responses in this species [122]. Several other animal species, including bats, can be infected by ZEBOV [106], but much remains unknown about potential host ranges of these viruses.

Filoviruses are relatively promiscuous in their binding and entry into numerous cell types *in vitro*, with only lymphocytes being wholly refractory [110,123], yet filovirus infections of mice, monkeys, and humans indicate substantial biases in the cells and tissues affected. Whether by virtue of higher receptor affinities (and/or unidentified coreceptors), or less specific phagocytic properties, it is striking that both Marburg and Ebola viruses preferentially infect cells of the monocyte–macrophage lineage early in infection [104,107,121]. What marks lethal infections is that viral infection proceeds to high levels (e.g.,  $10^8$  PFU/mL in blood, and higher in some organs) unchecked by an effective immune response [104,124], with death some 7–16 days (typically shorter in NHPs) after onset of febrile disease. Endothelial cell infection is prominent late in infection, as are infections of liver and other organs; but disease manifestations differ sufficiently among human cases in a single outbreak, among different filoviruses, and among animal models for a given filovirus, that a universal pathogenetic pathway has eluded description. Interferon was suggested as a potential therapeutic approach in mice [122] but only delayed death in NHP [125]. VP35 was found to act as an interferon antagonist [116], fitting into a pattern of viral

evasion of host innate immunity established previously with influenza virus and its interferon antagonist NS1. The mechanism by which host interferon responses may affect resistance is unclear, and host factors that affect viral replication in different cells or host species also remain to be identified.

### 1. Immune Responses in Animal Models

As with most infectious diseases, protection against filoviruses is thought to involve both innate and adaptive immune responses, the former perhaps crucial in the fate of nonimmune persons [124,126] and animals, the latter more the target of vaccine technology. Current knowledge of the roles of cellular and humoral immunity to filoviruses is at best an incomplete guide to the kinds and specificities of responses to be evoked by effective filovirus vaccines. Experimental transfers of sera or monoclonal antibodies, derived from convalescent or hyperimmunized animals, into naive (unvaccinated) animals, have yielded mixed results that ultimately do support a significant role for antibodies. For MARV, sera from guinea pigs—elicited by nonlethal infection or by vaccination with killed virus in adjuvant—was able to protect nonimmune guinea pigs [104,127]; moreover, murine monoclonal antibodies were moderately efficacious in guinea pigs [111]. For ZEBOV, certain murine monoclonal antibodies reactive with GP were proven capable of preventing lethal infection (in a murine disease model) in both prophylactic and therapeutic regimens, and the data suggested complex requirements of specificity, affinity, and perhaps isotype for optimal antibody effectiveness [112]. A human monoclonal antibody showed some efficacy against ZEBOV in guinea pigs [114]. In NHPs, the protection afforded by transferred antibodies has been more difficult to demonstrate, with reports of significant success [128] opposed by others that showed only a delay in viremia and death [125]. With both MARV [104] and EBOV [129], plasma or whole blood from convalescent patients has been used during outbreaks in attempts to mitigate disease in the later victims of the outbreak; the treatments were interpreted as harmless and arguably helpful, but were confounded by small sample sizes, patient selection criteria, and an observed tendency for mortality rates to decrease during filovirus outbreaks. A further complicating factor in filovirus vaccine development strategies is that no reliable laboratory correlate has been identified for the protective effects of antibodies: the term “neutralizing antibody” has proven wholly inadequate to describe events either *in vitro* or *in vivo* [112,117,118,127]. ZEBOV data affirm a longstanding observation with many viruses, namely, that some antibodies may lack any demonstrable neutralizing activity *in vitro* but nonetheless mediate protection *in vivo*. Except for a provocative assertion of protection by nonneutralizing anti-VP40 antibodies with Marburg virus [130], it appears that protective antibodies against filoviruses are directed against GP, and that, absent the discovery of particularly effective subpopulations, such antibodies by themselves may be inadequate to afford robust protection.

Although far from understood, the role for T cells in immunity to filoviruses appears to be highly significant. In

the murine model for ZEBOV, it was shown that CTLs are elicited by DNA- or RNA-based vaccines that contain NP [131,132] and that NP-specific CTL adoptively transferred into naive mice protected them against ZEBOV [132]. Similarly, the other internal or non-surface antigens of Ebola virions (VP40, VP35, VP30, VP24) were also proven capable of protecting against Ebola virus, and characteristic of T-cell responses, different antigens were shown more or less effective in different inbred strains of mice [133]. With MARV, the role of T cells was inferred from the capacities of NP and VP35 to protect guinea pigs [118,134], and from the capacity of NP to evoke incomplete protection in NHP [118]. In trials to determine which filoviral antigens are most effective in inducing protective immunity, GP has remained a principal candidate. That GP is a likely target not only for antibodies but also for T cells is supported by data obtained from mice [131,135] and by T-cell proliferation induced in NHPs and measured against sGP antigen [136].

Efficacy studies of Marburg virus vaccines in experimental animals have raised a notable caveat. In both guinea pigs and NHP, a minor proportion of vaccinated animals not only remained susceptible to lethal infection, but died earlier than unvaccinated controls, an accelerated but ineffectual immune response apparently exacerbating disease (reviewed in Ref. 119; see also Ref. 118). These observations underscore a need for caution in vaccine development, a lesson learned long ago with inactivated vaccines for another member of Mononegavirales, respiratory syncytial virus [137]. However, before despairing for the prospects of a safe vaccine, it should be noted that the altered disease course was only observed in the context of a viral infection that is nearly 100% lethal in unvaccinated animals. Some manifestation of “immune enhancement” is not unique to MARV, as incomplete immunity mediated either by antibodies or T cells has been shown previously in several models of viral disease to be potentially harmful. Similar observations of “early deaths” in vaccinated animals have not been reported with EBOV.

## 2. Antigenic Diversity of Filoviruses

Vaccine research to date has centered largely on the Zaire species of Ebola virus and on the Marburg virus clade that includes Popp and Musoke isolates. There exists very little serologic cross-reactivity between EBOV and MARV, and no cross-protection between these viruses has been observed. The emphasis on ZEBOV derives from its having the highest mortality rates among all filoviruses in humans, and from the experimental convenience that lethal animal models are well established for this virus in NHP, guinea pigs, and mice. However, the ability of a vaccine for ZEBOV to protect against the Sudan species (SEBOV), which has also caused major human outbreaks with high mortalities, is unknown. In particular, the GP molecule, incriminated as a principal target of protective immune responses, shares only 50% sequence identity between ZEBOV and SEBOV (Figure 2), and serological differences between these viruses are substantial [1,112]. Even for Marburg virus, where all isolates are considered a single species taxonomically, both polyclonal and monoclonal antibodies

underscore the substantial antigenic differences in GP between the Musoke and Ravn strains, imparted by 22% nonidentity in GP protein sequences [127]. The degree to which conserved epitopes [112] can be exploited to construct broadly protective vaccines versus a requirement for antigenically complex vaccines for both EBOV and MARV remains to be determined.

## C. Conventional Vaccine Approaches

### 1. Killed Vaccines

From the earliest attempts to develop classical vaccines for filoviruses, it was suggested that vaccination was feasible, yet potentially difficult. In particular, formalin-inactivated viruses evoked protective immunity in half or more vaccinated guinea pigs, with both ZEBOV [138] and MARV [119]. In subsequent studies, it was shown that purified and irradiated MARV, given in adjuvant, could evoke robust immunity in guinea pigs [127,139]. Cursory examinations of killed ZEBOV vaccines in NHPs illustrated little protective efficacy [140]. Combined with the obvious hazards of producing such vaccines, these results did little to encourage further development of killed filovirus vaccines.

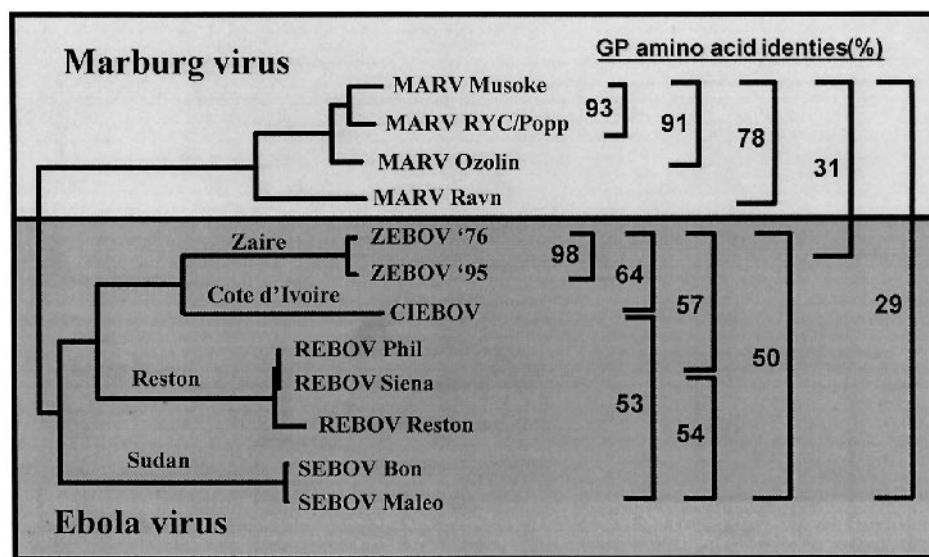

### 2. Live Vaccines

Although laboratory animals that survive filovirus infection are typically protected against lethal infection with the same isolate or a closely related virus [122,139], live-attenuated vaccines for filoviruses have not been considered widely as a safe alternative for human use. However, the recent capacity to recover infectious Ebola virus from cloned DNA and thereby insert attenuating mutations rationally and perhaps irreversibly into filoviruses [141,142] renders a live vaccine approach feasible.

## D. Recombinant DNA Vaccines

### 1. Subunit Vaccines Derived from Recombinant DNA Technology

Relatively little has been reported on the vaccine potential of individual filovirus antigens prepared first by recombinant DNA technology and then used as experimental vaccines. For MARV, some efficacy was noted with NP but not VP40 in guinea pigs [134]. The GP molecule was produced as a truncated soluble product (its C-terminal membrane anchor removed) by recombinant baculoviruses in lepidopteran cells; this antigen, together with adjuvant, was sufficient to protect most but not all guinea pigs from lethal challenge [127,139]. It was also found that the GP made in insect cells, though abundantly glycosylated, differed in its carbohydrates from the native GP made in mammalian cells [127]. EBOV vaccine efforts have largely bypassed subunit strategies in favor of other approaches [117]. As an alternative way to prepare recombinant antigen and present it to the immune system, it was recently found that viruslike particles, resembling ZEBOV or MARV both physically and antigenically, could be produced from mammalian cells in vitro; minimally, these particles required and contained both GP and VP40 [115].

**Figure 2** The phylogenetic basis of antigenic differences among filoviruses. Trees were determined from glycoprotein (GP) gene sequences. GP amino acid identities are approximations from BLASTP pairwise comparisons of translated GP genes. Marburg virus is considered a single species within its genus, while the Ebola virus genus is taxonomically divided into four species (see text, “Filoviruses and Filovirus Disease”).

## 2. Gene-Based Vaccination

A series of reports indicated that the filovirus GP molecule could serve as a protective antigen in guinea pigs or mice, and that efficacy could be achieved using any of several vaccine strategies that involved production of the antigen within the cells of vaccinated animals. Thus, recombinant GP expressed by recombinant vaccinia virus was shown to confer incomplete protection against ZEBOV [143]; GP expressed by alphavirus replicons was shown to protect against lethal MARV challenge [111,118] or ZEBOV [144]; and GP delivered as DNA plasmid was shown to protect against ZEBOV [131,135] and MARV [139] in guinea pigs or mice. When other proteins were examined, it was shown that MARV NP or VP35 delivered via alphavirus replicons could protect most guinea pigs [118], whereas the capacity of ZEBOV NP to protect guinea pigs was either negative [143,144] or equivocal [135]. In mice, where EBOV but not MARV virus could be tested in lethal challenge models, it was found that either replicon or DNA vaccines could protect, and that protective antigens included GP, NP, VP40, VP35, VP30, and VP24 [131–133,144].

The more rigorous tests of filovirus vaccine efficacies are in NHPs, the only known species for which primary isolates of filoviruses are generally even more lethal than in humans. Encouragingly, it was found that a replicon-based vaccine for MARV, whether comprised of GP or a mixture of GP and NP, afforded robust protection (no detectable viremia, no disease) in six of six cynomolgus macaques inoculated with a relatively high dose (8000 PFU) of the prototype MARV strain, Musoke. By itself, NP elicited only incomplete protection, i.e., two of three animals survived but were viremic and symptomatic [118]. An identical vaccination

protocol using a replicon expressing Ebola GP, with similar serological indices of successful vaccination (Hevey, unpublished), resulted in no protection from viremia or death in cynomolgus macaques infected with 1000 PFU Ebola virus [140]. While DNA vaccines containing GP protected the majority of monkeys from MARV (C. Schmaljohn, unpublished), neither DNA vaccines nor vaccinia recombinants proved efficacious against ZEBOV, affirming the apparently greater difficulty of protecting cynomolgus macaques from ZEBOV [140] as compared either to MARV in this primate species, or to ZEBOV in rodents.

## 3. Prime-Boost Vaccination in Nonhuman Primates

More recently, an alternative experimental approach has been used to vaccinate monkeys successfully against ZEBOV, providing new cause for optimism [136]. Cynomolgus macaques were vaccinated three times, at 4-week intervals, with a DNA-based vaccine that contained GP antigen genes from ZEBOV, SEBOV, and ICEBOV along with the NP antigen from ZEBOV. Animals were then “boosted” 12 weeks after the last DNA vaccination with  $10^{10}$  PFU of a defective adenovirus that expressed only ZEBOV GP. Twelve weeks later, after a substantial rise in antibody levels (ELISA) had been demonstrated, macaques were inoculated intraperitoneally with approximately 6 PFU of ZEBOV. Four of four vaccinated animals survived this challenge, while all four unvaccinated animals either died or were killed while symptomatic. Further studies are in progress to reconcile and explain the differences in outcomes with different vaccine approaches. Additional efforts are designed to define the mechanisms of protection and relevant immune correlates for human studies, as well as to define efficacy with

respect to viral challenge dose, route of infection, and breadth of protection against different viral isolates.

### E. Prospects for Human Vaccines

Vaccine discovery efforts with filoviruses suggest that safe and effective vaccines are achievable. Based on progress to date, the National Institutes of Health is proceeding toward a Phase 1 human safety/immunogenicity trial of a DNA-based vaccine for Ebola virus. Marburg virus vaccine candidates are also advancing through the necessary production and regulatory steps required for human trials. In either case, because controlled human trials are neither feasible nor ethical, vaccine licensure for human use will face a relatively new and daunting challenge: the requirement that efficacy in humans be unambiguously inferred from animal efficacy data. Understanding the nature of protective immune responses will be among the requirements for this task.

## IV. SUMMARY: VACCINES FOR VIRAL HEMORRHAGIC FEVERS

“Viral hemorrhagic fevers” is a collective term that is often used to simplify discussion of a highly diverse group of agents largely unfamiliar to and rarely encountered by Western medicine. As illustrated in this chapter for an important subset of these agents (hantaviruses, arenaviruses, and filoviruses), the diseases caused by these viruses are usually febrile, often deadly, but not always hemorrhagic [103]. Moreover, the antigenic structures, predominant forms of immunity required, and pathogenetic mechanisms of different viral hemorrhagic fevers are so divergent as to prevent their reduction to a single medical or vaccine problem. Recently, many have awakened to an unprecedented need to be vigilant about the natural or malevolent emergence of these viruses in society [103]. Fortunately, as shown in this chapter, much progress has already been made toward human vaccines for these viruses. Still, vaccines for hantaviruses, arenaviruses, and filoviruses remain largely untested or unproven in humans, and none is licensed for use in the United States. Adequate resources and commitment, required to bring vaccine discovery efforts to the full fruition of licensure, were previously lacking, and it remains unclear whether the recent surge in interest will be sustained.

### I. THE NEED FOR A VACCINE

Group A beta hemolytic streptococci (GABHS) cause a wide variety of infectious and postinfectious diseases ranging from the relatively benign to the very serious. Tissue-invasive forms of the disease, such as necrotizing fasciitis have a high mortality but are relatively uncommon. Pyoderma and pharyngitis are very common and can be debilitating but, in themselves, are not of major concern. Nevertheless, strep pharyngitis has been estimated to cost the U.S. economy up to \$2 billion per annum. However, these conditions can give rise to serious postinfectious diseases, rheumatic fever (RF), rheumatic heart disease (RHD), and glomerulonephritis. Untreated, between 0.3% and 3% of streptococcal pharyngitis can lead to RF and this figure can increase to up to 50% among individuals who have experienced a previous episode of RF/RHD [1]. World Health Organization (WHO) estimates that of the approximate 50 million people who die every year, 500,000 die as a result of RF/RHD [2]. This number may be an underestimate.

GABHS only infects humans, and the factors responsible for its spread include the virulence of different strains, the proximity of individuals to each other (crowding), and the degree of pre-existing immunity. It is thought by some that RF/RHD only became common during the Industrial Revolution when very large groupings in towns and cities were formed. There is little way to reliably look back at early

civilizations and estimate the prevalence of these diseases. What is clear is that there has been, overall, a dramatic decrease in RF/RHD throughout the last century in developed countries. This decrease commenced prior to the discovery of sulfonamides and penicillin, and the use of antibiotics for primary and secondary prevention [3]. A blip in this pattern of decreasing incidence occurred in the United States in the mid-1980s, when there was an approximate 10-fold increase in the number of cases of RF reported in many states [4]. Coincident with this, there has been a resurgence of all serious streptococcal diseases, including sepsis with toxic shock and necrotizing fasciitis. This change in epidemiology has raised interest in vaccine development by several biotech and pharmaceutical companies, National Institutes of Health (NIH), and university research groups. Factors responsible for the increase in disease are not clear, but evidence pointed to the circulation of more virulent strains. It was of interest that a history of a preceding strep pharyngitis was found in only 33% of patients in one study [1].

The overall decline in the incidence of RF/RHD in the developed world has not been mirrored among individuals living in developing economy nations, nor of some indigenous groups living in developed countries. Australia's aboriginal population, for example, experienced the highest reported incidence of RF worldwide (up to 650/100,000 per year) while living alongside the non-Aboriginal population, which has one of the lowest incidence figures for RF [5].

The relative death rate for Australia's Aboriginal population compared to the non-Aboriginal population for RHD is 25 (Australian Bureau of Statistics). In developing countries, RHD is a very common cause for admission to hospital relative to other cardiac conditions. In India, for example, up to 50% of all cardiac admissions are for RHD [6], with similar statistics reported in many other developing countries [7].

Given that RF only ever follows a pharyngeal infection with GABHS and that antibiotics can provide both primary and secondary prevention [8,9], there is very good reason to believe that a vaccine that prevented infection with GABHS would also prevent RF. Compliance with antibiotic prophylaxis is variable with many recurrences with RF due to poor compliance, giving further impetus to the need to develop a vaccine. A vaccine that prevents GABHS infection will obviously prevent all strep-related pathology; however, one concern is that a vaccine might stimulate a host immune response that could provoke RF [10]. Although the pathogenesis of RF is not completely understood, it is widely believed that the disease is autoimmune in etiology. In preclinical studies, candidate vaccines must be screened for their ability to induce host-reactive antibodies and T cells. Obviously, clinical trials must also monitor the development of any potentially pathogenic auto-reactive immune responses.

As in all vaccine programs, the choice of immunogen(s), the route of administration, the method of delivery, and presentation of the immunogen, and the choice of adjuvant are all likely to be critical. This chapter aims to summarize some of the current approaches looking at three different potential immunogens: C5a peptidase, group A carbohydrate antigen, and various components of the M protein. Native, recombinant, synthetic, and vectored antigens are being developed, and parenteral and mucosal delivery routes are under investigation. It is essential to develop good correlates of protection; however, antibodies are believed to provide the likely mechanism of protection. One of the major challenges facing all approaches is to provide broad protection against the majority or all of the serotypes of GABHS present in the population. There is estimated to be over 150 different serotypes, based on the M protein, but the actual number of M protein sequence types is certainly much larger.

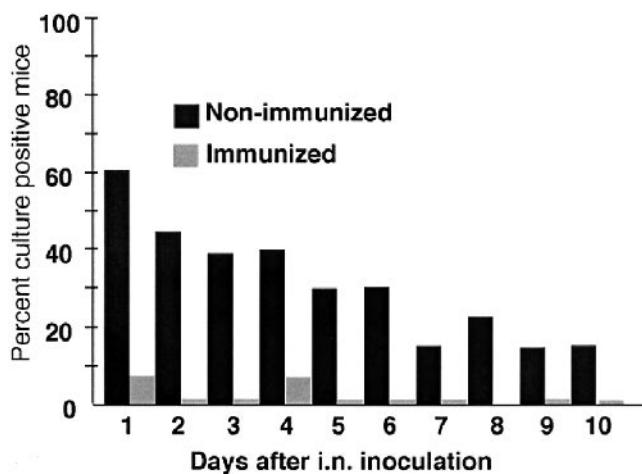

## **II. STREPTOCOCCAL C5a PEPTIDASE-SEROTYPE INDEPENDENT PROTECTION AGAINST *STREPTOCOCCUS PYOGENES***

GABHS are a moving target for M protein-based vaccines as the dominant serotypes in any given population are constantly changing with over 150 serotypes now recognized. This was most clearly demonstrated by Kaplan et al. [11], who reported nearly a complete shift from M1 to M6 strains responsible for pharyngitis over just a 6-month period in an isolated population. This observation indicates that a vaccine must contain multiple type-specific M epitopes, or peptide antigens that are antigenically conserved across serotype boundaries. One approach has been to focus vac-

cine development on the C5a peptidase, a large surface protein expressed by most, if not all, GAS serotypes. The discovery of C5a peptidase in 1985 suggested a new concept in bacterial pathogenesis [12]. It was proposed that surface-bound streptococcal C5a peptidase (SCPA) arms streptococci with the potential to destroy C5a chemotaxin at the bacterial surface, where it is formed by activation of the complement pathway, and to impede influxes of phagocytes at the initial loci of infection. C5a chemotaxin can be detected within 5 min following an inflammatory insult [13], and is therefore considered to be among the earliest initiators of a phagocytic response. Therefore, destruction of C5a is expected to delay phagocyte recruitment, providing GAS a window of time to replicate and adjust to their microchemical environment. Considerable support for this idea has accumulated over the past 15 years. In murine models, isogenic SCPA<sup>-</sup> streptococci are cleared more rapidly than parent SCPA<sup>+</sup> streptococci from subdermal sites of infection [15], and from the oral-nasal mucosa [15]. As predicted, infiltration of polymorphonuclear leukocytes PMNs and macrophages is more robust in response to SCPA<sup>-</sup> than SCPA<sup>+</sup> GABHS [14]. One surprising observation was that M protein had no measurable effect on the clearance of streptococci from the oral-nasal mucosa.

The intranasal infection model in mice was adapted to investigate whether immunization with recombinant SCPA influenced clearance of streptococci from throats of mice following infection. In initial experiments, mice were immunized without adjuvants by multiple intranasal inoculations with affinity purified SCPA protein that had been cloned from M49 streptococci [16]. Mice responded with strong serum IgA and IgM responses. Moreover, SCPA-specific secretory IgA (sIgA) was detected in saliva. Throat cultures following intranasal challenge of mice demonstrated that immunized animals cleared streptococci more rapidly than nonimmunized controls. Cross-protection against serotypes M2, M11, M1, and M6 was observed. An example of data is shown in Figure 1.

Four years ago, a collaboration between the team of Pat Cleary and Wyeth Lederle Vaccines was set up to develop a vaccine that would prevent colonization, pharyngitis, and carriage of GAS by children. Regulatory barriers were anticipated; therefore, the initial goal was to develop a traditional injectable vaccine. One of the first questions was whether parenterally administered antigen would produce protection against an intranasal challenge. The SCPA1 gene from an M1 streptococcal strain was cloned, genetically inactivated, and expressed in *Escherichia coli*. Again, protection studies made use of the intranasal infection model, except that CD1 mice were vaccinated by subcutaneous (SQ) injection with SCPA1 protein, mixed with adjuvants. Clearance of streptococci was assessed by daily throat swabs, or appraised quantitatively by viable bacterial counts in homogenized nasal tissue. Control mice were immunized with tetanus toxoid mixed with the same adjuvants. Figure 2 shows data from three experiments. Mice were immunized with recombinant SCPA1 or SCPA49 and then intranasally challenged with either serotype M1 or M49 streptococci. Immunization with either recombinant protein induced high titers of SCPA-specific serum IgG and these mice cleared

**Figure 1** Clearance of M49 streptococci by mice that were intranasally immunized with recombinant SCPA49 protein [16]. Throat cultures were performed daily following intranasal inoculation of CD1 mice by strain CS101. Mice were immunized with a truncated form of SCPA49 (gray bars) or tetanus toxoid (black bars). Each experimental group contained 13 mice. (Data from P. Cleary.)

intranasally inoculated streptococci more efficiently than controls, which had been immunized with tetanus toxoid.

Until recently, it was assumed that protection was based on antibody that neutralized C5ase enzymatic activity. New experimental results, however, indicate that SCPA and SCPB proteins are also invasins, i.e., they promote ingestion of streptococci by epithelial cells. Moreover, SCPA is also a fibronectin binding protein. Rabbit anti-SCPA or anti-SCPB inhibits ingestion of GABHS and group B streptococci, respectively. These findings raised the possibility that antibody which inhibits invasion of epithelial could be as important as C5ase activity for more rapid clearance of streptococci from the oral-nasal mucosa.

Although GABHS are a far greater public health problem,  $\beta$  hemolytic forms of groups C and G streptococci are also associated with pharyngitis, and more rarely, sepsis and other serious complications [17]. Human  $\beta$  hemolytic iso-

lates of groups B, C, and G streptococci uniformly produce SCP protein [18–20]. A vaccine that also reduces the incidence of infection by these species would be especially attractive. Hill and colleagues were the first to demonstrate production of a C5ase enzyme by group B streptococci, then it was shown that all serotypes harbor a single *scpB* gene [19]. SCPB is 95–98% identical in amino acid sequence to SCPA. Franken et al. [21] recently showed that *scpB* resides on a 7-kb composite transposon in the chromosome of group B streptococci, which can be lost during cultivation in the laboratory, leaving behind a flanking insertion sequence (IS) element. Bovine strains rarely retain the transposon, and therefore, they fail to produce peptidase. It was postulated that a single peptidase protein could induce immune responses that would protect against these other species of  $\beta$  hemolytic streptococci. Cleary's laboratory reported that anti-SCPB antibody is opsonic in whole blood, and induces killing of group B streptococci by primary bone marrow macrophage [22]. Moreover, both opsonization and macrophage killing are serotype-independent. SCPB was also found to be an exceptional carrier protein when conjugated to serotype III capsular polysaccharide. Without a protein carrier, group B streptococcal capsular polysaccharides are virtually nonimmunogenic. Recent protection experiments clearly demonstrate that SQ vaccination of mice with SCPB induces serotype transparent protection against lung infection by this species (Cheng and Cleary, unpublished).

A safe vaccine with few side reactions is the goal of any development project. It was postulated that neither SCPB nor SCPA proteins are likely to induce an autoimmune response in humans or animals. In contrast to GABHS infection, autoimmune disease is never associated with group B streptococcal infections. This epidemiological observation strongly argues that neither SCPB nor SCPA will induce a pathogenic, tissue cross-reactive immune response. SCPA protein is now under intensive scrutiny for its potential to induce a tissue reactive immune response. Although still incomplete, studies to date have not observed autoimmune antibodies in rabbits or mice following vaccination with purified recombinant protein.

The failure of children to develop a protective immune response following pharyngitis or impetigo is not understood and questions whether any GABHS product will

Vaccine Antigen	Challenge Strain	Percent positive cultures	
		Tet-toxoid Control	Peptidase Immunized
SCPA1S512A	M1	23% (5)	8%
SCPA49S512A	M1	33% (5)	8%
SCPA49S512A	M49	58% (4)	8%

**Figure 2** Parenteral vaccination with recombinant SCPA49 or SCPA1 peptidase enhances clearance of streptococci following intranasal infection. CD1 outbred mice were inoculated with recombinant antigen mixed with Alum and Monophosphoryl lipid A (Ribbi Inc.). Vaccinated mice were challenged with  $1 \times 10^9$  CFU of log phase culture. The number in parentheses is the day cultures were taken after infection. Throat cultures with one  $\beta$  hemolytic colony were considered positive. (Data from P. Cleary.)

induce protection in children. Adults are thought to be more immune to infection, but they are not absolutely resistant to streptococcal disease as evidenced by occasional outbreaks of disease among military personnel. Healthy adults do not have high levels of type-specific antibody for multiple M proteins or other protein antigens. In a small study, more than 70% of saliva from adults contained measurable levels of SCPA-specific secretory IgA and IgG [23]. This was in sharp contrast to sera obtained from children below 10 years old. Less than 15% of their saliva was found to contain SCPA-specific antibody. Measurements of SCPA-specific antibody in acute and convalescent sera also confirmed that children mount an antibody response to SCPA following infection, yet there is no evidence that these children are resistant to subsequent infection. It is not uncommon for children to have multiple infections by the same strain of streptococcus. Why don't they develop a protective immune response? One possible explanation is that streptococci suppressed the appropriate response or that children must be exposed multiple times to streptococcal proteins in order for sufficient a number of memory T cells or levels of specific antibody to be attained. Studies are in progress to evaluate the subclass of IgG, and antibody function with regard to neutralization of ingestion of streptococci by epithelial cells and to neutralization C5ase activity.

In conclusion, (1) intranasal immunization induces IgG and IgA responses, and reduces colonization by streptococci following intranasal infection; (2) subcutaneous injections of peptide with adjuvant induces a strong IgG response that speeds clearance of streptococci from the oral–nasal mucosa; (3) both intranasal and parental routes of administration of a single peptide induce protection against multiple serotypes.

### III. GROUP A STREPTOCOCCAL CARBOHYDRATE

The general dogma for over 60 years has been that the broad-based immunity to group A streptococcal infections [24] which appears with increasing age is attributable to the presence of multiple type-specific antibodies in the serum of these individuals. Yet, as demonstrated by Dr. Lancefield's studies [25], the presence of multiple type-specific M protein antibodies in human sera is actually quite rare. In view of these observations, various groups looked for other antigens that might induce broad-based immunity and antibodies prepared against these antigens that might be both phagocytic and protective in an animal challenge model. A previous report [26] indicated that antibodies to the group A carbohydrate (GRA CHO) increased with age, antibodies were phagocytic for multiple type-specific streptococcal strains, and that specific removal of the antibody (leaving all others present in the serum) resulted in loss of phagocytosis. Furthermore, elution of the antibody from the *N*-acetyl glucosamine beads restored the majority of the phagocytic properties of the serum.

Several new questions have now been addressed: (1) whether these antibodies will passively protect in a mouse challenge model, (2) will active immunization with the GRA

CHO protect against a live streptococcal challenge, (3) do CHO antibodies increase with age and correlate with the presence or absence of group A streptococci in the throats of normal Mexican schoolchildren? Is there any evidence of cross-reactive antibodies induced by the GRA CHO?

1. Table 1 demonstrates that rabbit sera obtained from animals immunized with streptococcal group A CHO conjugated to TT were capable of significant passive protection against a lethal challenge mouse model using live group A streptococci.
2. Animals were actively immunized with streptococcal group A CHO-conjugated to TT subcutaneously with an average of four doses. Three different  $M^+$  strains were used in these experiments, and the number of organisms needed to kill approximately 100% of the control animals is shown in Table 2. As can be seen, immunization with group A streptococcal CHO significantly decreased the number of deaths in immunized mice when compared to controls.
3. A study of 300 normal Mexican children has shown that the anti-CHO antibody titers increase with age, and these titers correlate with the presence or absence of group A colonization in the throat. The titers of other antistreptococcal antibodies were similar in both groups. In this study of children ages 5–14, it was determined that approximately 20% carried group A streptococci in their throats. Anticarbohydrate antibodies were measured in those children with positive Group A cultures and compared to those who had negative cultures. Figure 3A shows that the titers were twice as high in children with negative cultures when compared to children with positive cultures ( $p < 0.003$ ). Figure 3B demonstrates that other antistreptococcal antibodies were equally divided between the two groups suggesting that the anticarbohydrate titers were uniquely increased in those children with negative throat cultures.

Finally, the question of whether the group A carbohydrate antibodies cross-reacted with human tissue was addressed. These questions were originally raised by Dudding and Ayoub [27], and expanded upon by Cunningham et al. [28]. Using human frozen tissue from organs known to be involved in cross-reactions between streptococcal antigens and human tissues, no evidence was found that anticarbohydrate antibodies cross-reacted with human tissue.

**Table 1** Passive Protection Test in Balb/c Mice Against Group A Streptococcus Type 6 (S43/46)

Serum	Colonies	Mice <sup>a,b</sup>
NRS	200–500	3/26b** <sup>b</sup>
Group A CHO Ab	200–500	16/26

<sup>a</sup> Number of mice survived/injected.

<sup>b</sup> Similar protection was seen against Type 3 (D58/93/7).

\*\* $p < 0.001$ .

(Data from Sabharwal, Fuchs, and Zabriskie.)

**Table 2** Active Immunization Studies with Group A Streptococcal CHO in Mice Challenged with Live Type 14 (S23) Streptococci<sup>a</sup>

Group	Adjuvant	Inoculum Range	Survived/Injected
CHO-TT Conjugate	Alum	$3-3.6 \times 10^5$	18/23* <sup>a</sup>
TT	Alum	$3-3.6 \times 10^6$	5/22* <sup>a</sup>

<sup>a</sup> Similar protection was seen against two other M<sup>+</sup> types.

\* $p < 0.001$ .

(Data from Sabharwal, Fuchs, and Zabriskie.)

drate antibodies were directed to these human antigens both by immunofluorescence and by enzyme-linked immunosorbent assays (ELISAs) using known human cytoskeletal antigens (data not shown).

In conclusion, the group A carbohydrate can elicit antibodies that are both phagocytic and protective against several different type-specific M<sup>+</sup> streptococcal strains. High titers of CHO antibodies are associated with decreased colonization of the throat by group A streptococci and the CHO antigen does not induce cross reactive antibodies to human tissue organs. For these reasons, a case can be put that group A streptococcal polysaccharide, is an excellent candidate for use as an immunogen in the prevention of GABHS infections.

#### IV. THE M PROTEIN

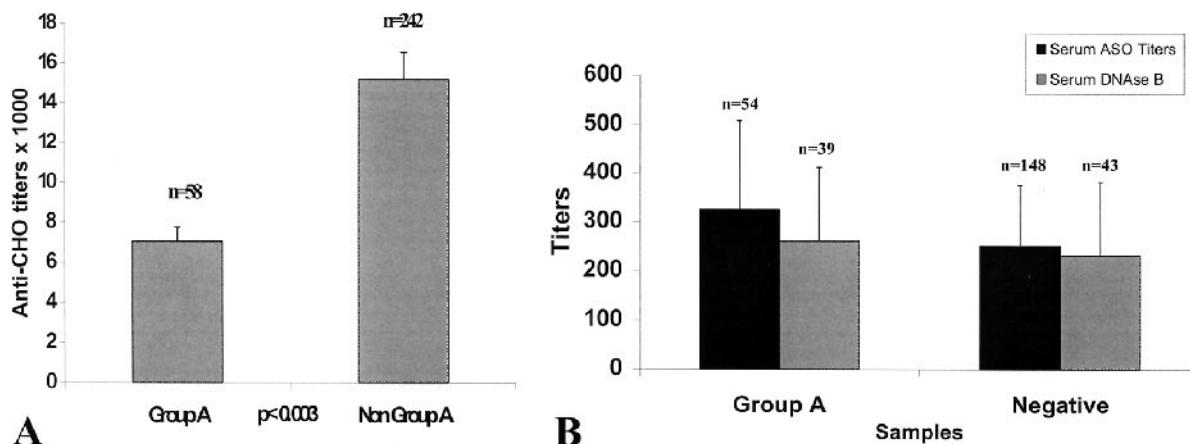

##### A. Structure and Function

Streptococcal M protein was identified over 70 years ago by Lancefield [29]. A review by Lancefield [30] clearly describes the studies carried out for nearly 35 years, defining this molecule as a major virulence factor for the streptococcus

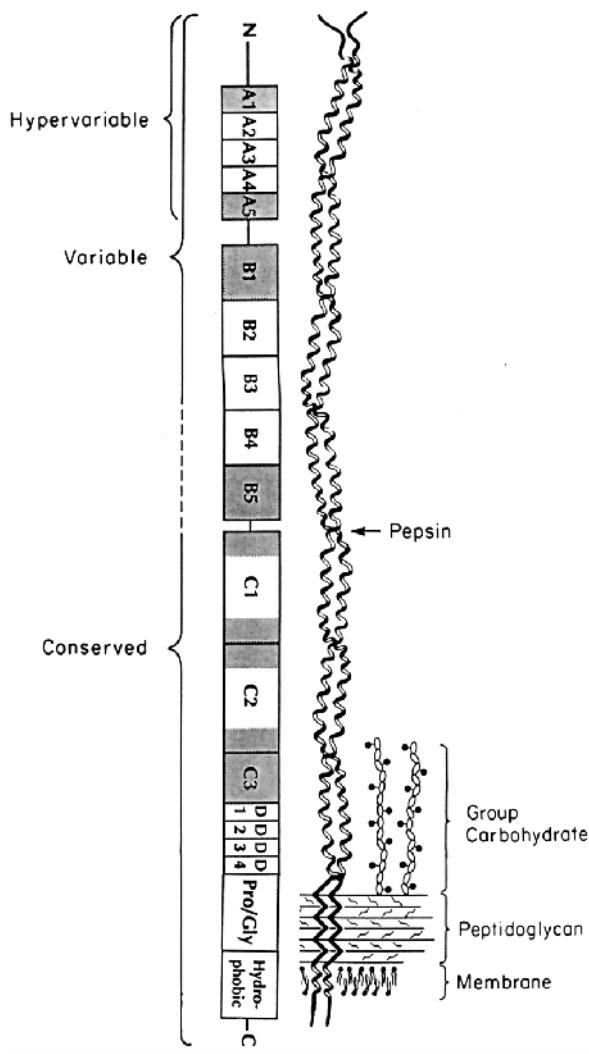

due to its antiphagocytic property. In 1974, a comprehensive review by Fox [31] delineated studies since the Lancefield review and underscored the knowledge to that time of the structure, function, and immunochemistry of the M molecule.

The streptococcal M protein is probably one of the best-defined molecules among the known bacterial virulence determinants. Clearly, protective immunity to group A streptococcal infection is achieved through antibodies directed to the M protein [32,33], a major virulence factor present on the surface of all clinical isolates. M protein is a coiled-coil fibrillar protein composed of three major segments of tandem repeat sequences that extends nearly 60 nm from the surface of the streptococcal cell wall [32] (Figure 4). The A- and B-repeats located within the N-terminal half are antigenically variable among the >150 known streptococcal types with the N-terminal nonrepetitive region and A-repeats exhibiting hypervariability. The more C-terminal C-repeats, the majority of which are surface exposed, contain epitopes that are highly conserved among the identified M proteins [34]. Because of its antigenically variable N-terminal region, the M protein provides the basis for the Lancefield serological typing scheme for group A streptococci [32].

The M protein is considered as the major virulence determinant because of its ability to prevent phagocytosis when present on the streptococcal surface and thus, by this definition, all clinical isolates express M protein. This function may in part be attributed to the specific binding of complement factor H to both the conserved C-repeat domain [35] and the fibrinogen bound to the B-repeats [36], preventing the deposition of C3b on the streptococcal surface. It is proposed that when the streptococcus contacts serum, the factor H bound to the M molecule inhibits or reverses the formation of C3b,Bb complexes and helps to convert C3b to its inactive form (iC3b) on the bacterial surface, preventing C3b-dependent phagocytosis. Some studies have shown that antibodies directed to the B- and C-repeat regions of the M protein are unable to promote

**Figure 3** (A) Anti-CHO antibody titers in serum of children with positive and negative throat cultures from group A streptococci. Note the titers in the negative sera were twice as high as those with positive cultures. (B) Serum ASO and DNAse B titers in the same population. Note that there was no significant difference in the titers of the antibodies in the sera of the patients whose throat cultures were positive or negative for group A streptococci. (Data from Sabharwal, Fuchs, and Zabriskie.)

**Figure 4** Proposed model of the M protein from M6 strain D471. The coiled-coil rod region extends about 60 nm from cell wall with a short nonhelical domain at the  $\text{NH}_2$ -terminus. The Pro/Gly-rich region of the molecule is found within the peptidoglycan. The membrane spanning segment is composed predominantly of hydrophobic amino acids and a short charged tail extends into the cytoplasm. Data suggests that the membrane anchor may be cleaved shortly after synthesis. The A-, B-, and C-repeat regions are indicated along with those segments containing conserved, variable, and hypervariable epitopes among heterologous M serotypes. Pepsin, designates the position of a pepsin susceptible site near the center of the molecule.

phagocytosis [37]. This may be the result of the ability of factor H to also control the binding of C3b to the Fc receptors on these antibodies, resulting in inefficient phagocytosis [38]. Antibodies directed to the hypervariable N-terminal region are opsonic, perhaps because they cannot be controlled by the factor H bound to the C-repeat region. Thus it appears that the streptococcus has devised a method to protect its conserved region from being used against itself by binding factor H to regulate the potentially opsonic

antibodies that bind to these regions. When this was found, Fischetti and coworkers reasoned that it could explain why even though adults are more resistant than children to streptococcal pharyngitis, they do get sporadic infections. If antibodies produced to the conserved region were in fact protective, then it would be expected that these antibodies would be protective to all serotypes encountered, because opsonic IgG is usually sterilizing (as is type-specific IgG). As this was not the case, it was suspected that another mechanism resulted in broad protection that could be occasionally breached.

### B. Rationale for Multivalent N-Terminal M Protein-Based Vaccines

As well as being a major virulence factor of the organism and being able to confer resistance to phagocytosis, the M protein is a major protective antigen. Serum antibodies against M protein are opsonic and promote bactericidal killing of group A streptococci that are mediated by polymorphonuclear leukocytes [30]. Type-specific bactericidal antibodies that develop after natural infection correlate with protection against subsequent infection with the same serotype [30] and may persist for many years [25].

These seminal observations, which were largely those of Dr. Rebecca Lancefield, have served as the basis for M protein vaccine development for over 70 years. The overall goal of multivalent M protein-based vaccines is to approximate the type-specific protection induced following natural infection [25]. Early studies by Fox and his coworkers clearly demonstrated the protective efficacy in humans of highly purified M protein vaccines [39,40]. Volunteers that were immunized parenterally [39] or locally via the upper airway [40] were protected against challenge infections with the same serotype of group A streptococci.

M proteins contain protective (opsonic) epitopes and in some cases, human tissue cross-reactive epitopes [11]. Because of the theoretical possibility of inducing autoantibodies, a challenge has been to separate the protective epitopes from the autoimmune epitopes so that vaccine preparations would contain only protective M protein peptides. Multiple studies from several laboratories have shown that the epitopes contained in the hypervariable, type-specific N-terminus of the M proteins evoke antibodies with the greatest bactericidal activity and are least likely to cross-react with host tissues [41]. In addition, the majority of the autoimmune epitopes of M proteins that have been identified are located in the middle of the mature M proteins and are distinct from the type-specific, protective epitopes [11, 41]. These observations led investigators to focus on the N-terminal type-specific peptides of M proteins for inclusion in multivalent vaccines [42–44]. Synthetic and recombinant peptides as small as 10 amino acids have been shown to protect animals against subsequent challenge infections with the homologous serotype of group A streptococci [45].

The finding that small peptides from the M proteins could evoke bactericidal antibodies that were not cross-reactive with human tissue prompted investigators to identify methods of designing and formulating vaccines that contained protective epitopes from multiple M serotypes.

One approach has been to design fusion proteins that contain multiple N-terminal M peptides in tandem. The first of these was a trivalent synthetic peptide that was linked to an unrelated carrier [46]. Subsequent vaccines were produced by using recombinant techniques in which specific 5' regions of the *emm* genes were amplified by polymerase chain reaction (PCR) and linked together in-frame using unique restriction sites. Vaccines containing 4 [42], 6 [44], 8 [43], and now 26 [47] peptides from different M serotypes have been shown to evoke broadly opsonic antibodies in animals without evoking tissue cross-reactive antibodies. Other approaches are to combine N-terminal peptides with minimal C-repeat peptides. Two clinical trials designed to assess the safety and immunogenicity of the hexavalent [44] and 26-valent [47] vaccine are currently in progress (see below).

### C. Defining a Minimal Conserved Epitope in the C-Repeat Region of the M Protein

The pathogenesis of RHD is believed to involve an autoimmune process. Studies have identified T cells in acute valvulitis lesions [48], and others have shown that such T cells can be stimulated by M protein peptides [49,50]. It has also been shown that human T-cell clones derived from the peripheral blood of individuals with or without a history of RF or signs of RHD and grown in response to a peptide from the conserved region of the M protein are able to react to myosin and an extract of human heart tissue [51]. These data suggest that while M protein-specific T cells may contribute to the pathogenesis of RHD, other factors are also required.

Given the evidence that the conserved region of the M protein can induce protection in animal models to GAS challenge [52,53], and that antibodies to conserved region peptides can be opsonic when a method based on a modification of Lancefield's original description is used [54], one approach to vaccine development has been to define minimal opsonic determinants on the conserved region of the M protein that do not stimulate T cells.

Because the M protein is conformational, it is critical that any minimal determinants are correctly folded in order to mimic native structure. A process was developed to display minimal M protein sequences within flanking non-GAS sequences designed to preserve the  $\alpha$ -helical structure of the determinant [55]. Such peptides are referred to as "chimeric" peptides, and two such peptides, "J8" and "J14," were shown to be capable of inducing opsonic antibodies in mice without stimulating T cells to the conserved region ([56,57], and Batzloff and Good, submitted). Mice vaccinated with the chimeric peptides were able to withstand an otherwise lethal GAS challenge.

### D. Combining Conserved and Serotypic Determinants

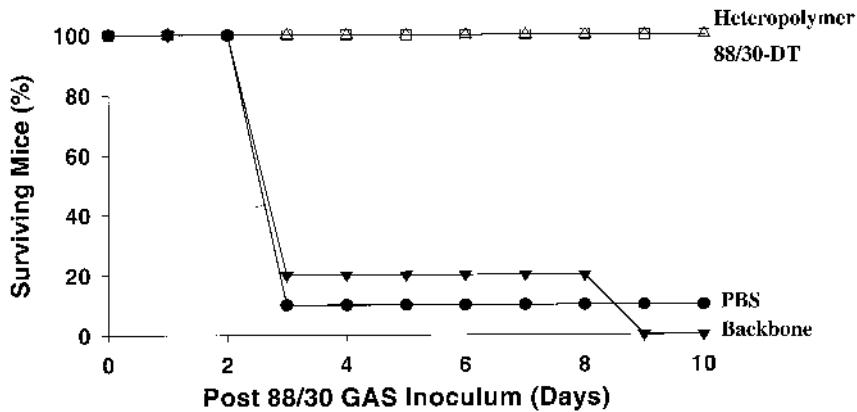

While a minimal conserved epitope can induce protection in mice against GABHS challenge [56] and can induce antibodies capable of opsonizing multiple strains of GABHS [58], it remains to be seen whether it will protect humans from GABHS and RF/RHD. We have no detailed knowl-

edge of how reliable the mouse model is for the human condition.

A theoretical concern is that antibodies to the minimal determinant are poorly opsonic compared with antibodies to the serotypic determinants [59,60]. Human antibodies specific for the conserved region taken from GAS-exposed volunteers can opsonize GABHS and there is a strong association between age-related acquisition of resistance to GABHS infection and age-related acquisition of serum antibodies to the conserved region of individuals living in highly endemic GABHS communities [61]. Nevertheless, short synthetic peptides may induce, in humans, antibodies of a different fine specificity and with less antibacterial efficacy. It could be argued that by combining a conserved epitope with a limited number of serotypic determinants representative of common strains, a more effective vaccine might result. The benefit of adding the serotypic determinants would be balanced by the drawback that strains that are common still vary between localities. Many of the strains from Thailand, for example, are "non-typeable" using reagents that can distinguish between strains common elsewhere. Strains that are common among the Australian Aboriginal population have been "typed" using a PCR approach [62] any many of these are "non-typeable" using serotypic reagents. The N-terminal peptides of seven of these common Aboriginal isolates were combined with the J14 minimal epitope using novel polymer chemistry [63]. The immunogen consisted of an alkane backbone and pendant side chains formed by the different epitopes. It is diagrammatically illustrated in Figure 5. Outbred mice were vaccinated with the polymer and the sera of the mice contained antibodies against each of the individual epitopes. The sera were able to opsonize two different strains of GAS—one of which had an N-terminal sequence present on the vaccine and one which had an N-terminal sequence not present on the vaccine. Both strains had a conserved sequence identical to the epitope found on J14. These data suggested that both the N-terminal and C-terminal-specific antibodies contributed to the bactericidal activity of the serum. Following challenge with an otherwise lethal dose of either strain, the vaccinated mice demonstrated complete protection (Figure 6).

**Figure 5** Space-filling model for "heteropolymer" immunogen consisting of alkane backbone and pendant side chains representing M protein epitopes. (From Refs. 63 and 56.)

**Figure 6** Heteropolymer with N-terminal and conserved peptide pendant side chains induces immunity to GABHS challenge (see Figure 5 and Ref. [56].)

While these data are promising, a potential drawback of this technology is that the polymerization technology cannot enable the ordering of the epitopes on the polymer to be defined. Thus it is expected that there would be batch-to-batch variation in the composition of the product which could affect immunogenicity. New polymer chemistries are being developed which will enable the production of a product with a defined order of epitopes on the polymer. Alternative approaches would be to produce a polymer as a recombinant protein or as a DNA vaccine with all epitopes joined head to tail (see above).

#### E. Toward a Mucosal Vaccine and Nontype-Specific Protection

Nearly 50% of children between the ages of 5 and 7 suffer from streptococcal infection each year. Furthermore, the siblings of a child with a streptococcal pharyngitis are 5 times more likely to acquire the organism than one of the parents. This decreased occurrence of streptococcal pharyngitis in adults might be explained by a nonspecific age-related host factor resulting in a decreased susceptibility to streptococci. Alternatively, protective antibodies directed to antigens common to a large number of GABHS serotypes might arise as a consequence of multiple infections or exposures experienced during childhood. This could result in an elevated response to conserved M protein epitopes. This latter hypothesis is partly supported by earlier studies on the immune response to the M protein, where it was found that the B-repeat domain (see Figure 4) was clearly immunodominant [64]. When rabbits were immunized with the whole M protein molecule, the first detectable antibodies were directed to the B-repeat region which rose steadily with time. It was only after repeated M protein immunization that antibodies were produced against the hypervariable A- and conserved C-repeat regions.

Unlike antibodies to the N-terminal region, antibodies directed to the exposed C-repeat region were not opsonic using the classical Lancefield methodology [37]. This result

differed from data from Good's laboratory, but may be explained by differences in the technique of the opsonization assays used by the different laboratories. In any case, experiments were performed to explore whether mucosal antibodies to this conserved region of M protein could play a role in protection from infection. Taking advantage of the pepsin site in the center of the M molecule (separating the variable and conserved regions) (Figure 4), the recombinant M6 protein was cleaved and the N- and C-terminal fragments separated by SDS-PAGE and Western blotted. When the blots were reacted with different adult human sera, all adults tested had antibodies to the C-terminal conserved region while, as expected, only sera that were opsonic for the M6 organisms reacted with the N-terminal variable region [65,66,67]. Similar studies performed with M protein isolated from five different common serotypes (M3, M5, M6, M24, M29) revealed that sera from 10 of 17 adults tested did not have N-terminal-specific antibodies to these M types, while only two sera reacted with two serotypes and the remaining five sera with only one serotype. However, all sera tested reacted to the C-terminal fragment of the M molecule. Similar results were seen when salivary IgA from adults and children were tested in ELISA against the N- and C-terminal halves of the M6 molecule (V. Fischetti, unpublished data). Overall, this is further evidence that the relative resistance of adults to streptococcal pharyngitis is clearly not due to the presence of type-specific antibodies to multiple types, but may perhaps be a result of the presence of antibodies to conserved determinants.

From these findings, it was reasoned that an immune response to the conserved region of the M molecule might afford protection by inducing a mucosal response to prevent streptococcal colonization and ultimate infection. In view of the evidence that the conserved C-repeat epitopes of the M molecule are immunologically exposed on the streptococcal surface [34], it should be possible to generate mucosal antibodies that are reactive to the majority of streptococcal types using only a few distinct conserved region antigens for immunization.

### 1. Passive Protection

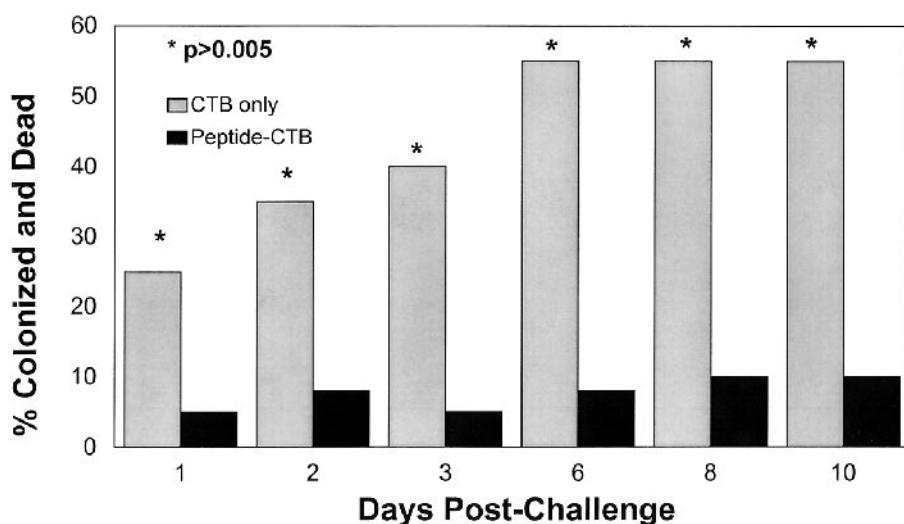

Secretory IgA (sIgA) is able to protect mucosal surfaces from infection by pathogenic microorganisms [68] despite the fact that its effector functions differ from those of serum-derived immunoglobulins [69]. When streptococci are administered intranasally to mice, they are able to cause death by first colonizing and then invading the mucosal barrier resulting in dissemination of the organism to systemic sites. Using this model Fischetti and coworkers first examined if secretory IgA (sIgA), delivered directly to the mucosa, plays a role in protecting against streptococcal infection. Live streptococci were mixed with affinity-purified M protein-specific sIgA or IgG antibodies and administered intranasally to the animals [70]. The results clearly showed that the anti-M protein sIgA protected the mice against streptococcal infection and death, whereas the opsonic serum IgG administered by the same route was without effect. This indicated that sIgA can protect at the mucosa, and may preclude the need for opsonic IgG in preventing streptococcal infection. These studies were also one of the first to compare purified, antigen-specific sIgA and serum IgG for passive protection at a mucosal site.

In another laboratory, passive protection against streptococcal pharyngeal colonization was also shown by the oral administration of purified lipoteichoic acid (LTA) but not deacylated LTA prior to oral challenge in mice [71]. The addition of anti-LTA by the same route also protected mice from oral streptococcal challenge. While several in vitro studies showed the importance of M protein [72–74] and LTA [75] in streptococcal adherence, these in vivo studies together with those presented above suggest that both M protein and LTA may play a key role in the colonization of the mouse pharyngeal mucosa. However, it is uncertain whether this is also true in humans.

### 2. Active Immunization with Conserved Region Peptides

To determine whether a local mucosal response directed to the conserved exposed epitopes of M protein can influence the course of mucosal colonization by group A streptococci, peptides corresponding to these regions were used as immunogens in a mouse model [66,67]. Overlapping synthetic peptides of the conserved region of the M6 protein were covalently linked to the mucosal adjuvant cholera toxin B subunit (CTB) and administered intranasally to mice in three weekly doses and boosted 30 days after the last dose with the peptide mixture. Ten days later, animals were challenged intranasally with live streptococci (either homologous M6 or heterologous M14) and pharyngeal colonization by the challenge organism was monitored for 10–15 days. Mice immunized with the peptide-CTB complex showed a significant reduction in colonization with either the M6 or M14 streptococci compared to mice receiving CTB alone [66,67] (Figure 7). Thus despite the fact that conserved region peptides were unable to evoke an opsonic antibody response in these studies [37], these peptides have the capacity to induce a local immune response capable of influencing the colonization of group A streptococci at the nasopharyngeal mucosa in this model system. These findings were the first to demonstrate protection against a heterologous serotype of group A streptococci with a vaccine consisting of the widely shared C-repeat region of the M6 protein.

Confirmation of these findings was later published independently using different streptococcal serotypes as the immunizing and challenge strains [76]. As mentioned above, in a separate study, Prusakorn et al. [51] found, using a different criteria for streptococcal opsonization than previously published [25], that when a peptide derived from the conserved region of the M protein was administered to mice,

**Figure 7** The extent of colonization of mice challenged with group A streptococci after oral immunization with M protein conserved region M6 peptides linked to CTB or CTB alone. Orally immunized mice were swabbed each day after challenge with M14 streptococci and plated on blood plates to determine the extent of colonization compared to mice vaccinated with CTB only. Plates showing group A streptococci were scored as positive.

it induced antibodies capable of opsonizing type 5 streptococci and streptococci isolated from Aboriginal and Thai rheumatic fever patients. These findings were in sharp contrast to the earlier studies of Jones and Fischetti [37], who showed that antibodies to the conserved region of M protein were not opsonic. However, as the peptide reported by Quinn et al. [50] is similar to one of the peptides used by Bessen and Fischetti [65,67] in their mucosal protection studies (see above), the induction of serum IgG during mucosal immunization may offer added protection against streptococcal infection.

#### F. Vectoring the M Protein

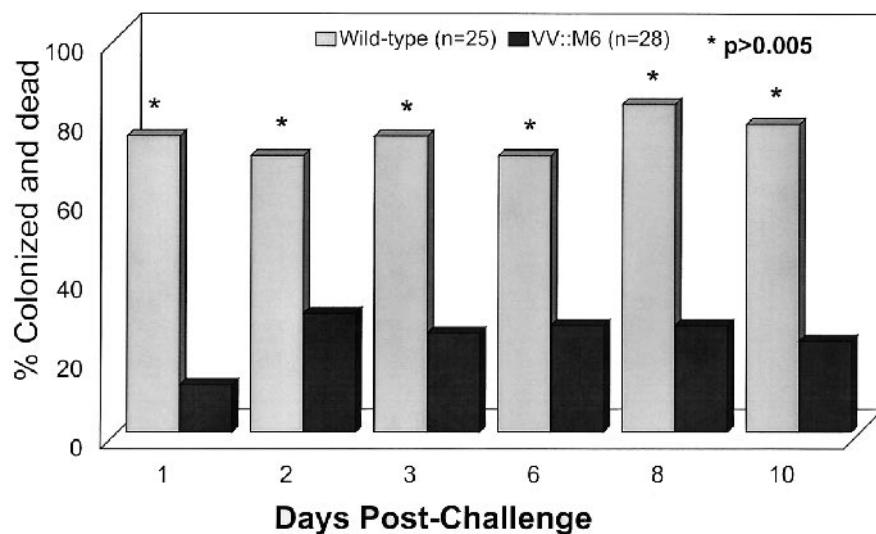

To further verify the validity of using the M protein conserved region as a streptococcal vaccine, experiments were repeated in a vaccinia virus vector system. In these studies, the gene coding for the complete conserved region of the M6 molecule (from the pepsin site to the C-terminus, see Figure 4) was cloned and expressed in vaccinia virus producing the recombinant VVM6 virus [77,78]. Tissue culture cells infected with this virus were found to produce the conserved region of the M6 molecule. Animals immunized intranasally with only a single dose of recombinant virus were significantly protected from heterologous streptococcal challenge compared to animals immunized with wild-type virus (Figure 8). When the extent of colonization was examined in those animals immunized with wild-type or the VVM6 recombinant, the VVM6-immunized animals that exhibited positive swabs, showed a marked reduction in overall colonization compared to controls, indicating that mucosal immunization reduced the bacterial load on the mucosa in these animals. Animals immunized intradermally

with the VVM6 virus and challenged intranasally showed no protection.

The approaches described above proved that induction of a local immune response was critical for protection against streptococcal colonization and that the protection was not dependent upon an opsonic response as defined using the classical Lancefield method. However, in the event that the streptococcus was successful in penetrating the mucosa and establishing an infection, only then would type-specific antibodies be necessary to eradicate the organism. This idea may perhaps explain why adults sporadically develop a streptococcal pharyngitis, i.e., a mucosal response may be breached when a large number of streptococci are encountered on the mucosal surface. The success of these strategies not only forms the basis of a broadly protective vaccine for the prevention of streptococcal pharyngitis but may offer insights for the development of other vaccines. For instance, a vaccine candidate previously shown by the parenteral route may prove to be successful by simply changing the site of immunization. Furthermore, these results emphasize the fact that in some cases antigens need to be presented to the immune system in a specific fashion to ultimately induce a protective response.

#### 1. *Streptococcus gordonii* as a Vector

The importance of the C-terminal region in the attachment of surface proteins in gram-positive bacteria was previously demonstrated using the protein A from *Staphylococcus aureus* as a model system [79,80]. Surface proteins in gram-positive bacteria (which could number more than 20 in a single organism) are synthesized and exported at the septum, where new cell wall is also being produced and translocated to the surface [32,81]. Thus the C-terminal hydrophobic

**Figure 8** The extent of colonization of mice challenged with group A streptococci after oral immunization with recombinant vaccinia virus containing the gene for the whole conserved region of the M6 protein or vaccinia virus alone. Orally immunized mice were swabbed each day after challenge with M14 streptococci and plated on blood plates to determine the extent of colonization compared to mice vaccinated with wild-type vaccinia only. Plates showing group A streptococci were scored as positive.

domain and charged tail in these proteins function to control the export and anchoring process by acting as a temporary stop to position the LPXTG motif (the anchor motif common to >100 surface proteins on gram-positive bacteria [82]) precisely at the outer surface of the cytoplasmic membrane. This sequence motif, being an enzymatic recognition sequence, is cleaved resulting in the attachment of the surface-exposed segment of the protein to a cellular substrate [79]. This idea is supported by studies indicating that the C-terminal hydrophobic domain and charged tail are missing from the streptococcal surface M protein extracted from the cell wall [79,83].

Because the anchor region is highly conserved among a wide variety of surface molecules within several different gram-positive species, could it be fused to a foreign antigen and used to deliver the resulting fusion protein to the surface of a gram-positive bacterium, ultimately anchoring it to the cell? To answer this, the streptococcal M protein was employed in a model system.

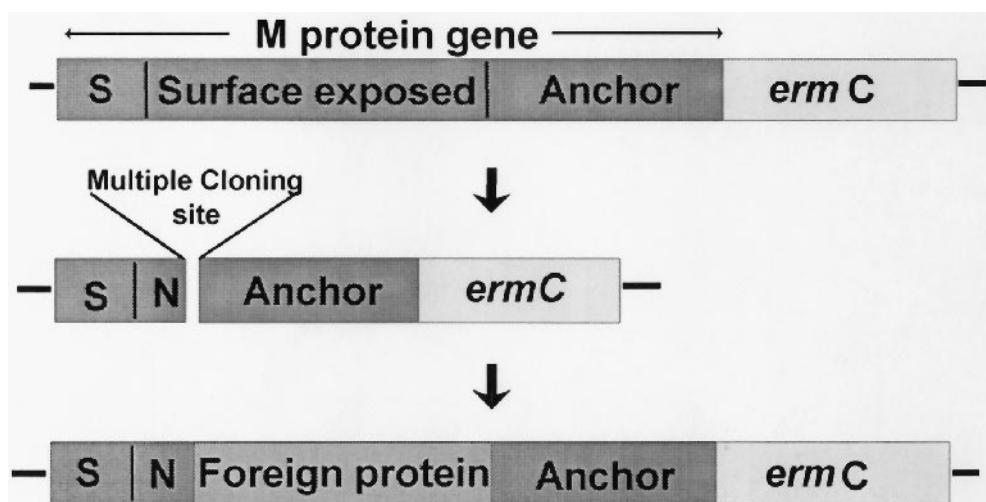

Pozzi et al. [84,85] were the first to deliver a fusion protein to the surface of the gram-positive human oral commensal *S. gordonii*. The approach utilized a knowledge of the location of the surface-exposed and wall-associated regions of the fibrillar M protein [34,83]. Thus deleting the surface-exposed segment of the M molecule and replacing it in frame with the gene for a foreign protein (i.e., the E7 protein from human papillomavirus, consisting of 294 base pairs [85]), the fusion molecule could be presented on the bacterial cell surface and tightly anchored. Using this same strategy, a variety of protein antigens ranging from a few hundred to over 700 amino acids have now been successfully expressed on the surface of the human commensal *S. gordonii* ([85–88], and unpublished data).

To be certain that the expression of the recombinant molecule would be stable for many bacterial generations, the

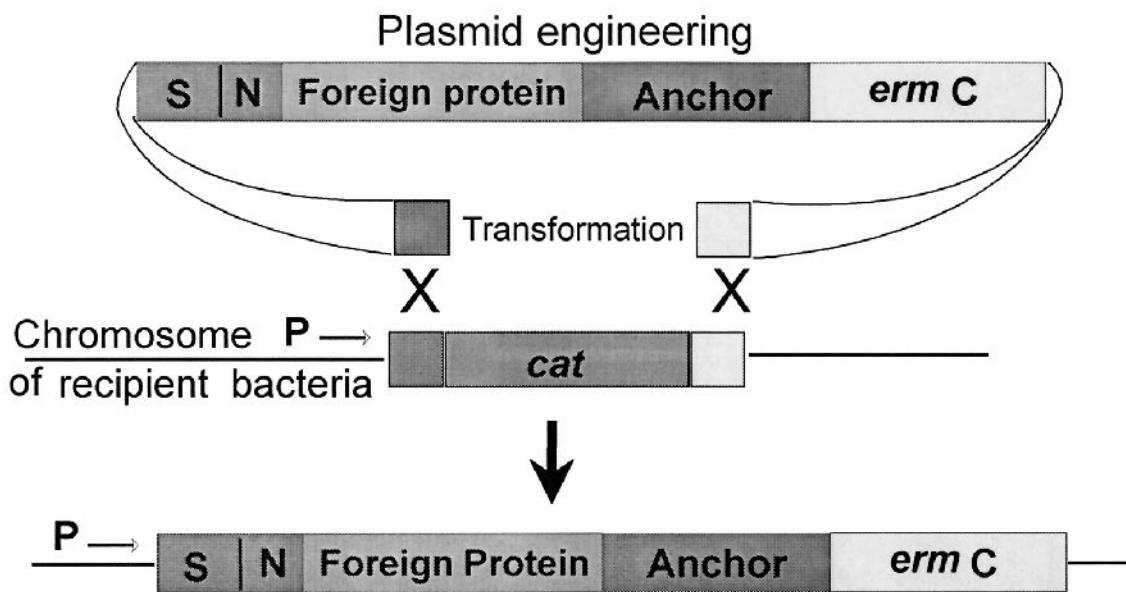

recipient *S. gordonii* was engineered such that the recombinant gene would be expressed from the chromosome under the control of an efficient resident promoter [84,85] (Figures 9 and 10). This strategy is one of the few in which the gene in question is chromosomally expressed. In contrast, most other reported live vaccine vector systems regulate their genes from high expression plasmids. Translocation of the recombinant molecule to the surface is assured by inclusion of the signal sequence and a short segment of the N-terminal region of the carrier M protein.

While the studies of Pozzi et al. [85] showed the feasibility of expressing a wide range of foreign proteins on the surface of gram-positive bacteria, an important question remained: would this mode of delivery induce an immune response, particularly a mucosal response in animals colonized by the recombinant organism? To answer this and to further verify the ability to deliver a diversity of proteins to the bacterial cell surface using this approach, Medaglini et al. [87] elected to express a 204-amino acid protein allergen from the white-faced hornet (Ag5.2) [89] on the surface of *S. gordonii*, essentially using the same methods described above [85,87] (see Figures 9 and 10). These studies clearly showed that mice colonized with the recombinant *S. gordonii* expressing the allergen were able to mount not only a mucosal response, but a serum IgG and T-cell response specifically to the allergen expressed on the *S. gordonii* cell surface.

Although still in development, the gram-positive commensal seems promising as a versatile live vector for vaccine delivery. Because the system induces both a mucosal and systemic immune response, it may be a more natural way of generating a protective response to a pathogen than systemic delivery alone. Although the animal studies indicate that this approach is feasible, human studies must be performed to determine if the same responses will be achieved. Early

**Figure 9** Engineering a fusion protein for surface expression. On a plasmid, the surface exposed region of the M protein is excised and replaced by a multiple cloning site. The foreign protein to be expressed on the bacterial surface is then inserted in frame in the multiple cloning site. The signal sequence (S) and a short segment of the M protein N-terminal sequence (N) is included in the construct to allow proper processing of the signal peptidase. The *ermC* antibiotic marker is used for selection of the construct.

**Figure 10** Insertion of the fusion protein into the gram-positive chromosome. A cassette is inserted in the chromosome of *S. gordonii* in front of a *hi* expression promoter selected at random. The cassette consists of a *cat* antibiotic reporter gene flanked by a short segment of the 5' end of the signal sequence of the M protein gene (S) and the 3' end by a short segment of the *ermC* marker. Because *S. gordonii* are naturally transformable, the linearized plasmid inserts the M-protein fusion precisely in the chromosomal cassette in front of the promoter.

experiments show that when reintroduced into the human oral cavity, *S. gordonii* is capable of persisting for over 2 years [90]; therefore, it remains to be seen if the recombinant will perform similarly and induce an immune response to the fusion protein expressed on its surface. Although an immune response is in fact generated to commensal flora [91] even in humans ([92], and unpublished data), it is not a clearing response, however, it may be expected that the same would occur with the newly introduced recombinant strain.

### G. Clinical Trials

#### 1. Preclinical Evaluation of a 26-Valent M Protein-Based Vaccine

Current epidemiological data indicate that the majority of group A streptococcal infections in the United States are caused by relatively few serotypes. Surveillance of invasive disease conducted by the Centers for Disease Control and Prevention has shown that during 1998–2000, 19 serotypes accounted for 84% of the total isolates [93]. In ongoing studies to determine the serotype distribution of group A streptococci recovered from pediatric cases of pharyngitis in the United States, it was shown that 16 different serotypes accounted for 97% of all cases of pharyngitis [94]. These data indicate that a multivalent vaccine containing M protein fragments from a limited number of serotypes could potentially have a significant impact on the overall incidences of streptococcal infections within a population. Therefore, a 26-valent vaccine was designed to include N-terminal M peptides from epidemiologically important serotypes of

group A streptococci. These include the serotypes commonly responsible for serious infections, uncomplicated pharyngitis in children, and the serotypes that are currently or historically associated with acute rheumatic fever. Based on this information, serotypes included in the 26-valent vaccine (Figure 11) account for 78% of all invasive infections, 80% of all cases of uncomplicated pharyngitis, and theoretically 100% of all “rheumatogenic” serotypes. Also included in the vaccine is a new protective antigen of group A streptococci (Spa) that is expressed by at least several serotypes [95]. Thus the 26-valent vaccine actually contains 27 distinct peptides.

The 26-valent vaccine consists of four component fusion proteins (Figure 11) that were mixed in equimolar ratios and formulated with alum to contain 400 µg of protein/dose. Three rabbits that received three intramuscular (IM) doses of the vaccine at 0, 4, and 16 weeks developed broadly opsonic antibodies that were not cross-reactive with human tissues. Antibody titers were determined by ELISA using serum obtained at 18 weeks against each of the purified recombinant dimeric peptide components of the vaccine. All preimmune titers were less than 200. Of the 81 immune serum titers determined (27 antigens × 3 rabbits), 69 titers (85%) increased by fourfold or greater. The vaccine elicited fourfold or greater increases in antibody levels against 25 of the 26 serotypes represented in the vaccine. To determine the functional activity of the M protein antibodies evoked by the 26-valent vaccine, *in vitro* opsonization and bactericidal tests were performed by using each of the 26 serotypes of group A streptococci. Opsonization assays were designed to determine the percentage of neutrophils that engulfed or

**Figure 11** Schematic diagram of the four recombinant fusion proteins contained in the 26-valent M protein-based vaccine. The number of amino acids contained in each M protein fragment is indicated below the M type. The four proteins are mixed in equimolar amounts and formulated with alum for intramuscular injection. M101 was formerly *stNS5* and M114 was formerly *st2967*. The M13 is strain M13W, which has been newly designated as M94.

were associated with streptococci after rotation in nonimmune human blood that contained either preimmune or immune rabbit serum. The preimmune sera from all three rabbits resulted in  $\leq 10\%$  opsonization of each of the 26 serotypes tested, indicating that the donor blood used for these assays did not contain antibodies against the test organism and that each organism was fully resistant to opsonization in nonimmune blood. Using 30% opsonization in the presence of immune serum as a positive threshold result, 18 of the 26 serotypes (69%) were opsonized by at least one of three immune rabbit sera.

Bactericidal assays were also performed as an additional measure of the potential protective efficacy of the 26-valent vaccine. In these assays, each of the 26 serotypes of group A streptococci was rotated in nonimmune blood for 3 hr in the presence of either preimmune or immune rabbit sera. In all experiments, the test mixture containing preimmune serum resulted in growth of the organisms to eight generations or more, again indicating that the human blood did not contain opsonic antibodies against the test strains and that each organism was fully resistant to bactericidal killing in nonimmune blood. Using 50% reduction in growth (percent killing) after the 3-hr rotation in blood containing immune serum compared to the preimmune serum as a positive threshold, bactericidal activity was observed against 22 of the 26 serotypes tested. When the results of the opsonization and bactericidal assays were combined, 24 of the 26 serotypes (92%) tested were opsonized by the immune sera in one or both assays.

In summary, these results show that a highly complex 26-valent M protein-based vaccine was immunogenic in rabbits and evoked broadly opsonic antibodies against the vast majority of vaccine serotypes. This vaccine is now being tested in Phase I clinical trials to assess its safety and immunogenicity in normal adult volunteers (see below).

## 2. Clinical Experience with Multivalent Vaccines

There are currently two Phase I clinical trials in progress to determine the safety and immunogenicity of multivalent group A streptococcal vaccines. The first trial is under the direction of Karen Kotloff, and is being conducted at the Center for Vaccine Development at the University of Maryland. This is a dose-escalating study of a hexavalent vaccine [44] formulated in alum to contain either 50, 100, or 200  $\mu\text{g}$  per dose. Each group of 8–10 adult volunteers is receiving three IM doses at 0, 4, and 16 weeks. The first two dose groups have been fully enrolled and have received the entire series of injections. Thus far, the vaccine has been well tolerated and is immunogenic. A complete analysis of the type-specific and opsonic antibody responses will be forthcoming after the completion of the 200- $\mu\text{g}$  dose study, which is the target dose for this vaccine.

The second clinical trial is as a Phase I/II study to determine the safety and immunogenicity of the 26-valent vaccine described above [47]. This study is under the direction of Scott Haperin at the IWK Grace Health Center, Dalhousie University, Halifax, Canada. In the Phase I component of this study, 30 adult volunteers are receiving 400  $\mu\text{g}$  of the 26-valent vaccine formulated with alum administered IM at 0, 4, and 16 weeks. The trial has been fully enrolled and is scheduled to be completed in 2002. Because the primary target population for this vaccine is preschool children, the Phase II trial will include two groups of 200 each, ages 3–6 and 10–14, who will receive 400  $\mu\text{g}$  of the vaccine at 0, 4, and 16 weeks.

## 3. Toward Vaccine Trials with Recombinant *S. Gordonii*

Convinced that the use of a commensal bacteria as a vaccine delivery vehicle is a safe, effective, and inexpensive way to

induce a mucosal response, a recombinant *S. gordonii* was prepared which contained the C-terminal half of the M protein containing the exposed conserved region of the molecule. This segment was similar to that used successfully in the vaccinia virus experiments (see above) [77]. *S. gordonii* expressing this conserved fragment of the M protein on its surface was used to successfully colonize for up to 12 weeks all of the 10 rabbits colonized. During this time, the animals raised a salivary IgA and serum IgG response to the intact M protein. The amount of M protein-specific sIgA was up to 5% of the total IgA in the saliva of these animals. Experiments revealed that conserved region-specific IgA and IgG induced by this method do not cross-react with human heart tissue as determined by immunofluorescence assay [96].

If proven to be successful, the commensal delivery system may be ideal for the developing countries. Being a live vector, it would be easy to administer and not likely require additional doses. Also, because gram-positive bacteria are stable for long periods in the lyophilized state, a cold chain would not be required. Early studies show that when reintroduced into the human oral cavity, *S. gordonii* is capable of persisting for over 2 years, and is transmitted to other members of the family [88]. For a developing country, this factor could be ideal considering that the whole population is rarely able to immunize. However, it remains to be seen if the recombinant will induce in humans a protective immune response to the M protein fragment expressed on its surface.

Because of the uncertainties of using *S. gordonii* in humans as a live vaccine vector system, safety trials were performed utilizing this organism delivered orally and nasally to adult volunteers. To be certain that the *S. gordonii* recovered were in fact the ones installed in the volunteers, two antibiotic resistance markers were introduced in the study strain (streptomycin and 5-fluro-2-deoxyuridine). Also, under the direction of Karen Kotloff, at the Center for Vaccine Development at the University of Maryland, over 100 volunteers were tested with differing doses of the marked *S. gordonii*, and in all, the vector was well tolerated with no observed adverse events. This result not only leads us to the use of this vector system for the delivery of the M protein conserved region, but sets the stage for the utilization of this vector system for a wide variety of protein antigens.

## V. CONCLUSION

In this chapter, we have attempted to outline some of the different strategies being followed in an attempt to develop a vaccine to prevent infection with GABHS and subsequent pathology. The organism is relatively simple in its structure and life cycle, compared to some other organisms, such as the malaria parasite. Consequently, the number of strategies and vaccine candidates are more limited. This alone gives great hope. A challenge, however, and similarity with the malaria parasite, is that the greatest burden of disease is carried by people in the poorest parts of the world, making it more difficult to attract major funding from industry.

As in all areas of scientific discovery, there are the inevitable, yet healthy, differences of opinion regarding choice

of antigen and rationale for inclusion in a vaccine. The current clinical trials, either underway or planned, will shed important light on the approaches that we must focus on and hopefully convince philanthropic, government, and business organizations to invest in the development of this much-needed vaccine.

### I. GROUP B STREPTOCOCCAL DISEASE BURDEN

#### A. Newborn and Young Infants

Group B *Streptococcus* (GBS) has been a leading cause of serious bacterial infection in neonates and young infants for more than a quarter of a century. Increased awareness of this important disease resulted in prompt initiation of empiric antimicrobial therapy for suspected cases of neonatal infection based on delineated risk factors, and has been associated with a very significant reduction of mortality and an improved prognosis for infants with invasive GBS disease. During the 1990s, the overall case fatality rate was about 5%, but in prematurely born infants this is nearly 25%. Contemporary appraisal of the epidemiology of neonatal disease has affirmed that low birth weight and black ethnicity continue to be associated with enhanced risk for early-onset (age <7 days) neonatal disease and also has identified enhanced risk among infants born to Hispanic women [1]. The predominant serotypes of GBS currently causing neonatal and young infant disease are types Ia, III, and the new serotype which appeared in the 1990s, type V. Taken together, these three account for ~80% to 85% of invasive infections identified in a racially and ethnically diverse cohort from metropolitan areas in the United States [1].

Despite reduced case fatality rates, disease incidence was stable from the 1970s until the mid-1990s, when recommendations based on clinical trials demonstrated the efficacy of maternal intrapartum antibiotic prophylaxis (IAP) with intravenous penicillin G or ampicillin in preventing early-onset disease. Associated with the widespread implementation of consensus guidelines endorsed in 1996 by the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists and the Centers for Disease Control and Prevention, there has been a substantial decline in the incidence of early-onset disease. Active, multistate,

population-based surveillance has documented a 65% decrease in incidence from 1.7 cases per 1000 live births in 1993 to 0.6 per 1000 in 1998 [2]. Early-onset infection most commonly manifests as bacteremia, but ~6–7% of infants present with meningitis and a similar proportion with pneumonia. Maternal IAP has not decreased the number of late-onset (7–89 days of age) infant infections; the incidence persists at 0.3–0.5 cases per 1000 live births. Approximately one-fourth of infants with late-onset GBS disease present with meningitis and a substantial number of survivors (estimated at 20%) have neurological sequelae. Despite the widespread implementation of maternal IAP in the United States, it is projected that 2200 infants 0–6 days of age and 1400 infants 7–89 days of age will develop invasive GBS disease yearly and that 140 of these will have fatal infection.

#### B. Children

Group B streptococcal disease in children from 90 days to 14 years of age comprises a small but important portion of the total disease burden. A multistate active bacterial surveillance group tracking a population base of more than 12 million from 1993 expanding to 20 million in 1998 reported that 2% of cases of invasive GBS infections occurred in this age group, as opposed to 28% in the 0–90 days age group [2]. One-half of these patients were infants less than 6 months of age. The improved survival of extremely low birth weight infants, particularly those requiring long-term hospitalization in a neonatal intensive care unit, has extended the age of susceptibility for young infants beyond the classical definition for late-onset disease of 3 months. Many of these very late-onset infections manifest as bacteremia without a focus, and a benign outcome is typical. In children older than 6 months of age, the majority have an underlying condition predisposing to invasive infection, such as human immuno-

deficiency virus infection or a structural heart or central nervous system defect [3]. Taken as a group, the mortality rate for GBS disease in childhood is about 9% or nearly twice the case fatality in neonates.

### C. Pregnant Women

Lower vaginal or rectal colonization with GBS is a risk factor for invasive infections in pregnant women as well as their neonates. The risk of intra-amniotic infection or chorioamnionitis is significantly higher for women with high-density [ $>10^5$  colony-forming units (CFU) per mL] GBS vaginal colonization than for those with low-density colonization [4]. The advent of maternal IAP has had a small but significant impact upon invasive GBS disease, primarily bacteremia with or without endometritis or chorioamnionitis, among pregnant women, with a decline in incidence from 0.29 cases per 1000 deliveries in 1993 to 0.23 per 1000 in 1998 [2]. Despite this modest decline, there remains substantial morbidity attributable to GBS during pregnancy. Bacteremia accounted for approximately two-thirds of cases reported by investigators at the Centers for Diseases Control and Prevention; chorioamnionitis and endometritis each contributed 10% and septic abortion accounted for 7% of cases in the United States [2]. Among those for whom the outcome of pregnancy was known, 54% had infants who remained free from clinical illness, 17% had infants who had GBS disease but survived and 29% had spontaneous abortions, stillborn infants, or infants who had fatal invasive GBS infection.

### D. Nonpregnant Adults

The diminished number of neonatal GBS infections has highlighted the substantial contribution to total disease burden of invasive GBS disease in adults. More than two-thirds of all invasive GBS disease in the United States now occurs in adults and most of these infections are unrelated to pregnancy [5]. Within the past decade, a 2- to 4-fold increase in the incidence of invasive GBS disease in nonpregnant adults has been documented [6,7]. Disease rates rise with advancing age and, in two recent reports, adults 65 years of age or older had GBS infection rates of 11.9 and 28.3 per 100,000 population, respectively [5,8]. Nursing-home residents are at particularly high risk. The age-adjusted annual incidence of GBS per 100,000 population among those 65 years of age and older was 72.3 for nursing home residents and 17.5 for community residents (relative risk, 4.1) [9]. As in neonates, disease rates were significantly higher in black compared with white adults (about 2-fold higher). Adults older than 65 years of age are projected to account for ~6900 cases of invasive GBS infections in the United States yearly, or more than one-half of the total number of adult cases, and for more than 60% of the total deaths attributable to invasive GBS infections [2].

The majority of adults have at least one underlying condition that presumably enhances susceptibility to invasive GBS infection [10]. Diabetes mellitus is the most common of these and 20–40% of nonpregnant adults developing invasive GBS infection have diabetes. A number of other

conditions, including cirrhosis or other chronic liver disease, breast cancer, neurogenic bladder, and decubitus ulcer also are associated with significantly increased risk [5]. In one report, 49 of 51 episodes of GBS bacteremia in nonpregnant adults occurred in association with at least one underlying condition [6]. The aging of the population in the United States, together with improving treatments for such chronic diseases as diabetes mellitus, predict that GBS disease in nonpregnant adults will pose an ongoing and increasing proportion of the disease burden.

## II. CLINICAL TRIALS WITH VACCINES FOR GBS

This following discussion is arranged chronologically from the earliest candidate vaccines [purified capsular polysaccharides (CPS) of GBS] to the development of more recent vaccine constructs (polysaccharide–protein conjugates). Clinical trials began with monovalent capsular polysaccharides for serotype III, followed by those for types Ia and II, based on the significant perinatal disease burden attributable to these serotypes in the 1970s and 1980s. With the availability of GBS conjugate vaccines, serotypes Ib and type V vaccines have also been evaluated in healthy adults. Recently, additional studies have been completed, including testing of the effect of an adjuvant or a second dose on the immune response to type III conjugate vaccine, and of a bivalent type II/III conjugate vaccine. Most of these candidate GBS vaccines were developed and prepared at the Channing Laboratory (Boston, MA).

### A. GBS Capsular Polysaccharide Vaccines

The premise that antibodies against the capsular polysaccharides of GBS would be important in protective immunity was first suggested by Lancefield's observations in a mouse model of lethal infection. The first data indicating that CPS-specific antibodies were protective in human disease was reported by Baker and Kasper [11]. These investigators demonstrated that neonates at risk for invasive GBS disease (either early- or late-onset) were those born to women with very low concentrations of III CPS-specific antibodies in delivery sera. This initial observation was confirmed and extended by several others for serotypes Ia and Ib [12, 13]. Additional evidence implying the biologic importance of serum antibodies against GBS CPS antigens is the ability of these antibodies to promote opsonization of homologous capsular types for phagocytosis and killing by human polymorphonuclear leukocytes *in vitro* and to provide *in vivo* protection from lethal infection in several animal models. These data suggested that active immunization of pregnant women with GBS CPS antigens might elicit protective levels of antibodies, thus preventing infant GBS disease.

Initial characterization of the CPS antigens of GBS had employed hot acid extraction from whole organisms. This method was discovered to degrade terminal sialic acid moieties, rendering these antigens "incomplete." This was especially important for serotype III GBS, in which the terminal sialic acid moiety of the repeating side chain of

the polysaccharide was found to dictate the tertiary structure of the molecule that defined the critical epitope for protection. Once "complete" Ia, II, and III CPS structures had been purified and characterized, their use as candidate vaccines in healthy adults was evaluated. Success was expected based on results with the multivalent pneumococcal polysaccharide vaccine, but while quite well tolerated GBS polysaccharides were variably immunogenic. It was discovered that the overwhelming majority of young healthy adults had low concentrations of CPS-specific antibodies in their preimmunization sera, and these low levels often predicted a poor immune response to immunization. In adults with low concentrations of CPS-specific antibodies prior to immunization with II CPS, 88% developed significant immune responses, but for Ia and III CPS, the response was 40% and 60%, respectively [14].

Despite these disappointing results, indicating the need for development of improved candidate GBS vaccines, an important study was conducted using type III polysaccharide vaccine. A total of 40 healthy pregnant women were immunized with purified III CPS at a mean of 31 weeks of gestation. Among the 25 women who developed an immune response, 90% had infants with presumably protective levels of III CPS-specific antibodies in their cord sera and the majority of sera from these infants promoted opsonophagocytosis and killing of type III GBS through age 3 months. These observations supported the concept that maternal immunization with a GBS vaccine could elicit potentially protective CPS-specific, IgG class antibodies that would be passively transferred to neonates and young infants to prevent GBS disease during the first 3 months of life [15].

### B. GBS Type III CPS–Protein Conjugate Vaccine

The decision to begin GBS conjugate vaccine development with serotype III was based on the high proportion of disease caused by this serotype in neonates and young infants (currently estimated at 60%), and the abundance of data indicating that antibodies directed at the III CPS were protective against infant infection [11,12]. Strategies to improve the immunogenicity of the GBS CPS included the use of enzymatically derived oligosaccharides and of native polysaccharides as haptens. Conjugate vaccines prepared with III CPS oligosaccharides were highly immunogenic in animals and useful as reagents to study immune responses to a polymer that possesses conformationally dependent epitopes [16,17]. However, methods to derive III CPS oligosaccharides and the end-linking chemistry were inefficient, so these vaccines could not be made on a large scale. Conjugate vaccines using native type III CPS and tetanus toxoid (III-TT) with two different coupling chemistries [18,19] resulted in vaccines that were immunogenic in animals, elicited antibodies in adult mice that protected neonates from experimental challenge, and produced functionally active III CPS-specific IgG in mice, rabbits, and baboons [19–21]. To date, all GBS conjugate vaccines used in clinical trials have been developed by using the reductive amination coupling chemistry [19,22]. Issues of conjugate size, polysaccharide size and degree of polysaccharide–protein cross-linking all influence the immunogenicity and protective efficacy of III-TT con-

jugate vaccines [23]. These structural properties have been considerations in the vaccines formulated to date.

The first GBS conjugate vaccine for Phase 1 clinical trials was created by using purified III CPS with a  $M_r$  of approximately 200,000; aldehydes were formed on 26% of sialic acid residues before coupling to monomeric TT. This first III-TT conjugate vaccine was 56% carbohydrate and 44% protein, and was prepared at the Channing Laboratory (Boston, MA), under good laboratory practices (GLP) conditions [24]. As for all GBS conjugate vaccines, this first conjugate vaccine passed tests for general safety, microbial sterility, and pyrogenicity required by the Food and Drug Administration. A total of 60 healthy nonpregnant women, between 18 and 40 years of age, were randomized to receive a single intramuscular injection of III-TT conjugate at a dose containing of 58, 14.5, or 3.6 µg of III CPS or the unconjugated III CPS at a dose of 50 µg. Each vaccine and each dose of III-TT conjugate was well tolerated. The majority of women experienced no local symptoms or only tenderness at the injection site and a minority (25%) had soreness with arm movement. No more than 27% developed redness or swelling at the injection site and when this occurred, it was mild (<3 cm) in the majority, resolving within 72 hr after vaccine administration.

The geometric mean concentration (GMC) of III CPS-specific IgG in sera from the 30 recipients of the 58-µg dose of III-TT rose from 0.09 µg/mL before immunization to 4.89 µg/mL at 2 weeks after immunization. The III CPS-specific IgG GMC remained relatively unchanged 8 weeks after immunization (Table 1), and was 3.02 µg/mL 18 weeks later. The immunogenicity of III-TT was dose-dependent, with a substantially lower GMT in 8-week postimmunization sera from subjects who received the 3.6-µg dose than in sera from recipients of either of the two higher dosages. Proportional response rates ( $\geq 4$ -fold rises) 8 weeks after immunization were 97% in recipients of the highest dose but only 64% in those receiving the 3.6-µg dose. The group of women receiving unconjugated III CPS had significantly inferior immune responses (data not shown). Sera obtained before and 4 weeks after vaccination were tested for functional activity in an opsonophagocytic assay. A positive correlation ( $r = 0.7$ ) was shown between killing of type III GBS by healthy adult polymorphonuclear leukocytes and the concentration of III CPS-specific IgG. The functional activity of III CPS-specific IgG also was examined by protection studies in mice. A pooled standard human reference serum (SHRS III) from five III-TT recipients (83.5 µg of III CPS-specific IgG) was administered intraperitoneally to pregnant dams. Among the 41 pups born to dams given SHRS III, 30 (73%) survived a usually lethal challenge of type III GBS, whereas each of the 11 pups born to a dam given normal human serum died [24]. Thus these Phase 1 trials demonstrated, in concept, the potential for GBS conjugate vaccines to prevent GBS disease in neonates and young infants through maternal immunization.

### C. GBS Types Ia and Ib CPS Conjugate Vaccines

Two variables influence the number of aldehydes formed on GBS CPS, the size of the CPS (and thus the number of sialic

**Table 1** Eight Weeks Postimmunization Response to GBS Conjugate Vaccines in Healthy Adults<sup>a</sup>

GBS vaccine (CPS dose in µg)	Number of subjects	Geometric mean concentration (µg/mL) of CPS-specific IgG, 95% CI and range			% with ≥4-fold increase in CPS-specific IgG by ELISA
III-TT (58)	30	4.53	[1.92–10.70]	(0.07–325.12)	97

<sup>a</sup> Source: Refs. 24, 25, 27, 35, and 36.

acid residues) and the amount of sodium periodate added to the sialic acid oxidation reaction. Unlike other GBS capsular polysaccharides, types Ia and Ib have a  $M_r > 800,000$ . When the number of aldehydes created on these two GBS polysaccharides exceeded ~40%, the reductive amination coupling with TT resulted in the formation of insoluble gels. Preclinical lots of soluble type Ia-TT and Ib-TT conjugate vaccines were immunogenic in mice and rabbits, and prevented neonatal GBS disease in the maternal vaccination-neonatal mouse model [25].

On the basis of these preclinical data, type Ia-TT and Ib-TT conjugate vaccines were prepared with 25% and 9%, respectively, of sialic acid oxidation. Both vaccines were composed of 66% and 34% carbohydrate and protein, respectively. The Ia-TT conjugate contained 60 µg of CPS/0.5-ml dose, while Ib-TT conjugate contained 63 µg of CPS/0.5-ml dose. A total of 120 healthy, nonpregnant women, ages 18–40 years, were randomized to receive a single intramuscular dose of either type Ia-TT or type Ib-TT conjugate vaccine [25]. Thirty women received Ia-TT or Ib-TT at dosages of either 60 µg (type Ia) or 63 µg (type Ib) of the polysaccharide component, and 15 women each received 4-fold or 8-fold lower doses of each vaccine. In general, the vaccines were well tolerated; no serious adverse effects were observed. Most of the women receiving either the Ia-TT or Ib-TT conjugate vaccines at any dose had only mild tenderness at the injection site or no local symptoms or signs. Moderate pain or mild redness or swelling was observed in 40% and 38%, respectively, of recipients of the two highest vaccine doses.

Before vaccination, sera from each of the vaccine dose groups had low concentrations of Ia or Ib CPS-specific IgG ( $\leq 0.6 \mu\text{g/mL}$ ) [25]. Among the recipients of the 60 µg Ia-TT conjugate vaccine dose, the Ia CPS-specific IgG GMC increased to 21.6 µg/mL 2 weeks after vaccination and peaked at 26.2 µg/mL 8 weeks later (Table 1). The 15-µg dose of Ia-TT conjugate evoked a GMC that did not differ significantly

from that in the sera from 60-µg-dose recipients, whereas the Ia CPS-specific IgG evoked by the lowest dose (3.75 µg) was significantly lower. Ninety-three percent of the 30 women who received the 60-µg dose of Ia-TT conjugate and 80% of those given the 15-µg dose had  $\geq 4$ -fold increases in serum Ia CPS-specific IgG 8 weeks after vaccination (Table 1).

Recipients of the two higher doses of the Ib-TT conjugate vaccine had immune responses that did not differ significantly from each other, but evoked a significantly higher GMC of Ib CPS-specific IgG than the recipients of the 3.94-µg dose. The antibody responses to the two higher doses peaked 4–8 weeks after vaccination and changed little in the ensuing 18 weeks. In an analysis 2 years after vaccination, the Ib CPS-specific IgG GMC in sera from 13 recipients of the 63-µg dose was 10.7 µg/mL (range 0.26–147.7), indicating that this immune response was durable. When immunogenicity was analyzed by 4-fold increases in Ib CPS-specific IgG, 78% and 80% of recipients of the 63- and 15.75-µg doses, respectively, achieved these fold-rises.

When testing the functional activity of sera before and after immunization with these two conjugates by opsonophagocytic assay, there was a correlation between the concentration of Ia and Ib CPS-specific IgG and neutrophil-mediated killing by sera from recipients of type Ia TT ( $r = 0.65$ ) and type Ib-TT ( $r = 0.80$ ) vaccines. Taken together, the Phase 1 trials with these first three GBS serotypes—Ia, Ib, and III—documented consistently low reactogenicity, substantial immunogenicity, in vitro function of vaccine-induced specific antibodies, and a durable immune response.

#### D. GBS Type II CPS Conjugate Vaccine

GBS type II CPS contains sialic acid as one of two monosaccharide side chains in its seven-sugar repeating unit [26]. The relationship between the amount of sodium periodate added and the formation of aldehydes on sialic acid residues was found not to be direct, as had been observed with GBS

types Ia, Ib, and III. This may be due to the proximity of sialic acid residues on the II CPS to the backbone sugars, unlike the other serotypes (Ia, Ib, III–VII) where sialic acid is two to three sugars away from the backbone. This structural difference demanded that a higher concentration of sodium periodate be added to create a sufficient number of aldehydes on the type II CPS for coupling to a protein carrier. To determine the degree of sialic acid oxidation that would yield immunogenic and efficacious conjugate vaccines, preclinical lots of II CPS–TT conjugate vaccines were prepared with CPS containing 31%, 57%, and 73% sialic acid oxidation. Immunogenicity and protective efficacy indicated that the II CPS prepared with 57% oxidation was the most consistently immunogenic and protective, results that prompted the preparation of II–TT conjugate vaccine for clinical trials with CPS containing 35% sialic acid oxidation [27]. GBS II–TT conjugate was composed of 51% carbohydrate and 49% protein. The choice to bottle the II–TT vaccine as a lyophilized multidose preparation was based on observations that lyophilized GBS oligosaccharide conjugates retained antigenic properties [28], and that this was a more conventional manner of bottling vaccines. The II–TT lyophilized vaccine used sucrose as the excipient to serve as a stabilizer and to add bulk to the mixture. When the multidose vial was reconstituted with saline containing 0.01% thimerosal, each 0.5-ml dose contained 57 µg of conjugate II CPS and 55 µg of TT. This vaccine was 95% protective in a mouse maternal vaccination-neonatal challenge model of GBS disease, a measure of GBS vaccine potency. This potency persisted 4 years after it was vialled [28], thus demonstrating the long-term stability of a lyophilized GBS conjugate vaccine.

The type GBS II–TT conjugate vaccine was well tolerated when given as a single intramuscular dose to 60 healthy, nonpregnant women between the ages of 18 and 45 years. Only one subject had systemic symptoms that were probably related to immunization. These symptoms consisted of low-grade fever, chills, and headache and resolved 36 hr after immunization. Most vaccine recipients experienced only mild or moderate pain at the injection sites, but a few had redness or swelling of <3 cm in diameter. Before immunization the GMC of II CPS-specific IgG in sera from the three

groups of women receiving 4-fold decreasing vaccine doses was low ( $\leq 0.5$  µg/mL) [27]. In sera from the 30 recipients of the highest II–TT dose (57 µg), the II CPS-specific IgG GMC increased to a peak of 47.1 µg/mL 2 weeks after immunization. Eight weeks after immunization, the II CPS-specific IgG GMC ranged from 11.2 to 34.3 µg/mL (Table 1), each representing a concentration that would ensure that adequate CPS-specific IgG would be available for placental transport. These II CPS-specific IgG responses were durable when assessed at 26 and 104 weeks after vaccination. Interestingly, the II–TT vaccine elicited substantial IgM- and IgA-specific antibody responses. For example, 8 weeks after immunization, the 3.6-µg dose elicited a II CPS-specific IgM GMC of 5.5 µg/mL (95% CI 3.0–10.2) and a IgA-specific GMC of 0.8 µg/mL (95% CI 0.4–1.5) (Table 2). The immunological explanation for this diversity of immunoglobulin isotype distribution in response to II–TT conjugate compared with type Ia, Ib, and III conjugate vaccines requires further study.

When the functional activity of sera from adults immunized with II–TT conjugate vaccine to promote opsonization, phagocytosis and killing of an opsonoresistant type II GBS strain before and 4 weeks later was studied, there was a significant increase from  $<0.3$  mean  $\log_{10}$  reduction in colony-forming units (CFU) to  $0.9 \log_{10}$ . Also, there was a correlation between the concentration of II CPS-specific IgG and opsonophagocytic activity of sera from vaccine recipients, again indicative of the significant relationship between vaccine-induced antibodies and their in vitro functional activity.

#### E. GBS Type V CPS Conjugate Vaccines

Epidemiological studies during the 1970s and 1980s documented that virtually all invasive GBS infections in the United States were caused by serotypes Ia, Ib, II, and III. In the early 1990s, however, a new GBS serotype emerged [29–31]. Jelinkova and Motlova [32] first described the new type V GBS in the mid-1980s. With this finding of a new GBS serotype adding to the burden of serious GBS perinatal infections, the type V polysaccharide was purified and structurally characterized [33]. Type V polysaccharide has

**Table 2** Isotype-Specific Immunogenicity of Type II and Type V GBS Conjugate Vaccines in Healthy Adults 8 Weeks After Immunization<sup>a</sup>

Vaccine (µg)	Number of subjects	ELISA	Geometric mean antibodies (µg/mL) by ELISA		
			[95% CI]	(Range)	
II–TT (3.6)	15	IgG	11.2	[6.1–20.8]	(0.9–83.1)
		IgM	5.5	[3.0–10.2]	(1.2–26.6)
		IgA	0.8	[0.4–1.5]	(0.3–2.8)
V–TT (50)	15	IgG	8.2	[3.2–21.1]	(0.6–125)
		IgM	17.8	[7.0–45.6]	(0.6–277)
		IgA	4.8	[1.8–12.4]	(0.4–97.9)
V–CRM (50)	15	IgG	5.7	[2.2–14.9]	(0.2–435)
		IgM	27.8	[14.8–52.4]	(4.8–182)
		IgA	7.2	[3.6–14.2]	(1.2–138)

<sup>a</sup>Source: Refs. 27 and 35.

structural uniqueness with respect to other GBS polysaccharides, but like the others, it possesses a side chain, which terminates with sialic acid [33]. This property meant that reductive amination could also be utilized to create a type V conjugate vaccine. GBS type V CPS conjugate vaccines were prepared with TT as the carrier protein and tested in rabbits and mice. Unlike the uncoupled V CPS, the V-TT conjugate induced type-specific antibodies in rabbits that opsonized the type V strain in vitro for killing by human polymorpho-nuclear leukocytes [34]. Like the other GBS serotypes, type V-TT conjugate vaccine also was superior to uncoupled type V CPS in protective efficacy against bacterial challenge to neonatal mice born to vaccinated dams [34].

Two lots of GBS type V conjugate vaccine were prepared for use in Phase 1 clinical trials. The first used TT as the carrier protein and was 76% carbohydrate and 14% protein, and the second cross-reactive material 197 (CRM<sub>197</sub>, kindly provided by R. Rappuoli, IRIS, Siena, Italy) and was 73% carbohydrate and 17% protein. Both conjugate vaccines were prepared with purified type V CPS (173,000 M<sub>r</sub>) that had of 18% of its sialic acid residues oxidized [35]. Like GBS II-TT conjugate, these type V conjugate vaccines were prepared as multidose lyophilized preparations with sucrose as the excipient.

Each of the type V conjugate vaccines was well tolerated by healthy, young adults [35]. Reactogenicity rates were comparable to other GBS conjugate vaccines and to each other. Thirty healthy, nonpregnant women, aged 18–45 years, were randomized to receive one of these type V conjugates. Sera from both groups of women had similarly low preimmunization concentrations of V CPS-specific IgG (GMC ≤ 0.2 µg/mL), and developed significant increases at each postvaccination interval through 26 weeks (Table 1). Type V-TT conjugate vaccine recipients had somewhat higher V CPS-specific IgG concentrations in their sera following immunization compared to the V-CRM group [e.g., GMC of 8.2 vs. 5.7 µg/mL at 8 weeks (Table 1)], but these differences were not statistically significant. Four-fold or greater increases in V CPS-specific IgG were observed in 93% of subjects in each conjugate vaccine group, and these increases persisted in 85% (V-TT) to 93% (V-CRM) of women 2 years later, indicating good durability of vaccine-induced antibodies. Thus in this pilot study in a small number of adults, both protein carriers appeared capable of providing the necessary T-cell help required for eliciting a response to the GBS type V CPS.

In contrast to results using type Ia-, Ib-, and III-TT conjugate vaccines but similar to those with II-TT conjugate vaccine, it was evident that a substantial proportion of the V CPS-specific antibodies produced after immunization with either V-TT or V-CRM were of isotypes other than IgG. Study participants had similarly low GMCs of V CPS-specific IgM and IgA GMCs in their pre-immunization sera. However, immunization induced a brisk V CPS-specific IgM and IgA response, and interestingly, the V CPS-specific IgM GMCs exceeded those for IgG (Table 2). Both groups of type V conjugate vaccine recipients had significant increases in V CPS-specific IgM and IgA 4 and 8 weeks after immunization, and these antibody levels persisted for 2 years. Further, recipients of V-CRM conjugate had substantially greater

increases in V CPS-specific IgA than those who received V-TT conjugate, but this apparent difference was significant only at the 2-week interval.

Sera from V conjugate vaccine recipients before and 4 weeks after immunization were tested for in vitro functional activity against a relatively opsonoresistant type V GBS strain, G-106, in an opsonophagocytosis assay. The 4-week postvaccination sera from both groups of conjugate vaccine recipients promoted mean log<sub>10</sub> reductions in type V CFU of 0.81 and 0.79 for GBS V-TT and V-CRM groups, respectively. There was no significant difference in the functional activity of antibodies induced by either of these conjugate vaccines.

#### F. GBS Type II-TT/III-TT Bivalent Vaccine

In moving toward the development and testing a multivalent GBS conjugate vaccine, a clinical trial was designed to determine whether the administration of two monovalent GBS conjugate vaccines, II-TT and III-TT, in a single syringe stimulated immune responses comparable to those elicited by either of the monovalent vaccines [36]. A Phase 2 randomized, double-blinded trial in 75 healthy adults between the age of 18 and 45 years was conducted. One group received II-TT (3.6 µg CPS/3.4 µg TT), another III-TT (12.5 µg CPS/16.1 µg TT), and the third the bivalent II-TT/III-TT (3.6 II µg CPS/12.5 µg III CPS/ 19.5 µg TT), each as a single 0.5-mL intramuscular dose. The choice of the concentration for each antigen in the bivalent vaccine was based on our earlier finding that at these concentrations nearly 90% of the volunteers receiving a single antigen showed a ≥4-fold increase in the specific IgG titers. Each vaccine was well tolerated. Mild injection site pain or redness was found in a minority of subjects and brief, mild systemic symptoms were noted in two (4%) III-TT conjugate vaccine recipients. Bivalent II/III-TT conjugate elicited increases in II or III CPS-specific IgG that were similar to those stimulated by the separate conjugate vaccine components. A ≥4-fold increase in II CPS-specific IgG was noted in 80% of sera from II-TT or bivalent vaccine recipients and in >90% of sera from subjects vaccinated with III-TT containing vaccine. Unexpectedly, 25% of III-TT subjects also developed ≥4-fold rises in II CPS-specific IgG, indicating immunologic cross-reactivity between the two structurally similar disaccharides in these two GBS CPSs. No immune interference from combining these vaccines was observed, results suggesting the feasibility of developing a multivalent GBS CPS-protein conjugate vaccine [36].

#### G. Booster Dose of GBS Type III Conjugate Vaccine

Each of the conjugate vaccines discussed above was prepared at the Channing Laboratory in Boston. However, to achieve the ultimate goal of evaluating the safety and immunogenicity of GBS conjugate vaccines in pregnant women, a GBS type III-TT vaccine prepared under GMP conditions was needed. In 1995, GMP lots of III-TT vaccine were prepared at the Salk Institute (Swiftwater, PA). These lots were prepared in multidose vials containing sucrose

excipient. Approximately 30% of the sialic acid residues of III CPS were periodate oxidized to create reactive aldehydes as sites for coupling to tetanus toxoid (61% carbohydrate and 39% protein by weight for the first lot and 44% carbohydrate and 56% protein by weight for the second). The second vaccine lot was used in a trial designed to evaluate the effect of two doses of vaccine on immunogenicity [37].

A total of 36 healthy adults, aged 18–50 years and vaccinated previously with III-TT, were given a second 12.5- $\mu$ g dose of III-TT conjugate 21 months later. The vaccine was well tolerated and there was no increase in the frequency with which local or systemic responses were observed with the booster dose. Four weeks after the second vaccine dose, the GMC of III CPS-specific IgG (8.4  $\mu$ g/mL) was similar to that measured after the first dose (8.8  $\mu$ g/mL), suggesting a lack of a “booster” effect. Of interest, a subset of 22% of the subjects who had undetectable III CPS-specific IgG levels (<0.5  $\mu$ g/mL) before the first dose of III-TT conjugate exhibited a “booster” response to the second dose. This was defined as a  $\geq 4$ -fold GMC of III CPS-specific IgG than after the initial immunization. Thus a second dose of GBS CPS conjugate vaccine may be required for adults previously “naïve” or “unprimed” to type III GBS CPS or to a related antigen. A second vaccine dose also might be useful to restore the initial peak III CPS-specific IgG serum levels in those previously responding to vaccination.

#### H. Alum as an Adjuvant for GBS Type III Conjugate Vaccine

Antibody response to GBS conjugate vaccines in healthy adults has been reported to be brisk, with peak serum levels achieved 4–8 weeks after administration of a single dose. In an effort to further improve the magnitude and proportion of immune responses to GBS conjugate vaccines, an adjuvant trial was conducted using III-TT conjugate. This vaccine was adsorbed to aluminum hydroxide gel in 0.9% saline (alum) that was prepared by the Massachusetts Public Health Laboratory (Jamaica Plain, MA), under good manufacturing practices (GMP) conditions using Alhydrogel 1.3% (aluminum hydroxide gel adjuvant) manufactured by Superfos Biosector (Vedbaek, Denmark) [37]. The rationale for choosing alum was based on its widespread use in human vaccines and its ability to improve the immunogenicity of GBS conjugate vaccines in mice [38] and baboons [20]. Thirty healthy adults, 18–50 years of age, received the III-TT vaccine adsorbed to alum. No increase in injection site pain, redness, or swelling was observed compared to III-TT conjugate without alum. Adsorption to alum did not improve the immune response to III-TT conjugate (12.5- $\mu$ g dose of III CPS). Four weeks after immunization, the GMC for the 15 recipients of the III-TT with and without alum were 3.3 and 3.6  $\mu$ g/mL, respectively. It is possible that because these human subjects were not immunologically naïve to tetanus, as are mice or baboons, the protein carrier is not suitable for adjuvancy. Children who received an 11-valent pneumococcal conjugate vaccine for which either diphtheria or TT was used as the protein carriers also have been reported to have no enhancement of immunogenicity with the addition of alum with vaccine [39].

#### I. Maternal Immunization with GBS Type III Conjugate Vaccine

Immunization during pregnancy is a strategy that takes advantage of the immunoresponsiveness of young healthy adults to provide protection passively for their immunologically immature infants. The value of this approach has been demonstrated globally with the eradication of tetanus neontorum through widespread immunization of pregnant women with tetanus toxoid vaccine [40]. Polysaccharide conjugate vaccines also have been administered safely to women during pregnancy. For example, *Haemophilus influenzae* type b conjugate vaccines have been safely administered to pregnant women in the United States and in developing countries [41].

Two animal models have been used to gain a better understanding of placental transfer of GBS CPS-specific IgG after maternal immunization with III-TT. In a murine model of infection, female outbred CD-1 mice received two intraperitoneal injections of III-TT and subsequently were bred [42]. In sera from dams, CPS-specific IgG1 accounted for 83.2% of the total IgG, with a mean level of  $9.1 \pm 3.9$   $\mu$ g/mL. All of the 27 pups born to immunized dams survived challenge with a potentially lethal challenge of III GBS. In contrast, none of the 32 pups born to dams given placebo survived the GBS III challenge.

Because nonhuman primates produce antibodies which are structurally and functionally quite similar to those produced by humans, the III-TT vaccine was evaluated in a baboon model of infection. The GMC of III CPS-specific IgG increased from 0.9 to 7.5  $\mu$ g/mL at delivery. Seven of nine baboons given the vaccine had  $\geq 4$ -fold rises in antibody from the baseline level. The percent of III CPS-specific IgG transferred to their offspring ranged from 26% to 185% of the maternal values. The function of the maternal and neonatal antibodies was equivalent when assessed in an opsonophagocytosis assay.

A prospective Phase 1, randomized, double-blind, placebo-controlled trial recently was conducted to evaluate the safety and immunogenicity of III-TT vaccine in pregnant women. Thirty women, 18–45 years of age, received a single dose either of III-TT conjugate (12.5  $\mu$ g) or placebo (0.9% saline) at a mean of 31 weeks of gestation [43]. The vaccine was well tolerated. Mild injection site pain occurred in 65% of vaccine and 10% of placebo recipients; no redness or swelling were observed in either group. All deliveries occurred beyond 37 weeks of gestation and each neonate was healthy and had normal Denver II developmental examinations at 6 months of age when the study concluded. The III CPS-specific IgG GMC in sera of the 20 women receiving III-TT conjugate was 0.18  $\mu$ g/mL before immunization and 9.98  $\mu$ g/mL 4 weeks later. The GMC remained stable at the time of delivery (mean 9.76  $\mu$ g/mL). By contrast, placebo recipients received 0.06  $\mu$ g/mL of III CPS-specific IgG before and 0.05  $\mu$ g/mL in sera after “immunization.” Vaccine recipients also developed immune response to the carrier protein, TT. The III CPS-specific IgG GMC in cord sera from infants whose mothers received vaccine was 7.48  $\mu$ g/mL, reflecting 77% maternal delivery-cord III CPS-specific IgG transmission. The predominant IgG subclass of III

CPS-specific antibodies was IgG<sub>2</sub>, as has been reported for *H. influenzae* type b conjugate maternal immunization [41]. Cord serum values remained elevated at 1 month (3.74 µg/mL) and 2 months (2.16 µg/mL) of age. Infant sera also promoted opsonization, phagocytosis, and killing of type III GBS, with 1.4 and 1.5 log<sub>10</sub> kill, respectively, at 1 and 2 months of age. These findings suggest that maternal immunization has the potential to prevent early- as well as late-onset GBS disease in infancy.

### III. FUTURE VACCINE DIRECTIONS AND ISSUES

#### A. Formulation and Target Population

Although the principle that conjugation technology improves the immunogenicity of GBS CPSs has been established, several questions remain regarding formulation of an effective vaccine for use in the United States and elsewhere. Because five GBS serotypes (Ia, Ib, II, III, and V) are responsible for the majority of disease in the United States, a pentavalent vaccine appears to be warranted. That a multivalent GBS vaccine could confer protection against the serotypes included in the vaccine has been demonstrated in mice with a tetravalent CPS (Ia, Ib, II, and III) conjugate vaccine formulation [21]. How to vial five individually prepared conjugate vaccines is a technical challenge akin to that encountered by the developers of the 7-valent pneumococcal conjugate vaccine [44] and is a task best left to experienced manufacturers. However, the clinical studies summarized in the foregoing discussion suggest potential doses for each GBS serotype. Formulation of a vaccine is predicated on knowing the amount of specific antibody required to be protective. This is not known with certainty for GBS and is complicated in the case of neonatal disease by the necessity to predominantly induce IgG class antibodies in pregnant women to assure passive protection to the infant. Clearly, the maternal levels must readily exceed the concentrations presumed to confer protection in the newborn, which from earlier studies are in the range of 1 µg/mL [45].

Generally, the amount of type-specific IgG elicited by GBS conjugate vaccines was dose-dependent. For types Ia-, Ib-, and III-TT conjugates there was no statistical difference in the amount of CPS-specific IgG elicited between 50–60 and 12–15 µg doses. It is possible that this latter dose range would be suitable for optimal immunogenicity. Type II-TT has been shown to be highly immunogenic (>10 µg/mL of II CPS-specific IgG) even at the lowest (3.6 µg) dose. It also induces II CPS-specific IgM and IgA [27]. Thus a relatively low dose (2–4 µg) could be included in a multivalent formulation. The amount of GBS type V-TT vaccine that would be included in a multivalent preparation will require further study [35].

Obviously, the formulation of a GBS conjugate vaccine will reflect the prevalence of GBS serotypes causing invasive disease in the country of its use. GBS colonization among pregnant women in Japan has been dominated by serotypes VI and VIII, which together accounted for 60% (44 out of 73) of isolates [46]. Although no clinical trials have been performed with type VI and VIII conjugate vaccines, pre-

clinical studies in mice with VI-TT and VIII-TT vaccines suggest that effective vaccines against these serotypes can be achieved [47].

#### B. GBS Protein-Based Vaccines

Not all GBS vaccine development focused on the CPS antigens. GBS possesses a number of surface-expressed proteins that have been tested as vaccine candidates or as carrier proteins for the CPSs. Indeed, even if GBS proteins cannot, by themselves, provide protection against GBS disease, a multivalent GBS CPS conjugate would benefit from using protein carriers of GBS origin rather than TT and CRM<sub>197</sub> that are in widespread use in licensed vaccines. A review of GBS surface components with potential for use in vaccines has been published [48]. While all GBS protein antigens have shown promise in animal models of GBS disease, a correlation between low antibody to GBS proteins and susceptibility to disease in humans is lacking.

##### 1. Alpha C Protein

Because the alpha C protein found in about 50% of clinical isolates of GBS and in 70% of nontype III GBS strains, this laddering protein is an attractive candidate for use in a GBS vaccine [49]. A III CPS conjugate vaccine prepared with a two-repeating unit alpha C protein conferred protection against GBS type III challenge in 95% of neonatal mice born to actively vaccinated dams, and 60% survival among pups challenged with a type Ia GBS strain containing the alpha C protein [49]. In addition, most (73%) of the pups born to mouse dams vaccinated with two-repeat alpha C protein alone survived lethal challenge with type Ia organisms, thus demonstrating the potential utility of this protein as an effective carrier for GBS CPS and an immunogen against alpha C protein-bearing GBS.

##### 2. Beta C Protein

This trypsin-sensitive C protein is found on about 10% of GBS strains, predominately those belonging to serotype Ib. GBS beta C protein induces protective antibodies in animals [50–52]. In addition to its being a good immunogen, this protein also has demonstrated characteristics of a thymus-dependent carrier for the type III CPS. A III CPS-beta C-protein conjugate elicited in mice protective antibodies against GBS strains bearing the type III antigen and beta C-proteins [53].

##### 3. C5a Peptidase

Streptococcal C5a peptidase (SCPB) is a conserved surface protein among many strains of GBS [54]. Recently, Cheng and colleagues [55] showed that preincubation of GBS types Ia, Ib, II, III, and V with antibody to SCPB enhanced in vitro opsonic-mediated killing by mouse bone marrow-derived macrophages. Moreover, GBS type III CPS covalently coupled to SCPB by reductive amination induced high levels of both CPS-specific and SCPB-specific IgG that opsonized not only GBS type III, but types Ib and V as well [55], suggesting cross-serotype activity. Whether active immuni-

zation of female mice with coupled and uncoupled SCPB will result in cross-serotype protection remains to be determined.

#### 4. Rib Protein

Found on GBS type III strains, Rib protein is structurally similar to, but antigenically separate from, the alpha C protein. Both proteins exhibit a laddering phenotype on sodium dodecyl sulfate-polyacrylamide gels and both are resistant to trypsin digestion [56]. Antiserum to this protein protected mice against GBS challenge, but only from GBS strains that did not contain the alpha C protein. A bivalent vaccine composed of Rib and alpha C proteins was protective [57].

#### 5. Sip Protein

Another GBS surface protein, surface immunogenic protein (Sip), was recently shown to induce cross-serotype immunity in mice [58]. Monoclonal antibody to the 53-kDa protein of Sip revealed its presence on GBS strains representing all nine known serotypes [59]. Moreover, CD-1 mice actively immunized with recombinant Sip were protected against GBS infection with Ia, Ib, II, III, V, and VI and newborn mouse pups born to Sip-vaccinated dams were effectively protected against challenge with GBS serotypes Ia, Ib, II, III, and V [60]. These data suggest that cross-protective IgG to GBS may be able to be induced in animals by vaccination with a single surface protein common to all GBS serotypes. What remains to be determined is the prevalence of antibodies in sera from populations at risk for invasive GBS disease, and the effectiveness of Sip in inducing functionally active antibodies in humans.

## IV. SUMMARY

Invasive GBS infection is a major health problem among infants, pregnant women, and nonpregnant adults, especially those beyond 65 years of age. The emergence of type V strains as a cause of a substantial proportion of invasive disease, especially that in nonpregnant adults, highlights the need for ongoing epidemiologic surveillance to correctly formulate a multivalent conjugate vaccine. However, the relative paucity of serotypes that contribute to human GBS disease by comparison, for example, with those documented to cause invasive pneumococcal infection, is an advantage for the development of GBS conjugate vaccines. In a recently published active statewide surveillance, Harrison and colleagues [61] determined the serotype distribution of invasive GBS isolates from over 500 infants, children, pregnant women, and adults. As with the pneumococcus, the serotype distribution differs between infants and adults. However, a pentavalent GBS vaccine, containing CPS from serotypes Ia, Ib, II, III, and V GBS would theoretically provide protection against more than 95% of the GBS isolates from both infants and adults.

The Phase 1 and 2 trials of monovalent GBS CPS-protein conjugate vaccines conducted to date and summarized in this chapter indicate the feasibility of developing a pentavalent GBS conjugate vaccine. The method for coupling to monomeric TT by reductive amination has gener-

ated custom vaccines of optimal immunogenicity. Each monovalent CPS-TT conjugate has been found safe, with only mild local reactions and on rare occasion, mild and time-limited systemic symptoms of less frequency than those associated with tetanus toxoid booster immunizations. These monovalent conjugates are highly immunogenic in healthy adults, with a  $\geq 4$ -fold increase in CPS-specific IgG from baseline in 80% to 100% of subjects. The response to immunization is durable, persisting for at least 104 weeks. The dose dependence in the amount of CPS-specific IgG elicited indicates that the total CPS dose in a pentavalent vaccine is unlikely to exceed 50–75  $\mu$ g. The main barrier to the development of a pentavalent GBS conjugate vaccine is the lack of a corporate partner willing to undertake the research and development necessary for approval by the Food and Drug Administration. The recent recognition that adults 65 years of age and older constitute the population with the greatest overall mortality caused by GBS may provide an opportunity to document efficacy first in this population because pregnancy with its attendant liability issues loom strong after a decades of outcry for a perinatal disease prevention strategy more practical than intrapartum antibiotic prophylaxis. Ultimately, the licensure and widespread use of a pentavalent GBS conjugate vaccine could result in thousands of lives saved annually in the United States alone.

*Institut Pasteur, Paris, France*

### I. SIGNIFICANCE AND BURDEN OF *SHIGELLA* INFECTION

*Shigella* is a global infection that is notorious for disseminating rapidly in settings where there is overcrowding, inadequate sanitation, and insufficient supply of clean water. The spectrum of symptoms ranges from mild watery diarrhea to fulminant bacillary dysentery, characterized by bloody stools, high fever, prostration, cramps, and tenesmus. An array of severe intestinal and extra-intestinal complications can occur, such as hemolytic-uremic syndrome and a protein-losing enteropathy that contributes disproportionately to diarrhea-related malnutrition in young children. Most shigellosis results from endemic disease among children 1–5 years old living in developing countries, where it causes an estimated 163 million cases of diarrhea and 1 million deaths each year [1]. However, one serotype, *S. dysenteriae* 1, can cause devastating pandemics with high case fatality rates in all age groups. Shigellosis also occurs among persons living in industrialized countries [1], many of whom belong to known risk groups, such as travelers to endemic regions. High infectivity and antimicrobial resistance are factors that have enabled this bacterium to elude routine control measures. Widespread use of a safe and effective *Shigella* vaccine has long been considered a desirable strategy for combating this infection.

### II. IMMUNITY TO *SHIGELLA*

#### A. Evidence for Protective Immunity

Demonstration, in several venues, that an initial wild-type *Shigella* infection prevents illness during subsequent expo-

sure provides a strong argument for using a live, oral, attenuated vaccine approach [2–4]. The protection seen in field trials with noninvasive, attenuated *Shigella* vaccines offers additional hope that a live vaccine can succeed [5,6]. To date, approaches that have conferred clinical protection have not precluded intestinal colonization [5,6], although fecal excretion has been reduced [4].

#### B. Homotypic Versus Heterotypic Immunity

Vaccine development must take into consideration the antigenically distinct serotypes of *Shigella*. Groups A (*S. dysenteriae*), B (*S. flexneri*), and C (*S. boydii*) contain multiple serotypes [13, 6 (15 including subtypes) and 18, respectively], while Group D (*S. sonnei*) contains only a single serotype. Whereas type-specific immunity has been shown unequivocally in field and clinical settings, the data are conflicting as to whether cross-serotype or cross-species protection can be achieved. Monkeys fed wild-type *S. flexneri* 2a were fully protected when rechallenged with the same strain, but all monkeys became ill upon challenge with *S. sonnei* [4] and *S. flexneri* 6 [7]. A lack of heterologous protection was also seen in a field trial which measured the attack rate of shigellosis among recipients of a streptomycin-dependent *S. flexneri* 2a vaccine compared to unvaccinated controls [5]. However, with the exception of *S. flexneri* 4, the attack rate of non-vaccine strains was so low that heterologous immunity could not be assessed definitively.

In contrast, there is evidence both in humans [8] and in animals [9,10] that cross-protection can be induced among *S. flexneri* serotypes based on shared group and/or type-specific antigens on the O-polysaccharide molecule. Moreover, investigators conducting field trials in Romania [11]

and in China [12] reported that the T<sub>32</sub>-Istrati *S. flexneri* 2a vaccine provided both cross-species and cross-serotype protection. Additional investigation into this important area is necessary to guide vaccine development.

### C. Specific Immunoprotective Responses

The examples of serotype-specific protection cited above are in agreement with the hypothesis that immunity is mediated by antibodies (serum or mucosal) directed against the LPS O-antigen [13,14]. The efficacy of parenteral *S. sonnei* O-antigen-specific polysaccharide conjugate vaccine in preventing *S. sonnei* disease among Israeli soldiers lends further support to this concept [15].

Immune responses to *Shigella* plasmid encoded outer membrane proteins (e.g., IpaA, B, C, and D and VirG/lcsA) are also encountered following wild-type infection [16,17]. In contrast to the O antigen, these peptides are shared among the four serogroups and thus could be exploited as a cross-protective vaccine antigen; however, a role in immunity has not been established.

The first line of defense must occur at the mucosa. The impact of mucosal immunity is illustrated by the efficacy of passively transferred type-specific oral immunoglobulin in preventing shigellosis [18], and perhaps the protective effects of breast feeding on disease severity in developing countries [19]. In volunteers, O-specific IgA antibody-secreting cells (ASCs) circulating in the bloodstream after vaccination are a measure of intestinal priming that has been correlated with vaccine efficacy [20,21].

Cell-mediated immune responses may also contribute to the defense against this intracellular pathogen. In animal models, IFN- $\gamma$  production by NK cells seems to be an essential component of innate immunity to *Shigella* infection [22,23]. Up-regulation of IFN- $\gamma$  production and expression of IFN- $\gamma$  receptor are seen in the epithelium of rectal biopsies from Bangladeshi patients convalescing from shigellosis [24], and elevated levels are found in both serum and stool [25]. IFN- $\gamma$  is the predominant cytokine produced by T cells in response to *Shigella* antigens, including highly purified Ipa proteins, following inoculation of volunteers with live attenuated *Shigella* vaccine candidates [26,27]. Nonetheless, prospective studies have not yet been performed in humans to correlate cell-mediated immune responses with protection.

## III. RUPTURE, INVASION, AND INFLAMMATORY DESTRUCTION OF THE INTESTINAL EPITHELIUM BY SHIGELLA: AN EMERGING SCHEME

### A. Genetic, Molecular, and Cellular Bases of the Invasive Phenotype: The Virulence Plasmid of *Shigella*

The invasive phenotype that characterizes *Shigella* pathogenesis encompasses several steps. First, the bacteria traverse the follicle-associated epithelium (FAC) located over mucosal lymphoid nodules, the inductive sites of the local

immune response [28]. Next, they are engulfed by phagocytic cells, particularly the resident macrophages located in the dome of the FAE [29]. Finally, the organisms invade the epithelial lining of the intestine through its basolateral pole and spread cell-to-cell [30].

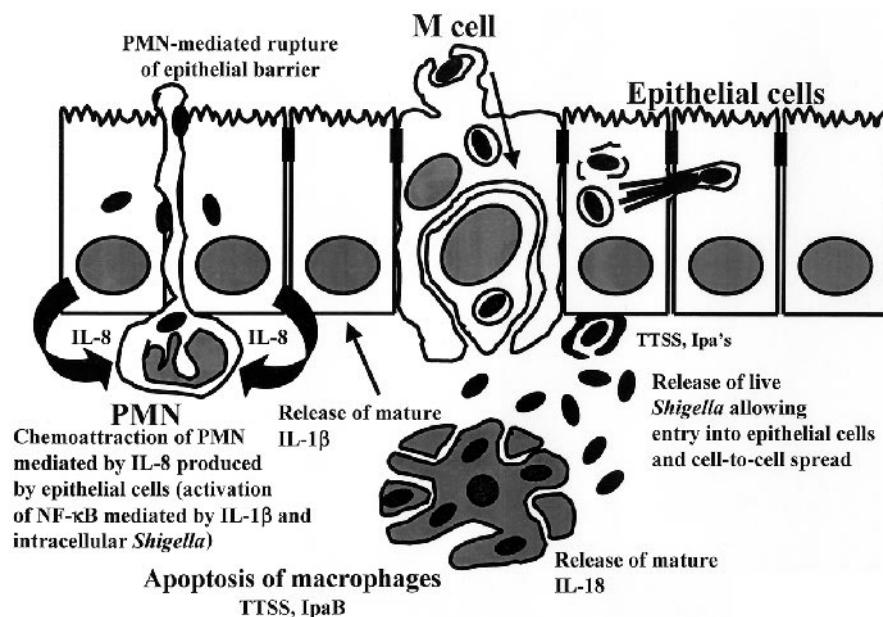

In all *Shigella* serotypes, a 214-kb virulence plasmid carries most of the genes required for invasiveness [31,32]. A block of 30 kb corresponding to a pathogenicity island encodes a type III secretory system (TTSS, *mxi-spa* operons) and at least five effector proteins (*ipa* operon, IpaA-D, IpgD) that are secreted through this TTSS [33]. IpaB and IpaC form a pore in the cytoplasmic membrane of the target cell through which the bacterium injects its effector molecules [34]. IpaC induces a signaling cascade involving small GTPases of the Rho family, Cdc42 and Rac, that leads to actin nucleation and polymerization [35,36] and formation of localized filopodes and lamellipodes that entrap the bacterium. Injection of IpaA through the pore induces maturation of this entry focus by a complex process involving binding of IpaA to the head domain of vinculin, then bundling and depolymerization of actin filaments [37].

The *Shigella* virulence plasmid also contains *icsA/virG* which encodes a 120-kDa outer membrane protein that mediates actin-dependent motility of *Shigella* [38,39]. Once anchored to the outer membrane through its C-terminus, IcsA/VirG exposes its N-terminal characterized by a series of Glycine-rich repeats, three of which constitute the binding domain (C. Egile, unpublished) for N-WASP [40]. Binding of N-WASP to IcsA/VirG unleashes a process that results in an IcsA/VirG–N-WASP–Arp2/3 actin–nucleator complex. The association of monomeric actin (G-actin) with this complex is necessary and sufficient to cause actin nucleation/polymerization (F-actin) and to elicit the motility process of *Shigella* [41]. *Shigellae* then engage with components of the intermediate junctions and propel themselves via protrusions that are engulfed by adjacent cells [42]. Finally, the bacteria escape from the surrounding eukaryotic membrane into the cytoplasm of neighboring cells. Figure 1 summarizes this remarkable mechanism of epithelial colonization that is contained within the sanctuary of the intracellular environment.

The virulence plasmid of *Shigella* contains genes that encode about 15 additional proteins that are also secreted by the TTSS (i.e., IpaH, Osp, VirA proteins [32]). These genes are transcribed only when the TTSS is active, thus linking the delivery of the proteins mediating the early stage of invasion with subsequently injected proteins that are likely to modulate the behavior of infected cells [43].

### B. Inflammatory Destruction of the Intestinal Epithelium

*Shigella* produce inflammation and destruction of the intestinal epithelium by several mechanisms that are illustrated in Figure 1. For one, macrophages that internalize *Shigellae* in the FAE undergo apoptotic death through a process that involves activation of Caspase-1 (a cysteine protease) by IpaB [44]. Pro-inflammatory cytokines such as IL-1 $\beta$  and IL-18 are released by dying macrophages [45]. The epithelial cell response to intracellular *Shigella* is also a major component

**Figure 1** Rupture, invasion, and inflammatory destruction of the intestinal epithelium by *Shigella*: an emerging scheme. PMN: polymorphonuclear leukocyte; TTSS: type III secretion system.

of the inflammatory response, which includes secretion of IL-8 [46] and rapid, sustained activation of the pro-inflammatory transcription system NF- $\kappa$ B through a signaling cascade that involves cytosolic proteins of the Nod family, particularly Nod1 [41]. Inflammation in turn enhances invasion by disrupting the epithelial barrier and facilitating access of the bacteria to sites that permit epithelial invasion. Eventually this process leads to massive chemotaxis of neutrophils and bacterial killing, although at the cost of epithelial destruction [47]. Endotoxin (i.e., lipid A of *Shigella*) is necessary for the expression of the invasive phenotype and also contributes to the rupture and destruction of the epithelial lining, mostly through TNF $\alpha$  [46].

### C. Role of Toxin in *Shigella* Pathogenesis

*Shigella* elaborate several toxins that contribute to virulence. *S. dysenteriae* type 1 is the only serotype that bears the chromosomal genes encoding the 70-kDa heterodimeric protein known as Shiga toxin. This potent cytotoxin also exhibits enterotoxicogenic, neurotoxic, and pro-inflammatory properties [48] and has been implicated in the pathogenesis of hemolytic-uremic syndrome. Two enterotoxins have been identified in rabbit ileal loop and Ussing chamber studies as likely mediators of the watery diarrhea often seen in early shigellosis [49–51]. *Shigella* enterotoxin 1 (ShET1) is an iron-regulated, 55-kDa protein with a A<sub>1</sub>–B<sub>5</sub> subunit configuration [51]. ShET1 is encoded by set, a chromosomal operon found almost exclusively in *S. flexneri* 2a [49]. *Shigella* enterotoxin 2 (ShET2) is a 62.8-kDa single-moity protein that is encoded by sen, which is found in the invasion plasmid of nearly all *Shigella* serotypes [50]. Watery diarrhea could also result from inflammation and release of mediators such

as adenosine by colonic leukocytes [52], or by up-regulation of receptors such as Galanin-1 in inflamed epithelial cells [53].

### D. Rational Construction of Live Attenuated *Shigella* Strains

The evolving understanding of the molecular pathogenesis of shigellosis is essential to the design of rational live-attenuated vaccines. For example, the organism's ability to traverse the FAE to reach the inductive sites of the mucosal immune system has been exploited to enhance the immunogenicity of vaccine candidates. The benefits of retaining triggers of macrophage apoptosis are less certain. On the one hand, this process generates a strong pro-inflammatory signal [54] that must be mitigated; on the other hand, apoptotic bodies of infected antigen-presenting cells are strongly immunogenic. Whereas preservation of epithelial cell invasiveness may enhance immunogenicity, elimination of cell-to-cell spread improves vaccine tolerance by minimizing the extent of the destructive intestinal lesion. The propensity for *Shigella* to cause watery diarrhea could be diminished with mutations in genes encoding enterotoxin synthesis. Clearly any *Shigella* vaccine formulation should be devoid of catalytically active Shiga toxin.

## IV. MODELS FOR EVALUATION OF VACCINE CANDIDATES

### A. Animal Models

The rhesus monkey model of shigellosis has been used extensively to assess the safety and efficacy of live oral vaccines.

The clinical and histologic response to intragastric inoculation closely mimics that seen during natural infection of humans, and diarrhea and dysentery are the principal clinical manifestations [55]. A disadvantage of this model is the frequent occurrence of *Shigella* infection among monkeys in captivity, which can render animals partially immune.

Small animal models have been developed for their practicality and lower cost. The Sereny test is a well-established model that measures the ability of *Shigella* inoculated into the conjunctival sac of animals (usually guinea pigs) to cause purulent keratoconjunctivitis [56]. Common practice is to demonstrate that a *Shigella* vaccine is Sereny negative before initiating Phase 1 trials. Nonetheless, some vaccines that are fully attenuated in the Sereny model have appeared reactogenic in humans. The model has also been adapted to assess vaccine efficacy [57].

The mouse intranasal challenge model can be used to evaluate the attenuation and protective efficacy of candidate vaccines. The simple columnar epithelium lining the tracheobronchial trees exquisitely is susceptible to invasion by *Shigellae* [23]. The lesions elicited by pulmonary *Shigella* infection are histologically similar to the colitis that characterizes shigellosis in primates and humans. The availability

of inbred mouse strains and cytokine reagents allows the characterization of the immune response generated by *Shigella* vaccines on a molecular level, but intranasal challenge model, such as the Sereny test, can only hint at the complexity of a protective immune response in the human colon.

## B. Volunteer Models for Vaccine Efficacy

Ultimately, the safety and efficacy of a *Shigella* vaccine must be determined by studies in humans. The experimental challenge model of *Shigella* in volunteers was developed in the 1960s [58] and its ability to detect protective efficacy has been validated using homologous strain re-challenge studies [3,4] which confirmed the immunizing ability of wild type that is observed in the field. Moreover, the *S. flexneri* 2a streptomycin-dependent vaccine which was efficacious in field trials [6] conferred significant protection in the volunteer challenge model (Table 1) [59]. In the 1990s, the *S. flexneri* 2a model was modified to administer the inoculum in sodium bicarbonate buffer rather than skim milk, which safely increased the attack rate and consistency of illness in control subjects and lowered the sample sizes necessary for an individual trial [4].

**Table 1** Clinical and Immune Response of Adult Volunteers from Industrialized Countries to Wild-Type Infection and Live, Attenuated *Shigella flexneri* 2a Vaccine Candidates

Immunogen	<i>S. flexneri</i> 2a parent	Ref.	Dose (CFU)	Percent of subjects with adverse reactions	Anti-LPS response <sup>a</sup>			Protective efficacy vs. challenge
					IgA ASC (GM)	IgG antibody

Ref = reference; CFU = colony forming units; ASC = antibody secreting cells; GM = geometric mean per 10<sup>6</sup> peripheral blood mononuclear cells; SmD = streptomycin dependent; nd = not done; na = not applicable.

<sup>a</sup> Study-specific definitions of ASC responses were used. For serologic responses, values represent the percent of subjects with IgG antibody responses, defined as fourfold rises, with the exception of the SC602 study, which considered a threefold rise to be a response.

<sup>b</sup> Protection in field trial was 82-100% [5,6,61,62].

<sup>c</sup> The protective efficacy of these two trials combined was 36%.

<sup>d</sup> These values represent a composite of published and unpublished studies (see text).

<sup>e</sup> The geometric mean was 43 among volunteers who participated in the challenge trial.

## V. LIVE *SHIGELLA* VACCINE STRAINS LACKING THE INVASIVE PHENOTYPE

### A. Streptomycin-Dependent (SmD) Vaccines

Mel and coworkers developed SmD mutants of *S. sonnei* and *S. flexneri* by serial passage on streptomycin-containing media [60]. The basis of attenuation is now believed to be spontaneous deletion of virulence genes from the invasion plasmid (F. Noriega, unpublished). Monovalent and bivalent combinations of *S. flexneri* (serotypes 1, 2a, and 3) and *S. sonnei* were safe and protective (82–100% efficacy) when given (with buffer) to nearly 8000 adults and children in controlled field trials in Yugoslavia [6,61,62]. Both freshly harvested and lyophilized formulations were used. Vaccine was excreted by 90% of recipients, for a mean of 3 days [62]. However, drawbacks of these vaccines are recognized, including 1) the need for multiple (4 to 5) doses, and the large inocula ( $2\text{--}6 \times 10^{10}$  CFU) required per dose (which affects cost) [5,6,61]; 2) the occurrence of vomiting and less often mild diarrhea (primarily after the first dose), which were minimized by giving gradually increasing inocula [5,6,61]; 3) the need for a booster dose at 1 year to maintain protection [62]; 4) occasional in vivo reversion to streptomycin-independence (without loss of attenuation) [63,64]; and 5) equivocal efficacy in preventing endemic shigellosis among institutionalized children in the United States [65].

### B. T<sub>32</sub>-ISTRATI Strain

Romanian scientists used the Sereny test as a screening device to identify spontaneous avirulent mutants of *S. flexneri* 2a. After 32 passages on nutrient agar, a mutant was identified as consistently Sereny negative. This strain was designated T<sub>32</sub>-Istrati, and it is now probably the most extensively tested live *Shigella* vaccine, having been administered to more than 60,000 individuals in Romania [66] and to more than 8000 subjects in China [12] between 1976 and 1980. The genetic basis of attenuation has since been shown to be a 32-MD deletion in the 140-MD plasmid of *S. flexneri* 2a [67]. This deletion eliminated the genes encoding the *Shigella* Ipa proteins and other virulence determinants such as *virF* (a positive regulator for *ipa* genes) and *virG/icsA*.

The Cantacuzino Institute of Bucharest manufactured T<sub>32</sub>-Istrati under the trade name Vadizen as a liquid, refrigerated formulation that was administered with buffer as five oral doses increasing from  $5 \times 10^{10}$  to  $2 \times 10^{11}$  CFU at 3-day intervals. Open-label Romanian trials carried out in 131 children's collectives (32,000 subjects) and 7 adult collectives (5000 subjects) suggested 81% protection against *S. flexneri* 2a using historical data for comparison. These studies also reported 89% protection against heterologous *Shigella* species including *S. sonnei* [66].

Seven placebo-controlled studies involving 11,128 individuals 4–60 years of age were carried out at the Lanzhou Institute of Biological Products in China using an enteric-coated, refrigerated version of T<sub>32</sub>-Istrati (without buffer). The vaccine was safe when administered in four doses of  $2\text{--}4 \times 10^{11}$  CFU (children received a lower dose) every third day. Most recipients excreted vaccine for 2 to 4 days after the

last dose; interestingly, 7% excreted T<sub>32</sub>-Istrati for 8 days. Efficacy was 85% against homologous disease and 63% against heterologous strains (*S. flexneri* 1b and *S. boydii* 1–6) [12].

### C. FS Bivalent Vaccine

In 1987, Wang and coworkers at the Lanzhou Institute of Biological Products described a mutant *S. sonnei* virulence plasmid, designated S<sub>7</sub>, that was used to construct a bivalent *S. flexneri*–*S. sonnei* (FS) vaccine based on T<sub>32</sub>-Istrati [68]. *S. sonnei* is unique among *Shigella* species because the *rbf* locus, encoding the form I (smooth) O-polysaccharide of LPS, is carried on a 120-MD virulence plasmid. The S<sub>7</sub> plasmid was found in a spontaneously occurring, noninvasive mutant of *S. sonnei* that expressed the form I O-antigen [68,69]. The mutant plasmid fails to hybridize with probes containing the *ipa* genes or the *virF* regulatory locus for the invasive phenotype [70] and probably suffered a spontaneous deletion similar to the attenuating deletion in the T<sub>32</sub>-Istrati virulence plasmid while retaining the form I encoding genes. The S<sub>7</sub> plasmid was tagged with Tn5 (kanamycin resistance) and mobilized into T<sub>32</sub>-Istrati using *E. coli* HU<sub>735</sub>. Like the T<sub>32</sub>-Istrati conjugal recipient, the FS hybrid is avirulent in HeLa cell invasion and Sereny tests. It protects rhesus monkeys against illness following challenge with both constituent strains. *S. sonnei* O-antigen expression is stable in vitro after 36 passages without kanamycin selection [68].

The FS vaccine was first evaluated in humans in a placebo-controlled trial using freshly harvested bacteria. At 3-day intervals, 34 volunteers received three ascending doses of  $2\text{--}5 \times 10^{10}$  CFU without significant reactogenicity. Most recipients had fecal antibody responses recognizing *S. flexneri* 2a LPS (68%) and *S. sonnei* LPS (62%), with a twofold mean rise. In this and subsequent field trials, FS vaccine was found to be as safe as placebo and was excreted by 67–75% of vaccinees for 1–3 days.

During the 1990s, two double-blind, placebo-controlled efficacy trials of the FS vaccine were conducted in Changge City, China. A three-dose regimen using a lyophilized FS product was administered at  $2\text{--}5 \times 10^{10}$  CFU to ca. 17,500 adults and children while 15,700 subjects received placebo. Passive surveillance for shigellosis was conducted for 5–6 months. Protective efficacy against *S. flexneri* 2a was 61–65% and against *S. sonnei* was 50–72%. Efficacy against heterologous *Shigella* spp. was 48–52% [71].

These data indicate that the noninvasive T<sub>32</sub>-Istrati and FS hybrid vaccines are safe for Chinese adults and children and confer short-term efficacy against both homologous and heterologous serotypes. The immunological basis of heterologous protection is unclear, and the effect may be detectable only in large-scale trials. Nonetheless, the need for a three-dose regimen containing over 10-logs of live bacteria is a daunting logistical prospect for most developing countries although the 60% level of protection against shigellosis could have a positive public health impact. Additional trials of the FS vaccine specifically targeted to infants and toddlers could further define the public health application of this approach.

## VI. HYBRID VACCINES

### A. Bivalent *Salmonella* Typhi–*Shigella sonnei* Hybrid Vaccine

In the 1980s, efforts to develop improved live *Shigella* vaccines included heterologous carrier strains designed to invade and proliferate within the intestine to more effectively deliver *Shigella* antigens to the local immune system, simulating the protective immune responses that follow natural infection. The *S. typhi*–*S. sonnei* hybrid (strain 5076-1C) utilizes an invasive attenuated mutant of *Salmonella enterica* serovar Typhi, strain Ty21a, to carry the form I *S. sonnei* plasmid and express *S. sonnei* O antigen. This vaccine offered the potential to protect against both typhoid fever and shigellosis. In volunteers, a lyophilized formulation of 5076-1C was well tolerated and in initial trials protected against experimental challenge [14]; however, the efficacy results could not be replicated with subsequent lots of vaccine and further testing was not done [3]. Chemical and immunoblot analyses of 5076-1C indicated that the O-polysaccharide of *S. sonnei* was transported to the cell surface without covalent linkage with the core lipid A of *S. typhi* perhaps accounting for its erratic immunogenicity [72].

### B. *Escherichia coli* as a Carrier for *Shigella* Antigens

In the 1970s, a noninvasive *E. coli* carrier vaccine expressing *S. flexneri* 2a O-antigen on its surface was constructed [73]. Although the vaccine was safe and colonized the intestines of volunteers for several days, antibody responses to the type-specific O-antigen were meager and the vaccine did not confer protection against wild-type challenge. To enhance immunogenicity, second-generation *E. coli* carrier vaccine strains were constructed containing the invasion plasmid of *S. flexneri* 5 plus the chromosomal genes encoding *S. flexneri* 2a LPS [74]. These strains were invasive and expressed O-antigen but lacked full *Shigella* virulence [74]. An initial construct, designated EcSf2a-1, produced adverse reactions in subjects who ingested  $10^9$  CFU (with buffer), while at better tolerated doses (ca.  $10^6$  to  $10^7$  CFU), it did not protect against challenge [55]. A further attenuated aroD mutant was constructed and designated EcSf2a-2 [75]. Three oral doses of EcSf2a-2 over 1 week were well tolerated at doses up to ca.  $10^9$  CFU [55]. Although most recipients of ca.  $10^9$  CFU had immune responses, the vaccine conferred only 36% protection against challenge (Table 1). Subsequent studies attempted to improve safety by giving a lower, well-tolerated inoculum ( $7 \times 10^8$  CFU) and to enhance efficacy using a four-dose regimen. Unfortunately, immunogenicity was modest and vaccine efficacy was only 27% (Table 1) [20].

## VII. ENTEROINVASIVE DELETION-MUTANTS OF *SHIGELLA*

Molecular engineering has enabled the development of live, oral *Shigella* vaccine candidates with precise, genetically defined mutations. The strains described below retain inva-

siveness but are attenuated by mutations which either induce auxotrophy for metabolites that are essential for survival of the bacteria in vivo, such as genes in the aromatic or purine metabolic pathways, or inactivate virulence factors, such as VirG/IcsA and the *Shigella* enterotoxins 1 and 2.

### A. Aromatic Autotrophs

#### 1. Auxotrophic *S. flexneri* Y Vaccine Candidates

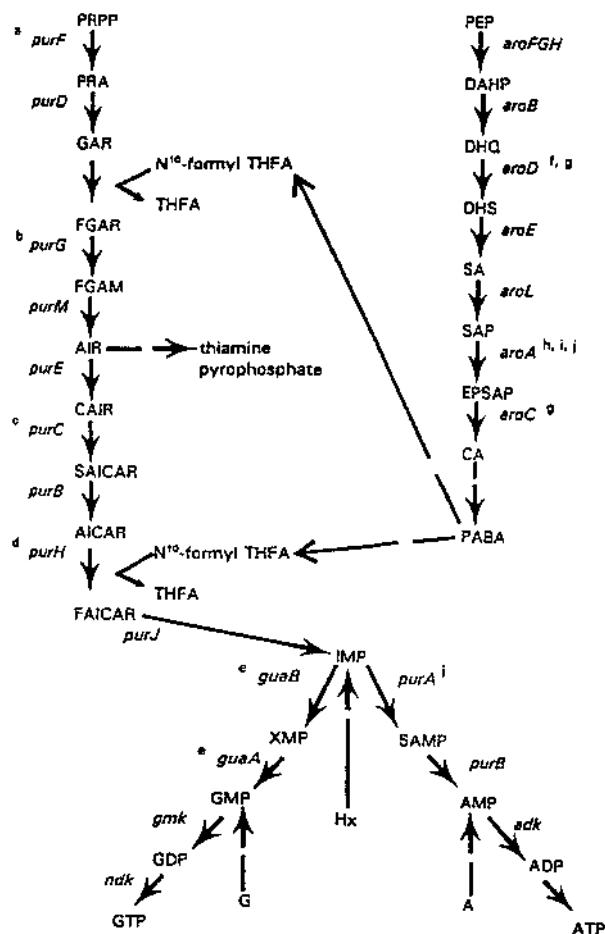

Mutations in genes involved in aromatic amino acid synthesis pathway prevent intracellular bacteria from making folic acid de novo (Figure 2). If environmental sources are not available, the growth of the mutant is severely hindered [76]. Lindberg and coworkers applied this strategy to *Shigella* vaccine development, constructing strain SFL124 with a transposon-generated 1400-bp deletion in the *aroD* gene of virulent *S. flexneri* Y, strain SFL1 [77]. They postulated that a serotype Y strain might provide cross-protection against other *S. flexneri* serotypes as its O-polysaccharide shares tetrasaccharide repeating units with all other *S. flexneri* except serotype 6. SFL124 is invasive, Sereny negative, and protective in animal models. A dose of  $10^9$  CFU was given with buffer to adult volunteers living in Sweden [78] and Viet Nam [79], and to 9–14-year-old Vietnamese children (20–30 subjects per group) [80]. SFL124 appeared safe and elicited both primary and anamnestic immune responses. Regrettably, the ability of  $\Delta$ aroD *S. flexneri* Y to confer homologous and heterologous immunity was never evaluated in humans.

#### 2. Auxotrophic *S. flexneri* 2a Vaccine Candidates

A similar attenuating deletion was introduced into virulent *S. flexneri* 2a strain 2457T, resulting in the  $\Delta$ aroD mutant SFL1070 [81]. When administered to 37 Swedish adults, SFL1070 exhibited a dose-dependent pattern of clinical tolerance, vaccine excretion, and immune responses [82]. Transient mild gastrointestinal symptoms occurred in 10–33% of subjects who received three doses of  $10^5$  to  $10^8$  CFU within 5 days. Vaccination with  $10^9$  CFU caused more severe symptoms (abdominal pain, watery diarrhea, or fever) in 44% of volunteers (Table 1). These results point to the importance of the inherent virulence of the parent strain in dictating the clinical tolerance of vaccines with identical attenuating lesions. The parent strain of SFL1070 is more pathogenic in humans than the SFL1 strain used to construct SFL124.

#### 3. Auxotrophic *S. flexneri* 2a with a Deletion in *virG*

Noriega and coworkers attempted to enhance the attenuation conferred by aromatic auxotrophy by introducing a specific, in-frame deletion in the plasmid gene *virG* of  $\Delta$ aroA *S. flexneri* 2a, resulting in double mutant  $\Delta$ aroA,  $\Delta$ virG strain CVD 1203 [83]. These specific deletions were obtained in strain 2457T by allelic exchange of the modified genes for their wild-type counterparts using suicide vectors [83]. CVD 1203 was attenuated and protective in the Sereny model [83]. A Phase I study was conducted at the Center for Vaccine Development [84]. After a single dose of ca.  $10^9$ ,  $10^8$ , or  $10^6$  CFU with buffer (10–11 subjects per group), brief clinical

**Figure 2** Purine de novo biosynthesis pathway and contribution of the aromatic metabolic pathway. Interrupted arrows illustrate pathways in which the individual steps are not represented. Enzymes are represented by their genes. Superscript letters represent selected published strains with a mutation of the gene involved in that reaction. Strains represented are: a: *purF1741::Tn10 S. dublin* SL5437 [85]; b: *purG876::Tn10 S. dublin* SL5436 [85]; c: *purC882::Tn10 S. dublin* SL5435 [85]; d: *purH887::Tn10 S. dublin* SL2975 [85]; e: *AguaBA S. flexneri* 2a CVD1204 and *AguaBA, AvirG* CVD1205 [87]; f: *aroD25::Tn10 S. flexneri* Y SFL114 [77], SFL124 [79], *S. flexneri* 2a 1070 [82]; g: *AaroC, AaroD S. typhi* CVD908 [107]; h: *hisG46 DEL407, aroA554::Tn10 S. typhimurium* SL3261 [76]; i: *AaroA S. flexneri* 2a CVD1201 and *AaroA, AvirG* CVD1203 [83]; j: *AaroA, AhisG, ApurA S. typhi* 541Ty [108]. reactions (fever, diarrhea, and/or dysentery) occurred in 72%, 18%, and 0% of volunteers, respectively. Anti-LPS IgA ASC responses were dose-related, occurring even at doses of  $10^6$  CFU where illness was not seen (Table 1). A striking component of the reactogenicity observed with CVD 1203 was the occurrence of watery diarrhea in approximately 25% of those who receive  $10^8$  or  $10^9$  CFU [84]. This finding supports the hypothesis that deletion of genes involved in the production of *Shigella* enterotoxins may further attenuate *Shigella* vaccines.

## B. Purine Auxotrophs

### 1. A Lineage of *S. flexneri* 2a Purine Auxotrophs: CVD 1204, CVD 1207, and CVD 1208

Stimulated by the observations of McFarland and Stocker on the attenuating effects of purine auxotrophy in the mouse model of *Salmonella* virulence [85], Noriega and coworkers constructed a new generation of *Shigella* vaccine candidates from *S. flexneri* 2a strain 2457T based on a mutation in the genes encoding two enzymes in the guanine nucleotide biosynthetic pathway, GMP synthetase (*guaA*) and IMP dehydrogenase (*guaB*) [86] (Figure 1). Using homologous recombinations with a suicide plasmid bearing the deleted alleles, they first created the *AguaBA* strain CVD 1204 [87]. Further mutations were added to this strain to find the optimal balance of safety and immunogenicity. To create CVD 1207 (*AguaBA, AvirG, Asen, Aset*), a second in-frame deletion was made in the plasmid gene *virG* [87]. The chromosomal mutation *Aset* was accomplished with deletion of 85% of the subunit A [9]. A *Asen* cassette was constructed by fusing two 700-bp segments that included the N and C termini of *sen* minus 300 bp corresponding to the putative active site in the N-terminal region [9]. An *ars* operon, conferring resistance to arsenite, was cloned into the *Asen* to facilitate transfer of the mutated virulence plasmid to other *Shigella* vaccine strains and as a marker to distinguish CVD 1207 in the field [88]. Finally, *AguaBA, Asen, Aset* strain CVD 1208 was derived by restoring wild-type *virG*. The lack of enterotoxic activity of CVD 1207 and 1208 was confirmed in Ussing chambers [9]. These strains appear highly attenuated and protective in the Sereny model [9]. Furthermore, when directly compared to *AaroA S. flexneri* 2a, the *AguaBA* strains are significantly less invasive for HeLa cells monolayers [87]. The mechanism for reduced invasiveness is unknown. The expression of IpaB and IpaC is not diminished, and the occurrence of other, spontaneous, metabolic mutations was ruled out by the recovery of the full invasive phenotype when the wild-type *guaBA* operon was reinstated.

### 2. Phase 1 Trial to Evaluate *AguaBA, AvirG, Asen, Aset* Strain CVD 1207

CVD 1207 was evaluated for safety and immunogenicity in volunteers at the Center for Vaccine Development (Table 1). Group of 3 to 12 subjects ingested CVD 1207 (with buffer) at one of five doses ranging from  $10^6$  to  $10^{10}$  CFU. Vaccination was well tolerated at doses as high as  $10^8$  CFU. In comparison, one of 12 recipients of  $10^9$  CFU experienced mild

diarrhea and another vomited once, and one of five recipients of  $10^{10}$  CFU reported diarrhea and emesis. All recipients of  $10^8$  to  $10^{10}$  CFU excreted vaccine, most for fewer than 3 days, although two subjects had positive stool cultures 14 days post-vaccination and were treated with ciprofloxacin. Dose-related IgA ASC anti-LPS responses were seen, with geometric mean peak values of 6.1 to 35.2 ASCs/ $10^6$  PBMC among recipients of  $10^7$  to  $10^{10}$  CFU.

CVD 1207 achieved a remarkable degree of attenuation of virulent *Shigella* compared with earlier invasive *S. flexneri* 2a recombinant strains. Moreover, when occasional adverse reactions did occur at very high inocula, neither fever nor dysentery was encountered. Nonetheless, it is conceivable that at well-tolerated doses, CVD 1207 may be insufficiently immunogenic after a single dose. Therefore clinical trials are ongoing to evaluate *S. flexneri* 2a purine auxotrophs with fewer attenuating mutations, such as CVD 1204 (*AguaBA*) and CVD 1208 (*AguaBA*, *Asen*, *Aset*). These trials will also provide valuable information on the pathogenicity of *Shigella* enterotoxins in humans.

### C. *Shigella* Fundamentally Attenuated with a Mutation in *virG*

#### 1. *S. flexneri* 2a Harboring Deletions in *virG/icsA* and *iuc* (SC602)

Sansonetti and colleagues constructed a double mutant with deletions in both the *virG/icsA* gene and the *iucA-iut* chromosomal locus (encoding the aerobactin iron binding siderophore) from *S. flexneri* 2a strain 454. The *iuc* mutation was generated by recombination of *iuc::Tn10* into the chromosome using phage P1 transduction. Spontaneous excision of the tetracycline resistance gene and the flanking regions including the *iuc* locus was selected by growth on fusaric acid medium. The *virG* gene was inactivated by double recombination with a kanamycin resistance-sucrose sensitivity (*sacB*) cartridge carrying flanking regions of *virG*. The selected clone, designated SC602, harbored a deletion of the entire *virG* gene along with substantial flanking sequences totaling 10 kb.

SC602 (lyophilized) was tested in a series of inpatient dose-response studies at the U.S. Army Medical Research Institute for Infectious Diseases (USAMRIID). In the first trial, test doses ranged from  $10^4$  to  $10^8$  CFU, with three vaccinees and three-unvaccinated controls per dose group. No subject who received  $10^4$  to  $10^7$  CFU developed diarrhea, but four had fever (23%), and one had a severe headache. However, two subjects who received  $10^8$  CFU experienced diarrhea, fever, and constitutional symptoms. Next, 15 volunteers were inoculated with  $10^6$  CFU, and nine (60%) experienced diarrhea, fever, and constitutional symptoms (Table 1). When 12 additional subjects ingested  $10^4$  CFU, only one had a significant symptom (diarrhea). The peak geometric mean anti-LPS IgA ASC response to  $10^4$  CFU was 18 per  $10^6$  PBMC. This dose was deemed clinically acceptable and immunogenic, and a challenge study was performed. The peak post-vaccination geometric mean anti-LPS IgA ASC count was 43 per  $10^6$  PBMC in the subset of vaccinees who participated in the challenge study (18 per  $10^6$  PBMC).

Eight weeks after vaccination with  $10^4$  CFU of SC602, seven vaccinees and seven naïve controls were challenged with  $10^3$  CFU of virulent *S. flexneri* 2a strain 2457T. Fever and/or severe shigellosis occurred in no vaccinees and in six controls (86%). However, three of the challenged vaccinees (43%) did experience mild diarrhea (overall protective efficacy 50%) (Table 1). Immune correlates of protection against any symptom of shigellosis in this challenge trial included >40 IgA ASC per  $10^6$  PBMC recognizing *S. flexneri* 2a LPS and  $\geq 3$ -fold rise in serum IgA antibody against *S. flexneri* 2a LPS [21].

Next, the safety and immunogenicity of SC602 was evaluated in an outpatient trial at USAMRIID with 34 vaccinees and one control (T.S. Coster, unpublished). Vaccinees received either  $2.6$  or  $5.6 \times 10^4$  CFU of SC602. Eight subjects (24%) experienced a measurable clinical reaction (fever or diarrhea). The vaccine was isolated from stools of all vaccinees, but shedding did not begin until 10 days post-vaccination in some. The mean duration of colonization was 12 days, and 5% of vaccinees exceeded 4 weeks [89]. All volunteers received ciprofloxacin 35 days after vaccination. Thereafter, another inpatient study was conducted at USAMRIID in which nine volunteers received the 4-log dose with similar results (D.E. Katz, unpublished). Three additional subjects received  $10^3$  CFU without reactions, all of whom excreted vaccine and had IgA ASC anti-LPS responses (10, 75, and 277 ASC per  $10^6$  PBMC).

In sum, approximately 20% of the 58 subjects who received  $10^4$  CFU of SC602 experienced diarrhea or fever of brief duration, and 10% had headaches or cramps of sufficient severity to modify normal activities. Significant IgA anti-LPS rises were seen in 66% of the 24 subjects who had ASC responses measured, and 58% of subjects had threefold or greater rises in serum anti-LPS IgA (Table 1). SC602 completely protected against severe shigellosis and offered partial protection against any illness. Phase 2 trials of the 4-log dose are being designed to determine consumer acceptance of the symptoms associated with vaccination. In light of the prolonged excretion, inadvertent spread of SC602 to household contacts will be carefully monitored in future trials.

In October of 2000, clinical trials of SC602 began in Bangladesh, an endemic area for *S. flexneri* 2a (A. Baqui and D. Isenbarger, unpublished). One inpatient and three outpatient trials were conducted in adult volunteers, followed by similar trials in children 8 to 10 years old, at a dose of  $10^4$ ,  $10^5$ , or  $10^6$  CFU SC602 or placebo. Neither adults nor children experienced significant side effects, and SC602 was only rarely isolated from vaccinees. The final evaluation of SC602 in Bangladesh was a series of inpatient studies conducted in 12–36-month-old children who received escalating doses of  $10^3$  to  $10^6$  CFU. Diarrhea and/or fever occurred in a minority of subjects but was not dose related nor significantly more common in vaccinees than in placebo recipients. Neither vaccine excretion nor immune responses were detected.

The disappointing results of this attempt to use a minimally attenuated, live *Shigella* strain as a vaccine for children in the developing world suggests that safety and immunogenicity data from vaccine trials in adults of the

developed world are not easily extrapolated to endemic areas. Perhaps lactoferrin in the intestines of milk-fed toddlers acted synergistically with the aerobactin (*iuc*) mutation to incapacitate the vaccine by depleting its iron stores. Maternal antibody, actively acquired immunity even at a young age, and small bowel bacterial overgrowth may also mitigate intestinal colonization with a small number of *Shigellae* even if the attenuation of the pathogen is minimal.

## 2. *S. sonnei* Attenuated Solely on the Basis of a Deletion Mutation in *virG* (WRSS1)

In the rabbit ileal loop model, deletion in *iuc* provides little additional attenuation of *S. flexneri* 2a above that seen by inactivating *virG* alone [90]. This finding prompted Hartman and Venkatesan to develop a *S. sonnei* vaccine candidate attenuated solely on the basis of a deletion in *virG*. To minimize the predilection of *S. sonnei* to spontaneously lose its virulence plasmid, they chose a wild-type strain that exhibited stability of the form I phenotype [91]. The *sacB* suicide vector pCVD422 was used to replace wild-type *virG* allele with *virG* possessing a 212-bp deletion. This strain, WRSS1, was fully attenuated in the Sereny model and induced protective immunity [91].

A Phase 1 trial was conducted at the Center for Vaccine Development in which volunteers were randomized, in a double-blind fashion, to receive either placebo (seven subjects) or vaccine with buffer (27 subjects) at a dose of ca.  $10^3$ ,  $10^4$ ,  $10^5$ , or  $10^6$  CFU [27]. Self-limited illnesses (fever and mild diarrhea) occurred in 14%, 0%, 30%, and 33% of subjects in each ascending dose group, respectively. Subjective complaints (headache, abdominal cramps) were reported by 33% of vaccinees but no controls. Vaccination evoked vigorous IgA anti-LPS ASC responses, which often exceeded 100 per  $10^6$  PBMC. Geometric mean peak post-vaccination anti-LPS serum IgG and fecal IgA titers were also robust. For unknown reasons, the clinical, microbiologic, and immune responses in the 4-log dose group were weak. At all other doses, immune responses were similar in magnitude to those elicited by strains that prevent illness following experimental challenge [21], suggesting that WRSS1 may confer protective immunity.

Recent evidence indicates that knocking out the chromosomal and plasmid copies of the *S. flexneri* *msbB* genes that encode the full acyl-oxy-acylation of the lipid A induces a significant decrease in endotoxicity. As a consequence, the double-mutant has a diminished capacity to induce inflammatory destruction of the intestinal mucosa in a rabbit ligated intestinal loop model of infection [46]. Genetic attenuation of the endotoxin activity of currently available live attenuated vaccine candidates such as SC602 may eliminate residual reactogenicity, particularly the febrile component observed in some volunteers.

## VIII. THE CONCEPT OF POLYVALENT *SHIGELLA* VACCINES

It is not realistic to attempt to protect against all 47 serotypes of *Shigella*. An analysis of serotype-specific disease burden suggests that five *Shigella* strains (*S. sonnei*, *S. dysenteriae* 1,

and *S. flexneri* 2a, 3a, and 6) are most critical to include in a potential vaccine [1]. *S. dysenteriae* comprises a small proportion of the endemic episodes, but the severe manifestations typical of serotype 1, which constitutes about 30% of *S. dysenteriae* isolates, argue for its inclusion. *S. sonnei* and *S. flexneri* are essential as they represent the most common causes of endemic shigellosis worldwide [1]. However, the variability (both geographic and temporal) of the 15 *S. flexneri* serotypes presents a logistical conundrum to vaccine developers. Accordingly, Noriega and coworkers discovered that a composite of three serotypes, *S. flexneri* 2a, 3a and 6, provides cross-protection against the remaining 12 *S. flexneri* serotypes [9]. The immunological rationale is that among these three serotypes there is a type- or group-specific antigen shared by each of the 15 *S. flexneri* serotypes. The functional activity of these serological cross reactions was shown in studies involving Sereny test challenge of mucosally immunized of guinea pigs [9].

Little is known about the immune response that can be generated by immunizing humans with multiple *Shigella* serotypes. Cooper and coworkers in the 1940s immunized children parenterally with a *S. flexneri* vaccine consisting of inactivated serotype II, III, and VII strains (later respectively known as serotypes 2, 3, and X) [92]. The sera from immunized children protected mice against challenge with the homologous wild-type strains [92]. Later, Formal and coworkers constructed attenuated strains by conjugating virulent *Shigella* with an Hfr<sup>+</sup> strain of *E. coli* K12. Two oral doses of a vaccine comprising *S. flexneri* 1b, 2a, and 3 plus *S. sonnei* protected monkeys against each homologous serotype [7]. Finally, Mel and coworkers immunized adults and children with bivalent vaccines containing SmD *S. flexneri* serotypes 2a and 3 [61], *S. flexneri* 1 and 2a, or *S. flexneri* 3 and *S. sonnei* [6]. These studies demonstrated in humans that oral delivery of two serotypes combined did not interfere with the immune response to the individual strains and suggest that protection against multiple *Shigella* serotypes with an oral polyvalent *Shigella* vaccine is feasible.

## IX. SHIGELLA AS A LIVE VECTOR

### A. *Shigella* Expressing Foreign Antigens

Attenuated *Shigella* are also attractive candidates to serve as live vector vaccines. These strains are delivered orally, colonize the FAE, and elicit a broad immune response that includes serum and mucosal antibodies, cell-mediated immune responses and a form of antibody-dependent cellular cytotoxicity [88,93]; moreover, *Shigella*, which share a high degree of homology with *E. coli*, are readily manipulated genetically. In theory, oral vaccines against a variety of infectious diseases can be developed by stable expression of foreign genes encoding protective antigens in a *Shigella* live vector strain.

Initial uses of *Shigella* as a live vector employed  $\Delta$ *aroD* *S. flexneri* strain SFL 124 as a carrier for antigens from *S. dysenteriae* including shiga toxin B subunit and O-antigen determinants [94–96]. Such strains elicited immune responses in animal models against both *S. flexneri* and *S. dysenteriae* antigens. Additionally, attenuated strains of

*Shigella* have been used to express antigens from enterotoxigenic *E. coli* (ETEC) [97], VP of rotavirus [98], and the C3 epitope of VP1 of poliovirus [99]. Immunization with these strains elicited immune responses in animal models against both the heterologous antigen or epitope as well as the *Shigella* vector. Engineering of specialized stabilized plasmids has enabled reliable, high-level expression of multiple antigens from a single plasmid in attenuated *Shigella* strains. At the Center for Vaccine Development, investigators have used this system to express multiple different ETEC fimbriae as well as LT antigens in *AguaBA S. flexneri* vaccine strains that can elicit both serum and mucosal immune responses to the heterologous antigens as well as to the *Shigella* vector in animal models [100–102]. These systems demonstrate the possibility of constructing a multicomponent vaccine formulation capable of generating broad spectrum immunity against two important pathogens.

## B. DNA Delivery

The ability of *Shigella* to invade eukaryotic cells and gain access to the cytoplasm has been exploited for the delivery of DNA vaccines. Sizemore and coworkers [103] used the marker protein β-galactosidase, driven by the CMV promoter, to show that mucosal administration of an attenuated strain of *Shigella* could deliver a DNA plasmid to the cytosol of a eukaryotic cell and elicit immune responses in a mouse model. Subsequently, investigators have used attenuated *Shigella* strains to deliver DNA plasmids encoding fragment C of tetanus toxin [104], measles virus H and F antigens [105,105A], and HIV gp120 [106]. In each case immune responses to the encoded antigen were generated in immunized animals.

## X. CONCLUSIONS

The increasing knowledge of the *Shigella* genome has allowed investigators to target diverse genes for deletion mutations in an attempt to construct safe, attenuated oral *Shigella* vaccines. Experience suggests that the major impediment to creating a successful vaccine will be achieving safety in industrialized countries while retaining immunogenicity in developing countries. In the near future, it is expected that several promising vaccine candidates will reach Phase I clinical trials. The mutation or combination of mutations that demonstrates the best safety without compromising immunogenicity will likely be reproduced in other serotypes to form a polyvalent *Shigella* vaccine containing the most prevalent serotypes worldwide. It is possible that such a *Shigella* vaccine can also serve as a live vector vaccine to express antigens which confer protection against other relevant enteric pathogens.

### I. INTRODUCTION

Enterotoxigenic *Escherichia coli* (ETEC) is one of the most common causes of diarrheal disease in the developing world [1]. In these areas, on an annual basis, ETEC results in an estimated 280–400 million diarrheal episodes in children under 5 years and an additional 100 million episodes in children aged 5–14 years [2,3]. Moreover, ETEC causes substantial disease in indigenous adults in developing countries, with the estimated number of cases per year in persons above 15 years exceeding 400 million [3]. Additionally, Western travelers who visit developing countries are frequently infected with ETEC, which is responsible for one-third to one-half of all diarrheal episodes in travelers to Africa, Asia, and Latin America [4].

Enterotoxigenic *E. coli* causes disease by colonizing the small intestine and elaborating a heat-labile (LT) or a heat-stable enterotoxin (ST) or both toxins [5]. The resulting illness usually lasts from 3 to 7 days and ranges from mild diarrhea without dehydration to severe cholera-like disease [1,3]. Although the illness is typically mild, it does result in an estimated 300,000–700,000 deaths per year, mostly in young children with more severe presentations [2,3]. Disease severity may partly be related to the toxin profile of the causative strain. A recent study found that ETEC producing ST alone or ST together with LT induced moderate or severe disease in a significantly higher proportion of episodes than LT only producing strains [6].

During the first 3 years of life, children in less-developed countries typically experience up to three separate episodes of ETEC diarrhea per year, after which the age-specific incidence of ETEC disease declines dramatically [1]. In Bangladeshi children under 5 years of age, ETEC diarrhea

has been associated with growth faltering [7]. Thus an effective vaccine that could reduce ETEC morbidity and mortality may have great public health utility, particularly for children in developing countries.

In regions of the world where ETEC is highly endemic, the aforementioned decline in ETEC diarrhea incidence as well as the decreased ratio of ETEC disease to infection with increasing age [6,8,9] are consistent with the notion that protective immunity develops with repeated ETEC infections. That adults from industrialized countries experience high attack rates of ETEC diarrhea when visiting areas where ETEC diarrhea is endemic [4] suggests that the lower incidence of ETEC disease in indigenous adults is due to acquired immunity rather than to other age-related host factors. Additional support for the induction of protective immunity against ETEC disease has been drawn from trials of the oral cholera toxin B subunit-whole cell (CTB-WC) cholera vaccine (see Chapter 59 this volume). Oral immunization with CTB, which is immunologically cross-reactive with the B subunit component of *E. coli* LT (LTB), afforded highly significant, albeit short lasting, protection against diarrhea caused by LT producing ETEC in Bangladesh [10]. Comparable levels of protection against LT ETEC disease (ranging from 50% to 80%) were also observed in controlled trials of the oral CTB-WC vaccine in Finnish travelers to Morocco [11] and U.S. travelers to Mexico [12]. In a recent pilot study, an oral ETEC vaccine was also shown to provide significant protection against ETEC disease in Austrian travelers visiting countries in Asia, Africa, and Latin America [13]. Together, these findings strongly support the notion that an effective ETEC vaccine is achievable. The design of such a vaccine should be based on the knowledge of mechanisms of ETEC disease and immunity.

## II. PATHOGENIC MECHANISMS IN ENTEROTOXIGENIC *E. COLI* INFECTIONS

The critical virulence properties that contribute to the pathogenesis of ETEC diarrhea are the ability of bacteria to closely adhere to the mucosa of the proximal small intestine by means of colonization factors (CFs) and to elaborate enterotoxins that interact with enterocytes to yield electrolyte-rich watery secretions [5,14]. Clinical ETEC isolates are fairly diverse and comprise many different O:H serotypes, multiple antigenically distinct CF types, and three different toxin phenotypes (i.e., LT only, ST only, or LTST) [14–17]. The greatest diversity is in O and H serogroup expression. At least 70 different *E. coli* O groups have been found among clinical ETEC isolates [17]. Distribution of the different ETEC toxin profiles has differed considerably with time, population, and geographical area, although the proportion of ST only clinical isolates appears to have increased during recent years in children in endemic areas [6,15,17]. Thus until 5–10 years ago, the three toxin phenotypes were estimated to constitute approximately one-third each among clinical ETEC isolates [14,16], whereas epidemiological studies during recent years have found that around 50% of all clinical isolates produce ST only [6,17].

*E. coli* LT is similar to cholera toxin (CT) in that both toxins consist of a toxin-active A subunit attached to five B subunits that mediate binding to cell-membrane receptors. Both the LT A and B subunits cross-react immunologically with the corresponding CT subunits, although there are also unique A and B subunit epitopes on both toxins [16,18]. Immune responses against LT and CT are mainly directed against the B subunits [16]. Heat-stable enterotoxin a (STa) constitutes a family of closely related peptides that induce diarrhea both in humans and animals. There are two highly related STa congeners produced by ETEC, originally named for the source (STh, human; STp, porcine) from which the type strain was derived. Both are methanol-soluble peptides of 18 (STp) or 19 (STh) amino acids that activate guanylate cyclase C [19]. Both STa types are poorly immunogenic, but high titer polyclonal anti-STa sera or monoclonal antibodies can be obtained by immunization with conjugates consisting of STa coupled to a carrier protein [20].

Colonization of the small intestine is an important prerequisite for ETEC to cause disease [5,14]. All ETEC strains seem to possess distinct CFs. While most CFs display a fimbrial or fibrillar morphology, a few appear as structurally indistinct outer-membrane proteins (Table 1). At least 23 different CFs have been identified to date [14,21]. The best-characterized CFs are colonization factor antigens (CFA)/I, CFA/II, and CFA/IV. Whereas CFA/I is a homogenous protein, CFA/II consists of the three subcomponents CS1, CS2, and CS3; CS3 is usually expressed together with CS1 or CS2 [5,14]. Similarly, CFA/IV consists of CS4, CS5, and CS6. CS6, which is not a fimbrial antigen, is often expressed together with the fimbrial proteins CS4 or CS5. While prevalence of the different ETEC CFs shows considerable geographic variation [6,15,17,22–25], CFA/I, CFA/II, and CFA/IV are collectively expressed by as many as 40–80% of all clinical ETEC isolates in most surveys [6,14,23]. Surveys for additional putative CFs, e.g., PCFO159 (CS12),

**Table 1** Colonization Factors Identified on ETEC Isolated in Endemic Areas and from Travelers

Most prevalent CFs (40–80%)	Less common CFs (10–25%)	
CFA/I	CS12 CS14	(PCFO159) (PCFO166)
CFA/II	(CS1 + CS3) (CS2 + CS3) (CS3)	CS7 CS17
CFA/IV	(CS4 + CS6) (CS5 + CS6) (CS6)	

PCFO166 (CS14), CS7, CS17, and CFA/III (CS8), have shown that these factors are only expressed by 10–25% of all ETEC isolates [6,24,25]. In all epidemiological studies reported, a subset of ETEC has been found that does not express a CF [14], which may be due to the fact that assays were not used to detect all known CFs or that hitherto unidentified CFs are produced.

Accrual of more detailed data on temporal, geographic, and population-specific variations in CF prevalence is necessary because these represent the key somatic antigens for inclusion in any ETEC vaccine. Prospective studies that are presently in progress include a comparison of the distribution of CFs on ETEC isolated from children with diarrhea in endemic areas and from visitors to the same region who develop traveler's diarrhea (Svennerholm et al., unpublished data). Results from such studies may indicate whether one can extrapolate from studies of ETEC diarrhea in travelers to at-risk children living in the same country or vice versa.

Several of the different ETEC CFs have been shown to promote intestinal colonization, both in animal studies [26,27] and in human volunteers [28], indicating that they are indeed colonization factors. Volunteers ingesting CF-positive ETEC developed diarrhea, but individuals taking the isogenic CF-negative strain remained asymptomatic [29]. Furthermore, it has been shown that rabbits infected with CF-positive bacteria excreted the infecting strain in the stool for considerably longer time than rabbits receiving corresponding CF-negative mutants [26,27,30]. Similarly, patients infected with CF-positive ETEC strains had more frequent stools per day and longer duration of diarrhea than patients infected with CF-negative bacteria [29].

The various CFs are associated with a limited number of serogroups, some even with a single serotype [14]. Most LT only strains belong to serogroups that occur infrequently. Some CFs exclusively occur on strains producing ST, others exclusively on strains producing LT, and yet others on strains producing both toxin types [14]. Approximately 90% of the ETEC isolates that elaborate both LT and ST enterotoxins express known CFs, whereas such factors are found on about 60% of ST only strains [14]. Generally, only a small proportion of LT only strains bear the most prevalent CFs [5,14], i.e., CFA/I, CFA/II, and CFA/IV. Thus if a multivalent ETEC vaccine contained just CFA/I and the different subcomponents of CFA/II and CFA/IV, it could

theoretically provide protection against 40–80% of the ETEC strains in most geographic areas. If an LT toxoid, such as the nontoxic B subunit component of LT (LTB) or CTB, was included in a multivalent vaccine, it might provide relatively broad protection against about 70–80% of ETEC strains worldwide. Inclusion of less frequent fimbrial antigens (e.g., CS7, CS12, CS14, and CS17) in a multivalent vaccine might expand the spectrum of coverage to greater than 80% of ETEC strains [14,16].

### III. IMMUNE MECHANISMS AGAINST ENTEROTOXIGENIC *E. COLI*

The fact that both the bacteria and the toxins they produce are largely confined to the epithelial surface of the small intestine has suggested that antibodies produced locally in the small intestine should be the most important mediators of protective immunity [16,31]. These antibodies are mainly specific for the different CFs, LT, and other surface antigens. ST does not elicit neutralizing antibodies following natural infection. Thus, as shown in patients convalescing from ETEC diarrhea in Bangladesh, a majority responded with IgA antibody responses in intestinal lavage fluid [32] or IgA antibody-secreting cells in duodenal biopsies [33] against the CF of the infecting strain and against LT in those infected with LT only or LTST strains.

The assumption that intestinally produced antibodies may be protective against ETEC is based on studies in animals. Thus a highly significant correlation between the number of lamina propria cells producing anti-CF IgA antibodies and the diarrheal responses to challenge with ETEC producing the same CF has been observed [34]. Furthermore, intestinal infection with CF-positive ETEC, which is known to give rise to substantial mucosal anti-CF immune responses, has afforded significant protection against subsequent intestinal challenge with ETEC expressing the homologous but not heterologous CFs [26,27,30].

Antitoxic immunity is mainly mediated by locally produced antibodies against the B subunit of LT, although antibodies against the LT A subunit (LTA) have also been shown to have strong neutralizing capacity. Thus immunization with LT results in considerably higher levels of sIgA antibodies against LTB than against LTA in the small intestine. Induction of anti-LT immunity can provide solid protection not only against LT only, but also against LTST producing ETEC as shown in animal studies [31] and in clinical trials with the oral CTB-WC cholera vaccine [10–12]. This may suggest down-regulation of ST expression in LTST strains *in vivo*. The pentameric B subunits of CT and LT are very well suited as oral vaccine components due to their potent immunogenicity, lack of toxicity, and stability in the small intestine. Furthermore, they are capable of binding to the intestinal epithelium including the M-cells of the Peyer's patches, an important property for stimulating mucosal immunity [35]. Therefore either CTB or LTB may be suitable candidate antigens for providing anti-LT immunity.

The importance of anti-ST immunity for protection against ST producing *E. coli* seems to be modest. Infection with ST only ETEC provides solid protection against rein-

fection by the same strain, but against heterologous ST only or LTST strains, only when the original challenge strain and the reinfecting strain share common CFs [26,27,30]. This suggests that ST immunity is not critical for preventing ST-induced diarrhea. By coupling *E. coli* STa to a carrier protein, e.g., LTB or bovine serum albumin either chemically or recombinantly, conjugates that give rise to ST neutralizing antibodies have been achieved [20,36,37]. However, all of these immunogenic conjugates have been toxic and elimination of their ST toxicity has resulted in failure to induce ST neutralizing antibodies. Although it may be possible to produce nontoxic ST conjugates that give rise to neutralizing ST antibodies locally in the small intestine, it is uncertain whether such antibodies would play an important protective role since comparatively large amounts of anti-ST antibodies will be required to provide neutralization of the small ST molecule [31].

Antibacterial immunity against ETEC may largely be ascribed to local gut immunity against the different CFs, although mucosal antibodies against the O antigens may play a protective role against O-group homologous ETEC [14,31]. The great diversity of O groups associated with human ETEC [1,5,17] does, however, place practical limits on the use of LPS as protective antigens against ETEC disease. Prospective epidemiological studies have provided indirect evidence that acquired immunity against ETEC is directed against the CFs [9], although corroborative evidence from sero-epidemiological studies is lacking [38]. Strong support for a protective role of anti-CF immunity has been obtained from studies in animals showing that antibodies against CFs are very effective in conferring passive protection against ETEC expressing the homologous CF. Furthermore, anti-CF antibodies have been shown to cooperate synergistically with anti-LT antibodies in conferring passive protection against experimental infection with LT-producing CF-positive ETEC [39]. Using a nonligated rabbit intestine model, it was demonstrated that an initial infection with CF-positive bacteria protected against subsequent infection with ETEC expressing the homologous CF [26,27,30]. Also in this model, evidence of synergistic cooperation between antitoxic and anti-CF immunity has been achieved [26].

Studies in human volunteers have also supported the importance of immunity against homologous CFs for protection. Thus an initial clinical infection with CF-positive ETEC elicits significant protection against CF-homologous rechallenge but not against challenge with ETEC strains expressing a heterologous CF [28,40]. These findings strongly support that immunity against the CFs is type-specific. However, recent studies have suggested that cross-protection against some of the CFs may occur. Several of the different CFs can be divided into two groups that share a high degree of primary amino acid sequence identity. The CFA/I-like group includes at least seven different CFs, each of which is largely composed of a major stalk-forming subunit, that share a high degree of overall amino acid sequence similarity with one another [14]. Other recently recognized CF groups include (1) CS5 and CS7, which share identical N-terminal amino acid sequences; (2) PCFO159 (CS12), PCFO20 (CS18), and CS20, whose major subunits

share significant amino acid sequence similarity with one another and with the porcine ETEC CF 987P; and (3) CFA/III (CS8) and Longus (CS21), which are both type IV fimbriae [14]. Immunological cross-reactivity between the different fimbriae in the CFA/I group has been documented by immunoblot experiments suggesting the existence of common epitopes among these fimbriae [14]. The lack of immunological cross-reactivity in bacterial agglutination experiments, on the other hand, suggests that these common epitopes are not surface-expressed. However, they may be effective in vivo since experiments in animals have shown that a CF within the CFA/I-like group could both boost and prime immune responses against a heterologous CF within the same group [41]. Furthermore, patients living in an ETEC-endemic area, who most likely have been primed with different CFs, did not only mount an immune response against the CF of the infecting strain, but also against several different CFs of the homologous (CFA/I-like) group (Qadri et al., personal communication); such heterologous responses were, however, not observed in American volunteers infected with CFA/I-positive ETEC [42]. These findings leave open the possibility that immunization with an ETEC vaccine in an endemic population may induce immune responses against CFs that are not contained in the vaccine but are antigenically related to vaccine component CFs.

#### IV. DIFFERENT ETEC VACCINE CANDIDATES AND RATIONALE FOR AN INACTIVATED ETEC VACCINE

Based on the knowledge of the pathogenic and immune mechanisms in ETEC, an effective ETEC vaccine may be expected to evoke both anticolonization and antitoxic immunity locally in the intestine. The vaccine should contain the most prevalent CFs in highly immunogenic form in combination with a suitable enterotoxin and induce gut secretory IgA antibodies against CFs and enterotoxin(s). Such immune responses are most efficiently evoked by oral or intraintestinal antigen administration [16,42]. Thus an ideal ETEC vaccine should be given orally and contain a combination of highly protective, yet nonreactogenic, bacterial and toxin antigens. Based on these considerations, different approaches for effective immunoprophylaxis against ETEC have been attempted. They include both live and inactivated candidate immunogens that in the vast majority of the cases are given orally along with acid-neutralizing buffer or incorporated into microcapsules (Table 2), or administration of preformed anti-CF antibodies, e.g., derived from the milk of hyperimmunized cows [43].

##### A. Live Bacteria

A number of different live bacterial vaccine candidates, either nontoxicogenic derivatives of wild-type ETEC or attenuated heterologous carrier strains such as *Shigellae* or *Salmonellae* expressing the major CFs and producing an enterotoxin, have been developed and will be described elsewhere in this volume (see Chapter 70). The potential

**Table 2** Enterotoxigenic *E. coli* Vaccine Candidates Tested in Humans

Live	<ul style="list-style-type: none"> <li>• Toxin-negative, CF-positive <i>Escherichia coli</i></li> <li>• Live vectors expressing different CFs (e.g., attenuated <i>Salmonella typhi</i>, <i>Shigella</i>, <i>Vibrio cholerae</i>)</li> </ul>
Passive immunoprophylaxis	<ul style="list-style-type: none"> <li>• Milk formulas containing anti-CF and/or anti-LT anti-bodies</li> </ul>
Inactivated	<ul style="list-style-type: none"> <li>• Enterotoxoids (LTB or CTB or LTGST)</li> <li>• Purified colonization factors (CFs); alone or in microspheres</li> <li>• Inactivated CF-positive <i>E. coli</i> (e.g., colicin-inactivated)</li> <li>• Inactivated CF-positive <i>E. coli</i> together with enterotoxin (rCTB-CF ETEC)</li> </ul>

problem of coadministering several live strains with the risk of competition between strains in the intestine is a barrier to be overcome in the development of a live vaccine. Furthermore, the development of acquired ETEC immunity in persons living in ETEC-endemic areas may result in partial or complete protection against colonization, and hence effective immunization, by live ETEC vaccine strains. Thus it has been observed for other live oral candidate vaccines that considerably higher doses of bacteria are required for induction of significant immune responses in countries where the actual infection is endemic than in nonprimed populations, and that a vaccine dose that is protective in nonendemic areas fails to induce significant protection in a primed population [44]. High doses of a live vaccine may, however, even in endemic areas be reactogenic in those that have not been primed by natural exposure, e.g., very young infants and subjects that have been less exposed to ETEC during childhood. Therefore identification of a dose of live attenuated bacteria that is immunogenic and yet nonreactogenic in populations with different immune "preparedness" may be a difficult task.

##### B. Milk Formulas

Another approach that has been attempted is to immunize lactating animals with the key protective antigens and then to feed persons with antibodies derived from the milk or colostrum of the immunized cows or sows [43]. This approach obviously requires repeated administration of milk containing a suitable mixture of anti-CF, anti-LT, and perhaps also anti-ST antibodies during the entire period when the population is at risk of developing ETEC diarrhea.

##### C. Inactivated Vaccines

The third and perhaps most feasible current approach is to provide the key protective antigens in purified form or as expressed on inactivated bacteria.

1. *Purified fimbriae*. The most promising bacterial antigens for inclusion in an ETEC vaccine are those CFs that have the highest prevalence on ETEC

- strains in different geographic areas, namely, CFA/I and the different subcomponents of CFA/II and CFA/IV and probably a few additional CFs. Monovalent vaccines consisting of purified CFA/I, CS1 + CS3, or CS6 have been tested in humans [28,45,46]. Efficient processes for preparation of purified CFs at a reasonable cost are still being worked out. Since purified CFs are very sensitive to proteolytic degradation in the stomach, incorporation of these antigens into biodegradable microspheres has been tried [29,46]. In one study, multiple high doses of microencapsulated CS1 + CS3 were given to human volunteers, but failed to confer significant protection against subsequent challenge with ETEC expressing the homologous CFs [29,46].
2. *Enterotoxoids.* Since the immunologically cross-reactive purified B subunits of CT and *E. coli* LT (CTB and LTB) are strongly immunogenic and lack toxicity, they are suitable candidate antigens to provide anti-LT immunity. Furthermore, LTB and CTB are particularly well suited as oral immunogens because they are stable in the gastrointestinal milieu, are capable of binding to the intestinal epithelium, and are effective in stimulating mucosal immunity, including local immunological memory [16]. Although CTB has afforded significant protection against *E. coli* LT disease in humans, an LT toxoid may be somewhat more effective than CTB in inducing protective anti-LT immunity. However, a suitable and cheap production method for CTB is available, making it the most attractive candidate LT toxoid to date. Thus a recombinant *Vibrio cholerae* strain, from which the genes for the toxic A subunit have been deleted and that over-produce CTB, has been constructed [47] and a simple method that allows purification of recombinant CTB (rCTB) of this strain has been developed [48]. Such rCTB is presently used for immunoprophylaxis against ETEC in the oral inactivated CTB-WC cholera vaccine (Dukoral®). Cholera toxin B may later be replaced by a more LT-like B subunit since the structural gene for CTB can be modified to encode B subunits that also contain LTB-specific epitopes [49].
  3. *Inactivated whole cells.* The simplest approach to construct an inactivated ETEC vaccine is to prepare killed ETEC bacteria that express the most important CFs in immunogenic form on their surface. Such inactivated organisms may be combined with an appropriate toxoid component, e.g., CTB or LTB. Inactivation of the bacteria may be achieved by mild formalin treatment [50]. This procedure results in complete killing of bacteria without significant loss in antigenicity of the different CFs and O antigens. Formalin-inactivated bacteria retain 50–100% of the antigenicity of the CFs on the bacterial surface [14,16]. Furthermore, the fimbrial structure of the CFs as well as their capacity to bind to eukaryotic cell surfaces are retained. The CFs of the formalin-inactivated bacteria are more stable

than purified fimbriae in that they retain their antigenicity even after incubation in human gastrointestinal secretions or in the human stomach/small intestine [31,50].

An alternative method to inactivate ETEC bacteria that does not damage protein antigens associated with the organisms was developed by Evans et al. [51]. The procedure involved the treatment of bacteria with colicin E2, a drug that enters the bacterial cell by means of receptors on sensitive *E. coli* strains. However, the issue of whether colicin E2 treatment could be relied on for reproducible inactivation of different *E. coli* strains for use in human vaccines was raised, and this approach has not been further developed.

## V. ORAL INACTIVATED CTB-CF ETEC VACCINE

The ETEC vaccine that has been most extensively studied in clinical trials consists of different combinations of formalin-inactivated CF-expressing *E. coli* and CTB. In collaboration with SBL Vaccin, Stockholm, Sweden, an ETEC vaccine with the potential of providing broad protective coverage against ETEC disease in different countries has been developed [16,52,53]. The vaccine consists of a combination of CTB and formalin-inactivated *E. coli* bacteria that express CFA/I and different subcomponents of CFA/II and CFA/IV (CS1–CS5) as well as some of the O antigens that are commonly associated with ETEC [31]. The rationale for the design of this vaccine is indicated in Table 3.

### A. Testing of a Prototype Vaccine

Initially, a prototype of this vaccine consisting of a mixture of killed *E. coli* expressing CFA/I, CS1, CS2, and CS3 together with CTB was tested. The CTB component was provided by adding the oral CTB-WC cholera vaccine to inactivated *E. coli* bacteria [52,53]. Strains that belonged to common ETEC groups (O6, O78, and O139) and expressed the different fimbriae in high concentrations were selected. The safety and immunogenicity of the prototype CTB-CF ETEC vaccine were studied in adult Swedish volunteers with promising results [52,53]. Thus as shown in studies of adult volunteers, the vaccine was safe and gave rise to significant IgA immune responses in intestinal lavages against CFA/I

**Table 3** Rationale for the Design of the rCTB-CF ETEC Vaccine

- Synergy between antitoxic (anti-LT) and anticolonization immunity for protection against ETEC diarrhea
- CTB affords highly significant protection against ETEC LT and LTST disease in humans
- *E. coli* CFs are strongly protective against ETEC expressing homologous CFs in humans and animals
- Formalinized CF-positive *E. coli* are stable in the stomach and induce strong mucosal anti-CF immune responses
- Vaccine can be designed to include several CFs and recombinantly produced toxoid

and the different subcomponents of CFA/II as well as against CTB in a majority (70–90%) of the vaccines [51]. In most of the volunteers, intestinal immune responses were maximal after a second immunization. In some volunteers, there was even a decrease in CF response after the third as compared with the second dose [52]. The prototype ETEC vaccine also gave rise to significant increases in peripheral blood antibody-secreting cell (ASC) responses with specificity for CFA/I, CFA/II, and CTB in 85–100% of the volunteers [53]. Responses against the CFs were predominantly in IgA-producing cells suggesting that these cells were of mucosal origin. Antibody-secreting cell responses against CTB, on the other hand, were seen in both IgA and IgG cells but not in IgM. The results of these studies suggested that two oral immunizations are probably sufficient to induce optimal CF-specific immune response by the vaccine in immunologically naive volunteers.

### B. Development of Methods for Assessing Mucosal Immune Responses for Use in Clinical Trials of ETEC Vaccine

Despite inducing significant intestinal lavage as well as peripheral blood ASC responses that were probably intestinally derived, the prototype-inactivated vaccine was relatively inefficient in eliciting serum antibody responses against the different CFs [52]. The CTB component, on the other hand, induced serum antibody responses that were comparable both in frequency and in magnitude to the responses in intestinal lavage fluid. Therefore the conventional approach of assessing immunogenicity of the vaccine as its capacity to induce serum antibody responses was not suitable, at least for determining the immunogenicity of the CF components in a nonprimed population. Since initial studies in Swedish volunteers showed a strong correlation between IgA immune responses against the ETEC vaccine in intestinal lavage fluid and the IgA ASC responses in peripheral blood [54], the immunogenicity of the ETEC vaccine has, in most subsequent studies, been determined as circulating ASC responses. This method is clearly superior to the intestinal lavage method in simplicity and sensitivity. However, determination of ASC responses has several disadvantages, such as problems in standardization, difficulties in comparing preimmunization and postimmunization levels on the same day, need for relatively large volumes of peripheral blood and requirements for tissue culturing equipment, etc. Therefore much effort has been made to develop a simple, yet reproducible, approach for assessing mucosal immune responses against the ETEC vaccine. These approaches include determination of immune responses in fecal specimens [54], measurements of specific antibodies in saponin extracts of intestinal biopsies [33], or indirect determination of mucosal immune responses as reflected in serum in immunologically primed populations [55].

### C. Phase I/Phase II Trials of the rCTB-CF ETEC Vaccine in Adults

Based on the promising results with the prototype vaccine, a more definitive formulation of the CTB-CF ETEC vaccine

was developed (Table 4). This modified vaccine contained rCTB in combination with five different *E. coli* strains collectively expressing CFA/I and the different subcomponents of CFA/II (CS1, CS2, and CS3) and CFA/IV (CS4 and CS5), respectively. The rCTB-CF ETEC vaccine was first tested extensively in Phase I trials in Sweden and subsequently in the United States and in different ETEC-endemic countries. Such studies in several hundred adult volunteers who received one or two oral doses of the vaccine confirmed that the vaccine was safe and only gave rise to mild gastrointestinal symptoms and borborygmus in a few volunteers [33,54–60].

In initial Phase I trials in Swedish volunteers, the capacity of the rCTB-CF ETEC vaccine to induce ASC responses in peripheral blood was evaluated [56,58]. Two doses of vaccine given 2 weeks apart induced strong increases in CTB-specific IgA ASCs in 95–100% of the vaccinees and significant IgA ASC responses against CFA/I, CFA/II, and CFA/IV, respectively, in 85–95% of the volunteers (Table 5). In some of the volunteers, immune responses in intestinal lavage fluid, fecal extracts, and serum were also evaluated [54]. These analyses showed that ~70–90% of the volunteers responded with significant IgA responses to CFA/I, CFA/II, or CFA/IV in intestinal lavages, whereas 45–75% responded in fecal extracts. Responses against CTB were seen in 90–95% of the vaccinees irrespective of whether lavages or fecal specimens were tested [54,56].

Based on the results from these studies, determination of vaccine-specific ASCs in peripheral blood to the rCTB-CF ETEC vaccine has been done in subsequent studies in, e.g., the United States (Taylor et al., unpublished data), Bangladesh [57], Egypt [60], and Israel [59]. Results from studies in adult Bangladeshis and Egyptians show that the frequencies and magnitudes of ASC responses against the different CFs are comparable to those observed in Swedish volunteers (Table 5) [57,60]. Taken together, these trials in different countries indicate that the rCTB-CF ETEC vaccine gives rise to significant mucosal or mucosa-derived (blood ASC) immune responses against the CFs of the vaccine in a majority of the volunteers (70–95%) and against CTB in as many as 90–100% of them. The frequencies and magnitudes of serum antibody responses against the CFs, on the other hand, were considerably lower and were mainly of IgA rather than IgG type, suggesting their intestinal origin (Table 5). Serum antibody responses against CTB were

<sup>a</sup> Cumulative responses after a first or a second dose given 2 weeks apart; a positive response is a  $\geq 2$ -fold increase between ASC/10<sup>7</sup> MNC between preimmunization and postimmunization values. Magnitudes of responses represent the ratio between baseline and the highest postimmunization level (after one or two doses).

<sup>b</sup> Percent volunteers with significant  $\geq 2$ -fold increase in ELISA titers between preimmunization and postimmunization (after two doses) specimens.

observed in more than 90% of the vaccinees in all different studies. The magnitudes of IgA responses in Swedish volunteers were considerably higher than in vaccinees in ETEC-endemic countries, but this was mainly related to the considerably lower preimmunization levels in the nonprimed Swedes than in adult Bangladeshis or Egyptians.

#### D. Dose Dependence and Immunological Memory

The rCTB-CF ETEC vaccine has also been tested for reproducibility in production, dose dependence, and capacity to induce an immunological memory in adult Swedish volunteers. Different batches of the vaccine have induced substantial and comparable mucosal immune responses against the different CFs of the vaccine in a majority of the volunteers [58]. Studies have also revealed a clear dose dependence with regard to both mucosal and systemic antibody responses against the CF components of the vaccine, allowing the determination of optimal immunizing doses in different study populations [58]. Compared to adult Swedes given a full dose (see Table 4), those given a one-third dose of the whole cell component exhibited lower frequencies of IgA ASC responses against all the different CFs. The proportion of vaccinees responding with rises in serum IgA antibody titers against the various CFs was also lower after immunization with a reduced dose of ETEC bacteria, and responses in serum were considerably lower than the ASC responses. These findings suggest that measurements of circulating IgA ASCs can be used for quantitative assessment of the immunogenicity of individual fimbrial antigens in various preparations of ETEC vaccine. Based on these results, studies have recently been initiated in Bangladesh to compare a full dose, a half dose, and a quarter dose of ETEC vaccine in children, aged 6–36 months, to determine the lowest dose that can induce strong immune responses also in very young children (Qadri et al., unpublished data).

The immune responses after a single, two, and three doses of vaccine as well as against a booster dose given 1 year later have also been compared in adult Swedish volunteers. These analyses revealed that two doses were optimal in inducing mucosal immune responses in intestinal lavage fluid both against the whole cell component and against

CTB [52,56]. Thus a third dose of vaccine only occasionally resulted in higher anti-CF IgA antibody levels in intestinal lavage than two doses, and, in most instances, there was instead a decrease in IgA level after the third dose [52]. With regard to responses against CTB, on the other hand, equally or, even in a few cases, higher anti-CTB levels were observed after three than two doses. In subsequent studies, it was shown that two doses of vaccine induced considerably higher and more frequent antitoxin IgA levels in intestinal lavage fluid than a single dose. Thus whereas only 37% of 19 vaccinated adult Swedish volunteers responded with a mean 5-fold increase in specific antitoxin/total IgA levels after the first dose, as many as 89% responded with a mean 23-fold rise after the second dose (Åhrén et al., unpublished data). Also, the frequencies of intestinal lavage responses against the different CF components were higher after two than a single dose, although the differences were less marked than observed for the antitoxin immune responses. For example, 42% of the vaccinees responded with significantly elevated IgA anti-CFA/I levels after the first dose and 63% with comparable magnitudes of responses after the second dose (Åhrén et al., unpublished data). Similarly, two doses were more efficient than a single dose in inducing serum IgA antibody responses, i.e., the serum conversion rate was 50% after the first dose vs. 65% after the second dose for CFA/I, 15% vs. 40% for CS2, and 35% vs. 95% for CTB [58]. With regard to IgA ASC responses in peripheral blood, on the other hand, the frequencies and magnitudes of the different anti-CF ASC responses were comparable, or even lower, after the first and the second immunization, whereas the CTB-specific IgA ASC responses were considerably higher ( $P < 0.001$ ) after the second dose [58]. A single booster dose given after 1 year resulted in similar antitoxin responses both in intestinal lavages and as ASC responses in peripheral blood after two initial doses, whereas the CF responses seem to be comparable to those observed after the initial dose (Åhrén et al., unpublished data).

#### E. Protective Efficacy Studies in Adult Travelers

A number of different studies to evaluate the protective efficacy of the rCTB-CF ETEC vaccine have been initiated in adult travelers going from industrialized areas to different

countries in Asia, Africa, and Latin America. In an initial pilot study, the ETEC vaccine was tested for protective efficacy in European travelers going to 20 different countries in Africa, Asia, and Latin America [13]. The protective efficacy of the ETEC vaccine was compared with that of the CTB-WC cholera vaccine and *E. coli* K12 placebo. This study revealed very promising results in that the ETEC vaccine conferred 82% protective efficacy ( $P < 0.05$ ) against ETEC disease, whereas the effect of the cholera vaccine could not be evaluated due to the infrequency of cases associated with LT-positive ETEC. However, the number of cases fulfilling the inclusion criteria overall was low and the findings of this promising pilot study need to be supported in additional studies.

Another trial was initiated several years ago in European travelers going to Kenya. However, due to very few cases fulfilling the inclusion criteria, no conclusions of the protective efficacy of the vaccine could be deduced from this study (Steffen et al., unpublished data).

A large controlled trial was recently completed in American travelers going to Mexico and Guatemala [61]. In that study, 685 adult Americans either received the rCTB-CF ETEC vaccine or *E. coli* K12 placebo in a double-blinded fashion. The vaccine showed a protective efficacy of 77% ( $P = 0.039$ ) against nonmild ETEC diarrheal illness [61], but no significant protection was observed when ETEC diarrheal cases of any severity (also including mild cases) were considered. Another trial is now being completed in the same setting to carefully assess vaccine efficacy against ETEC diarrheal disease where symptoms interfere with the daily activity of the traveler (Bourgeois, personal communication).

## F. Pediatric Evaluation of the rCTB-CF ETEC Vaccine

From a public health standpoint, a vaccine against ETEC is most needed for infants and young children in developing countries. Save major improvements in sanitation in these settings, a vaccine is sought that substantially reduces the acute morbidity and mortality of ETEC diarrhea and conceivably stems long-term morbidity such as growth impairment. To investigate suitability of the oral rCTB-CF ETEC vaccine for a pediatric indication, clinical studies have thus far been conducted in Egypt and Bangladesh, two countries where a high incidence of ETEC diarrhea in childhood has been well documented.

Undertaking pediatric clinical trials with an ETEC vaccine presents some special challenges. Ethically, pediatric testing must be confined to children who are at risk from ETEC diarrhea, namely, those living in developing countries. Studies could only be initiated after the accrual of sufficient safety data from adults so as to minimize undue risk to children. In evaluating vaccine immune responses, attention must be paid to the possible effects of preexisting immunity and intercurrent boosting due to natural exposure to ETEC. In evaluating efficacy, the degree and duration of protection are both important considerations since at-risk children are frequently exposed to ETEC throughout child-

hood and beyond. Delay of onset of ETEC diarrhea rather than disease prevention would be an undesirable consequence of vaccination.

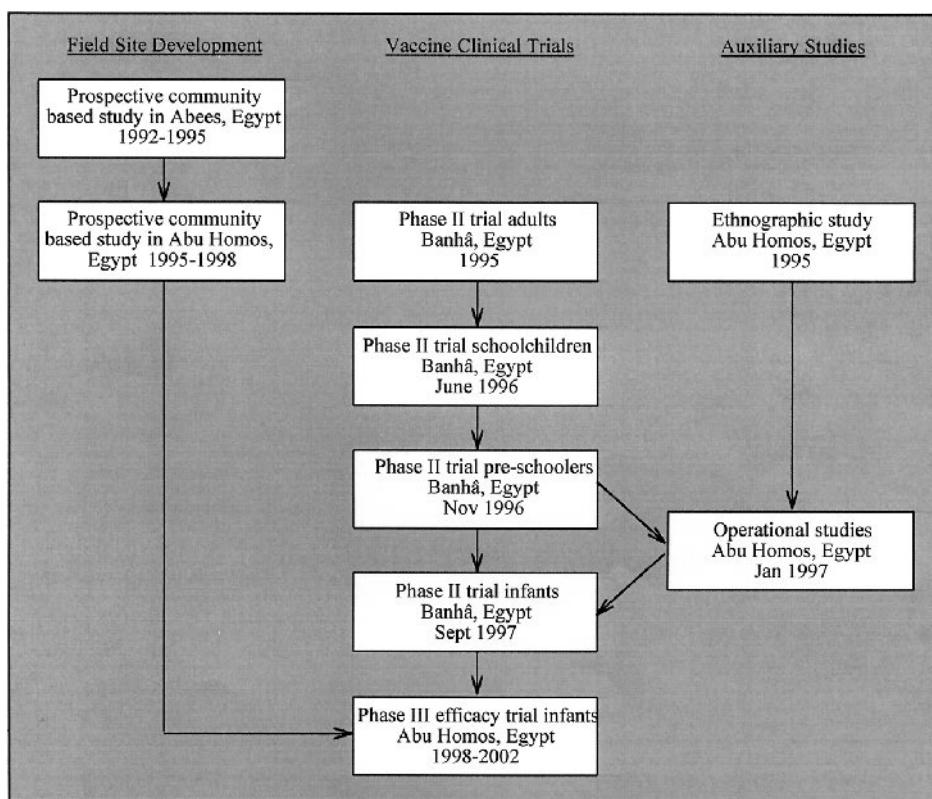

At the outset, a framework for evaluation of the rCTB-CF ETEC vaccine in Egyptian infants and young children was designed that would culminate in the evaluation of vaccine efficacy. As shown in Figure 1, this framework included epidemiological studies to ascertain disease incidence and establish the infrastructure for an efficacy trial and corollary studies to examine feasibility issues, both of which complemented the actual clinical trial pathway. Site selection for vaccine testing in Egypt was made in cooperation with national health authorities based on ETEC incidence data and community interest in the research project. Studies in Bangladesh utilized a longstanding research infrastructure for the evaluation of diarrheal disease interventions. In both locations, safety and immunogenicity studies were completed in native adults before initiating pediatric studies.

In both Egypt and Bangladesh, sequential studies in descending age groups of children have been completed, providing a comprehensive assessment of the safety and immunogenicity of the rCTB-CF ETEC vaccine. All of the trials in Egypt used a randomized, double-blind, placebo-controlled study design. The findings from these trials are summarized in the following sections.

### 1. rCTB-CF ETEC Vaccine Safety Data in Children

Egyptian children between 2 and 12 years of age given a two-dose (0, 2 weeks) schedule of the oral rCTB-CF ETEC vaccine, coadministered with a graduated dose of antacid, tolerated the vaccine very well. As shown in Table 6, a small proportion of children in this age range experienced gastrointestinal symptoms (i.e., diarrhea and vomiting) in the postdosing interval, with no difference between vaccine and control groups. Safety findings from an uncontrolled study in Bangladeshi children in the same age range were similar [57]. No systemic adverse events were associated with vaccine administration in this age range. Perhaps the most pertinent indicator of safety was the finding that the vast majority of Egyptian children receiving the rCTB-CF ETEC vaccine reported no disturbance in their general well-being after vaccination.

The next study done in Egypt evaluated a three-dose (0, 2, 4 weeks) schedule of the rCTB-CF ETEC vaccine in 6–18 months old children. The vaccine dose was the same as that given to adults and children in earlier trials and was coadministered with 1/10 the adult dose of antacid. Findings confirmed the safety of the vaccine in this age range, although it did raise questions about acceptability of the preparation. Diarrhea and vomiting were the most common adverse events. The proportion of subjects reporting these or other events did not differ significantly between vaccine and control groups, but generally occurred more commonly than in older vaccinated children. Subgroup analyses suggested that the vaccine was associated with an excess of gastrointestinal symptoms in children less than 1 year of age. Due to the mild nature of these symptoms observed in young Egyptian children, this was not regarded as a barrier for

**Figure 1** Schematic presentation of research program and interleaved studies undertaken to assess the safety, immunogenicity, and efficacy of the oral rCTB-CF ETEC vaccine in Egypt.

proceeding with an efficacy trial using the same dosing. In a controlled study performed in young Bangladeshi children, children under 18 months of age experienced higher rates of vomiting than older children. This prompted investigators to undertake a dose ranging study to identify a lower dose that resulted in less reactogenicity but undiminished immunogenicity. Preliminary analysis of this study suggests that one quarter of the adult dose of the rCTB-CF ETEC vaccine is well tolerated and immunogenic (Qadri, personal communication).

## 2. rCTB-CF ETEC Vaccine Immunogenicity in Children

Following the approach established in adult Phase I clinical trials of the rCTB-CF ETEC vaccine, measurement of circulating B-cell IgA antibody-secreting cell (IgA-ASC) responses to vaccine cellular (CF) antigens was used as the primary determinant of immunogenicity in the initial studies in older (2-12 year age range) Egyptian and Bangladeshi children. Serologic responses were also measured in these

**Table 6** Percentage of Egyptian Children with Diarrhea and Vomiting in the 3 days After Each Dose of the rCTB-CF ETEC Vaccine or *E. coli* K12 Control

Age group	Dose	<i>n</i> <sup>a</sup>	Diarrhea		Vomiting	
			Vaccine	Control	Vaccine	Control
6-12 years	1	52/55	4	4	0	2
	2	51/54	0	0	4	4
2-5 years	1	54/52	4	4	6	4
	2	49/48	4	6	4	4
6-18 months	1	48/47	19	19	25	17

	3	36/28	3	4	11	14

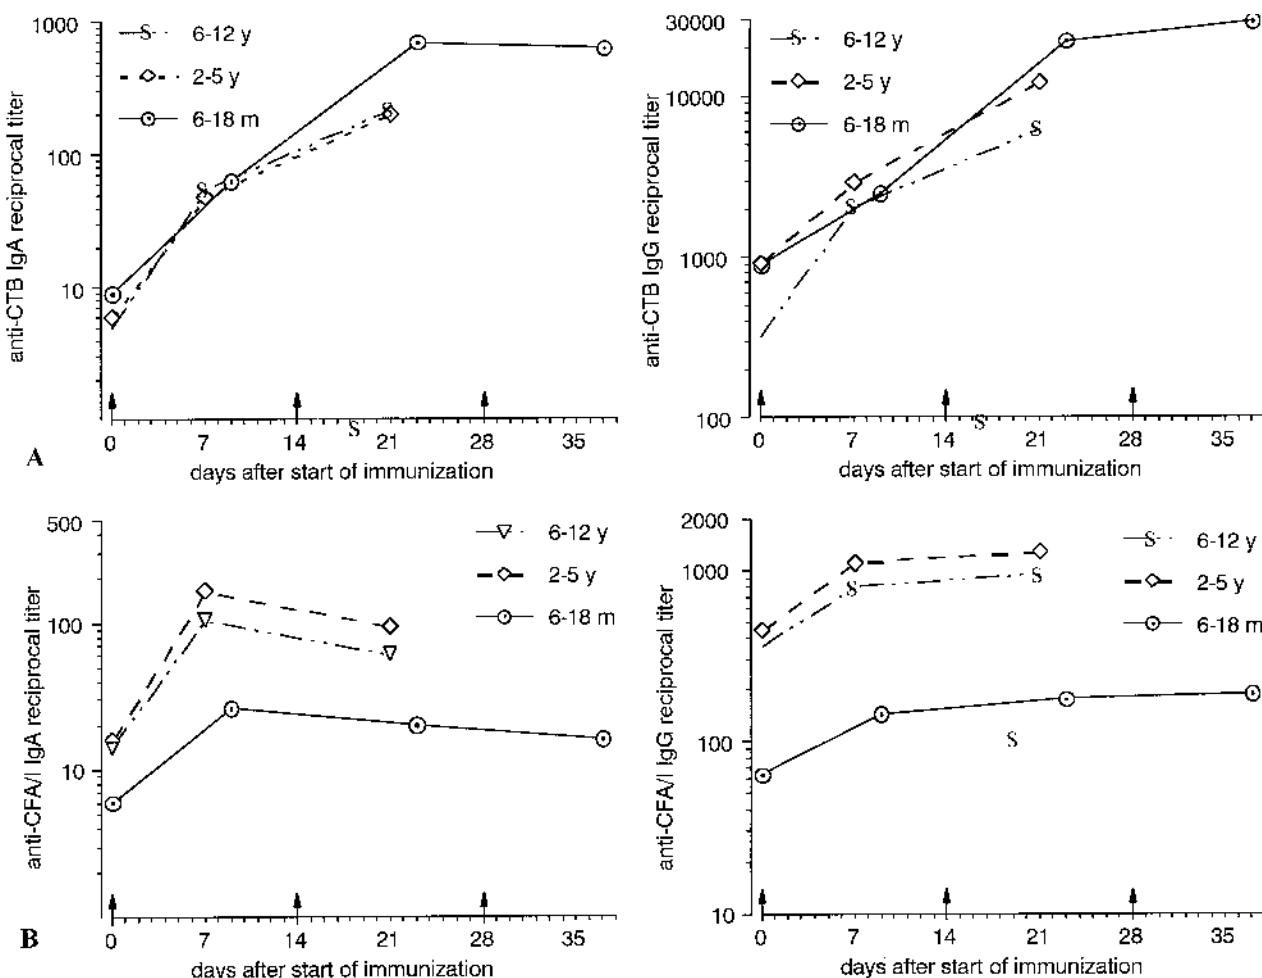

<sup>a</sup> Number in vaccine group/number in placebo group.

children, permitting an assessment of the correlation between seroconversion and antibody-secreting cell responses. With the exception of two studies in Bangladeshi children [57,62] in which circulating B-cell IgA responses to rCTB were measured, serum anti-rCTB antibody responses served as the endpoint for determining antitoxic immunity in all children. Anti-CF serologic responses were adopted as the primary immune measure in children under 2 years of age due to practical constraints in drawn blood volumes and demonstration that these measures were strongly predictive of IgA-ASC responses in older children as discussed below.

The rCTB vaccine component predictably evoked strong serological responses in the great majority of children [57,62–64]. IgA antitoxin titers increased after each of two doses given to Egyptian children as young as 2 years, whereas a third dose, given to 6- to 18-month Egyptian children only, did not result in a further titer increase (see Figure 2). Dose-to-dose boosting of IgG antitoxin titers was observed in older children given a two-dose vaccine schedule as well as in the 6- to 18-month-old children receiving three doses, as shown in Figure 2. The study in 3- to 9-year-old

Bangladeshi children found a significant correlation between circulating IgA-ASC responses and IgA serological responses to rCTB [57]. These findings extend upon earlier studies of the whole cell cholera B-subunit vaccine in older subjects to show that orally delivered rCTB is a very potent immunogen in children as young as 6 months of age.

Similar to findings in adult vaccinees in Egypt and Bangladesh, a high proportion of children 18 months–12 years of age exhibited circulating IgA antibody-secreting cell (ASC) responses to several of the CF components of the CTB-CF ETEC vaccine [57,62,63] (Table 7). Apparent differences in the timing of maximal CF-specific IgA-ASC responses, which occurred after the first dose in school-aged children in contrast to preschool children who exhibited similar or greater levels after both doses, may reflect the degree of past priming from natural ETEC infection. In Bangladeshi children, the magnitudes of the anti-CF IgA-ASC responses were lower than the corresponding antitoxin IgA-ASC responses [57,62]. These findings show that in children as young as 18 mo of age, the rCTB-CF ETEC vaccine stimulates mucosal immunity to the CF vaccine

**Figure 2** Antibody titers in serum of children of different age groups after 1, 2, and 3 oral doses of rCTB-CF ETEC vaccine. A = anti-CTB IgA; B = anti-CTB IgG; C = anti-CFA/I IgA; D = anti-CFA/I IgG.

components, inasmuch as this is reflected by circulating IgA B cell responses.

The most extensive evaluation of anti-CF serologic responses to the CTB-CF ETEC vaccine in children has thus far been carried out in Egypt. A majority of children aged 6 months to 12 years of age manifest IgG seroconversion (defined as a ≥2-fold increase over baseline titer) to CFA/I, CS2, and CS4 (Table 7), the proportion of seroresponders being comparable across age groups. Over two-thirds of children aged 2–12 years exhibited IgA seroconversion to these same antigens, while a lower proportion of 6- to 18-month-old vaccine recipients exhibited IgA seroconversion to CS2 and CS4. It was also shown that in the age range of 2–45 years, the magnitude of IgA serologic responses was inversely associated with age, even after controlling for baseline titer. This relationship did not, however, hold up with the inclusion of children under 2 years of age, inasmuch

as their fold increases in anti-CF antibody titers were distinctly lower than in 2- to 12-year-old children (see Figure 2).

Since both anti-CF IgA-ASC and plasma IgA and IgG antibody responses were examined in trials of school-aged and preschool Egyptian children, it was possible to assess how well these measures correlated. Considering the IgA-ASC responses as the standard, it was found that a twofold seroconversion of either IgA or IgG antibodies was highly predictive of a positive IgA-ASC response. IgA seroconversion had the advantage of being a more sensitive predictor of IgA-ASC response, whereas IgG seroconversion showed slightly higher specificity. Table 8 depicts these comparisons for CFA/I and CS2 over a range of cutoff points that signify seroconversion. These data suggest the validity of IgA and IgG seroresponses as measures of CTB-ETEC CF vaccine immunogenicity in an endemic population and support the decision of using serologic responses as the primary measure

**Table 8** Sensitivity, Specificity, and Positive Predictive Accuracy (Percentages) of IgA and IgG Antibody Seroconversion in Identifying IgA-ASC Responses over the Range of Cutoff Points from ≥2.0- to ≥4.0-fold Increase in Antibody Titer, in Egyptian Children Aged 2–12 Years

<sup>a</sup> Note that the predefined cutoff for defining a positive seroconversion in these studies was ≥2.0 fold-increase over baseline.

of ETEC vaccine immunogenicity in infants and young children. It must be kept in mind that no immune measure has yet to be correlated with protection against ETEC disease, either following natural infection or vaccination. The search for such a protective immune correlate is an important objective to be considered in the design of vaccine efficacy studies as well as studies of naturally occurring ETEC disease and acquisition of immunity.

### 3. Evaluation of rCTB-CF ETEC Vaccine Efficacy in Children

To date, the only pediatric study to assess efficacy of the rCTB-CF ETEC vaccine has been undertaken in rural Egypt (Savarino et al., unpublished data). Initiated in 1999 and recently completed, this randomized, double-blind, controlled trial was conducted in healthy 6- to 18-month-old children. Two cohorts were entered 1 year apart and randomized to receive a three-dose regimen at 2-week intervals of the rCTB-CF ETEC vaccine or *E. coli* K-12 control. Disease detection was based on active surveillance through semiweekly household visits and culture of fecal specimens from children with diarrhea. The primary disease endpoint is occurrence of a first episode of diarrhea associated with excretion of LTST ETEC or ST ETEC expressing one or more vaccine-shared CFs over the first year of surveillance. The required sample size, based on firm incidence data drawn earlier from the same population, has been achieved and is expected to allow detection of an efficacy of >70%. Forthcoming results from this trial, currently in the data analysis phase, should be very useful in determining the future course of clinical studies with this and other ETEC vaccines, particularly as it relates to a pediatric indication.

## Multivalent *Shigella*/Enterotoxigenic *Escherichia coli* Vaccine

Eileen M. Barry and Myron M. Levine

University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.

### I. INTRODUCTION

The disease burdens posed by enterotoxigenic *Escherichia coli* (ETEC) and *Shigella* are described in depth in the chapters by Svennerholm and Savarino and Kotloff et al., respectively. Both pathogens are important causes of diarrheal disease in children in developing countries and are major etiologic agents of traveler's diarrhea.

### II. SHIGELLA

#### A. Strategy to Achieve Broad-Spectrum Protection Against *Shigella*

A globally useful *Shigella* vaccine will have to protect against *Shigella dysenteriae* 1 (cause of severe epidemic disease in the least developed countries), all 15 serotypes of *S. flexneri* (main cause of endemic shigellosis in developing countries), and *S. sonnei* (the serotype most frequently associated with traveler's shigellosis and the most common serotype causing disease in industrialized countries). Infection-derived immunity against *Shigella* is directed towards O antigens. Based on shared O antigens among the 15 *S. flexneri* serotypes, Noriega et al. [1] hypothesized that a vaccine containing *S. flexneri* 2a, *S. flexneri* 3a and *S. flexneri* 6 O antigens could provide broad protection against all 15 *S. flexneri* serotypes. By means of challenge studies in guinea pigs, Noriega et al. [1] generated preclinical evidence supporting this hypothesis. Pursuing this strategy, investigators at the Center for Vaccine Development have concluded that a multivalent *Shigella* vaccine that includes O antigens of five carefully selected serotypes, *S. dysenteriae* 1, *S. flexneri* 2a, *S. flexneri* 3a, *S. flexneri* 6, and *S. sonnei*, could provide broad coverage against the most important *Shigella* serotypes that cause disease worldwide [1–3].

#### B. Shigella Harboring Mutations in *guaBA* and in the Genes Encoding *Shigella* Enterotoxins 1 and 2

Introduction of a deletion mutation in the *guaBA* operon (which impairs guanine nucleotide biosynthesis) of *S. flexneri* 2a wild-type strain 2457T, renders strain CVD 1204, which is markedly attenuated compared to its wild-type parent [4]. Nevertheless, at high dosage levels in humans, approximately one-half of subjects who ingested CVD 1204 still developed mild diarrhea and full clinical attenuation was not achieved until deletions in the genes encoding *Shigella* enterotoxin 1 (ShET1) (*set*) [5,6] and ShET2 (*sen*) [7] were also introduced, resulting in well-tolerated and immunogenic strain CVD 1208. Based on the favorable experience with *S. flexneri* 2a as a prototype, attenuated *S. dysenteriae* 1, *S. flexneri* 3a, *S. flexneri* 6, and *S. sonnei* strains are also being constructed [1,3] that similarly harbor deletions in *guaBA* and *sen*; in addition, the *S. dysenteriae* 1 strain has a deletion mutation in *stxA* that encodes the A subunit of Shiga toxin. These five carefully selected *Shigella* serotypes should provide broad coverage against the most important serotypes that cause shigellosis worldwide [1].

### III. ENTEROTOXIGENIC *ESCHERICHIA COLI*

#### A. Target Antigens

As a preliminary step in the pathogenesis of diarrhea, ETEC adhere to receptors on enterocytes in the proximal small intestine by means of fimbrial colonization factors, thereby counteracting the peristalsis defense mechanism. Once adherent, they elaborate enterotoxins that cause intestinal secretion, culminating clinically in diarrhea. Considerable evidence, as reviewed in the chapter by Svenner-

holm and Savarino, indicates that broad-spectrum, relatively long-lived, immunity to ETEC is mediated by intestinal immune responses directed against these fimbrial attachment factors.

### B. Antigenic Diversity Among Human ETEC Pathogens

Analysis of the antigenic structure of ETEC strains from endemic areas shows many different O:H serotypes, at least 10 distinct antigenic types of fimbrial colonization factors (of which the most common are CFA/I and CS1–CS6) and three different toxin phenotypes (LT, ST, and LT/ST) [8,9]. CFA/I is a single antigenic moiety. *Coli* surface antigens 1 (CS1), 2 (CS2) and 3 (CS3) constitute the CFA/II family of antigens. All CFA/II strains express CS3, either alone or in conjunction with CS1 or CS2. CS4, CS5, and CS6 comprise the CFA/IV family of antigens. All CFA/IV strains express CS6, either alone or in conjunction with CS4 or CS5. Other fimbrial colonization factors are much less frequent. Carriage of the genes that encode a particular fimbrial colonization factor is closely correlated with O:H serotype and toxin phenotype. Analysis of ETEC isolates from diverse geographic areas shows that CFA/I and CS1–6 are found on the majority of isolates. Circa 70–90% of isolates that elaborate both heat-labile and heat-stable enterotoxins (LT and ST, respectively) express these CFAs, while they are found on ca. 60% of ST-only strains. Generally, less than 10% of LT-only strains bear these CFAs. Thus, a multivalent ETEC vaccine that contained CFA/I and CS1–6 plus an appropriate antigen (such as B subunit or mutant LT) to elicit neutralizing LT antitoxin might broaden protection to cover ~80–90% of ETEC strains worldwide. Inclusion of less frequent fimbrial antigens in a multivalent vaccine could expand the spectrum of coverage, albeit at the price of even greater complexity.

### C. Infection-Derived Immunity to ETEC

Despite the antigenic heterogeneity of ETEC, evidence from both volunteer studies and from epidemiological surveys argues convincingly that prior clinical infection with ETEC confers immunity [10–12]. In endemic areas, multiple infections with strains bearing different fimbrial colonization factors must occur in order for broad-spectrum immunity to be elicited. In less-developed countries, infants and young children experience up to three separate clinical ETEC infections per year during the first three years of life, after which the incidence of ETEC diarrhea plummets [11]. The lower incidence in older persons is due to specific acquired immunity rather than to nonspecific age-related host factors, since adult travelers from industrialized countries who visit less-developed countries where ETEC pediatric diarrhea is endemic suffer high attack rates of ETEC travelers' diarrhea. The fimbrial colonization factor antigenic profile of strains that cause endemic pediatric diarrhea in developing countries and those that cause travelers' diarrhea is the same. Travelers from industrialized countries who remain

in less-developed countries for at least a year and travelers who arrive from other less-developed countries suffer significantly lower incidence rates of ETEC diarrhea than newly arrived travelers from industrialized countries [12]. These data further support the concept of acquired immunity. Data from a prospective epidemiological field study in Mexican infants and young children provide direct evidence that acquired immunity is largely directed at fimbrial colonization factors of ETEC [13].

### D. Lessons Learned from Studies with a Prototype Attenuated *E. coli* Live Oral ETEC Vaccine

*Escherichia coli* E1392-75-2A is a CFA/II-positive mutant strain derived in the Central Public Health Laboratory, Colindale, UK, wherein the genes encoding LT and ST spontaneously deleted from the CFA/II plasmid. Consequently, E1392-75-2A, which expresses CS1 and CS3 fimbrial antigens, is negative when tested with toxin assays and gene probes for LT and ST. Levine et al. [14–16] utilized strain E1392-75-2A to explore fundamental questions of anticolonization immunity in the absence of antitoxic immunity. All volunteers who were fed  $10^{10}$  CFU of strain E1392-75-2A developed significant rises in intestinal fluid SIgA antibody to CS1 and CS3 fimbriae. The geometric mean titer (GMT) of antifimbrial CS1 and CS3 SIgA antibody in these volunteers was 10-fold higher than the peak postvaccination GMT of volunteers who received enteral immunization with multiple doses of purified CS1 and CS3 fimbriae.

A group of vaccinees who were immunized with a single  $5 \times 10^{10}$  CFU dose of E1392-75-2A with buffer was challenged 1 month later, along with nonimmunized control volunteers. The pathogenic ETEC challenge strain used, E24377A, was of a heterologous serotype O139:H28 but expressed CS1 and CS3 and elaborated LT and ST. The vaccinees were significantly protected ( $P < 0.005$ , 75% vaccine efficacy) against ETEC diarrhea [14]. By means of bacteriological studies it was shown that anticolonization immunity was responsible for the protection. In the challenge study, all participants, both vaccinees and nonimmunized controls, excreted the ETEC challenge strain and there was no difference between the groups in the mean number of ETEC per gram of stool. In contrast, a striking difference was found in duodenal cultures that monitored colonization of the proximal small intestine, the critical site of ETEC–host interaction. The challenge strain was recovered from duodenal cultures of 5 of 6 controls (mean  $7 \times 10^3$  CFU per mL) versus only 1 of 12 vaccinees ( $10^1$  CFU per mL) ( $P < 0.004$ ). Levine et al. interpreted these results to mean that SIgA anti-CS1 and anti-CS3 fimbrial antibody in the proximal intestine stimulated by the live oral vaccine prevented challenge ETEC from colonizing the proximal small intestine. Since the immune response was not bactericidal, the ETEC organisms were carried by peristalsis to the large intestine where they could colonize without causing diarrheal illness. Strain E1392-75-2A caused mild diarrhea in approximately 15% of the recipients who ingested it, an unacceptable rate of adverse reactions that made it unworthy of further development. Nevertheless, this strain provided invaluable data on

the feasibility of eliciting protection in humans mediated by immune responses directed against fimbrial colonization factors.

#### IV. MULTIVALENT *SHIGELLA*-ETEC LIVE VECTOR VACCINE

##### A. Attenuated *Shigella* Strains Expressing ETEC Antigens

Investigators at the Center for Vaccine Development of the University of Maryland have shown that attenuated *Shigella* can be used as live vector vaccines to express ETEC fimbrial antigens and LT toxoids (B subunit or mutant LT) and deliver them to the immune system, resulting in SIgA antifimbrial and anti-LT responses [17–21], as well as *Shigella* anti-O antibody responses in mucosal secretions and serum.

##### B. The Multivalent Vaccine

The multivalent *Shigella*/ETEC vaccine under development contains five attenuated *Shigella* serotype strains (*S. dysenteriae* 1, *S. flexneri* 2a, *S. flexneri* 3a, *S. flexneri* 6, and *S. sonnei*), each expressing two different ETEC fimbrial antigens and an antigen (“LT toxoid”) to stimulate neutralizing LT antitoxin. Both LT B subunit and mutant LT moieties are being evaluated as possible LT toxoids, the former having the attraction of greater potential safety. LT from human ETEC pathogens (LTh), from domestic animals, and cholera toxin, or their respective B subunits, can all elicit antibodies that can neutralize LTh [22]. However, each of these antigens has unique epitopes and the highest antitoxin titers observed are against the homologous antigen [22–24]. Consequently, it is our contention that an antigen based on LTh should be used to stimulate LT antitoxin. Notably, expression of the ETEC fimbriae and LT toxoid does not diminish the capacity of the vector strain to protect against challenge with wild-type *Shigella* in a guinea pig model [17–21].

##### C. *Shigella* Can Express Combinations of ETEC Fimbria Not Found in Nature

The utility of attenuated *Shigella* as live vectors to coexpress CFA/I and CS3 fimbriae of ETEC, a combination never found in nature, was documented [17]. The immunogenicity of this bivalent *Shigella* live vector strain was evaluated in a guinea pig immunization model in which *Shigella* are administered intranasally following which mucosal SIgA responses are measured in tears. The *Shigella* live vector expressing these two ETEC fimbrial antigens elicited SIgA mucosal antibody responses to both CFA/I and CS3 [17].

##### D. Genetic Characterization of CS4

In constructing the multivalent *Shigella* live vector ETEC vaccine, one must be able to manipulate the operons encoding biogenesis of each of the fimbrial structures in the vaccine (CFA/I and CS1–CS6). Among these, the CS4 operon

was the last to be elucidated and cloned [20]. Altbaum et al. [20] showed that the CS4 (*cfa*) operon encodes a 17-kDa major fimbrial subunit (CsAB), a 40-kDa fimbrial tip protein (CsAE), a 27-kDa chaperone (CsAA), and a 97-kDa usher protein (CsAC). Furthermore, they showed that the predicted amino acid sequences of CS4 proteins are highly homologous to CS1, CS2, and CFA/I. With the successful cloning and expression of CS4, it is now possible to express all of the common ETEC fimbrial colonization factors in *Shigella* live vectors.

##### E. Combinations of *Shigella* Live Vector Strains Expressing Different ETEC Fimbriae

A hurdle faced by a multivalent live vector *Shigella*/ETEC vaccine is to demonstrate convincingly (ultimately in humans) that a mixture of vaccine strains, each expressing different ETEC fimbrial antigens, can elicit strong mucosal responses to all the different antigens in the combination. Towards this goal, initial preclinical studies in the guinea pig model were performed with two bivalent *Shigella* live vector candidates, one expressing CFA/I and CS3 [17] and the other CS2 and CS3 [19]. Each bivalent live vector elicited strong mucosal SIgA responses in tears against both fimbrial antigens; serum antibody responses were also robust. Studies were next undertaken with a pentavalent *Shigella*/ETEC vaccine consisting of attenuated *S. flexneri* 2a expressing either CFA/I, CS2, CS3, CS4 fimbriae or mutant LTh [21]. Following intranasal immunization, SIgA antifimbrial responses were measured in tears of guinea pigs immunized with either one of the monovalent vaccines or the multivalent vaccine (containing the five different live vector strains administered in combination). For each of the ETEC antigens, the combination vaccine, as well as each corresponding monovalent vaccine, stimulated significant rises in antifimbrial or anti-LT antibody. These groups of guinea pigs also exhibited strong *Shigella* anti-O antibody responses and were protected against challenge with wild-type *S. flexneri* 2a [21].

##### F. *Shigella* Live Vector Strains Expressing ETEC Fimbriae and LT Toxoids

Plasmids have been constructed that carry both operons for fimbrial biogenesis and for either mutant LTh or LTB subunit expression so that both antifimbrial and antitoxin responses can be stimulated [18,21]. In a related strategy, attenuated *Shigella* strains harboring LT toxoid genes integrated into the chromosome (and under control of a variety of promoters) and carrying plasmids allowing expression of ETEC fimbriae are also being constructed. Preclinical studies with these constructs, individually and in combination, will evaluate these different strategies and will pave the way for proof-of-principle clinical trials.

##### G. Summary Comment

A multivalent *Shigella*/ETEC vaccine is complex in development and with respect to the control of manufactured lots.

On the other hand, it has a number of distinct potential advantages. A single, albeit complex, vaccine would offer broad-spectrum coverage against two pathogens for which the target populations are the same, travelers and infants in developing countries.

### I. INTRODUCTION: THE QUEST FOR A GONOCOCCAL VACCINE

*Neisseria gonorrhoeae* is the causative agent of gonorrhea, a disease of high morbidity responsible for significant global public health consequences. More than 360,000 cases of infection per year are reported in the United States each year, and many millions of cases occur worldwide [1]. There are three important justifications for the development of a gonococcal vaccine. First, sequelae of mucosal infection in women, including pelvic inflammatory disease (PID) and tubo-ovarian abscess, devastate reproductive health and may become life-threatening [2,3]. Second, depending on the infectiousness of the index case and the susceptibility of the sexual partner, gonococcal infections appear to facilitate the transmission of human immunodeficiency virus type 1 (HIV-1) [4,5]. Gonococcal urethritis causes greatly increased shedding of HIV in mucosal secretions and semen [6,7]. Gonococcal infection recruits cells and cytokines capable of enhancing the acquisition of HIV [9], and likely leads to breaks in mucosal integrity, leading to increased virus infectivity [10]. Third, gonococci demonstrate increased resistance to most, if not all, available antibiotic agents [11–15]. Indeed, fluoroquinolone agents can no longer be employed in patients from Asia [16,17].

The National Institute of Allergy and Infectious Diseases initiated a research program in 1971 focusing on the biology of the gonococcus and other sexually transmitted pathogens, with an emphasis on vaccine development. This sustained support led to extensive studies by basic and clinical scientists on gonococcal epidemiology, physiology, ultrastructure, and pathogenesis that allow us to understand the molecular basis for gonococcal infection. Several excellent recent reviews highlight different aspects of gonococcal pathogenesis [18–22]. Animal and human models have provided insights into gonococcal infection, and a unique opportunity to develop and test vaccine candidates. In this

chapter, we describe the clinical, bacteriological, and immunological basis for the development of a gonococcal vaccine.

### II. PATHOBIOLOGY OF GONOCOCCAL INFECTION

#### A. Disease

Gonorrhea is caused by the gram-negative diplococcus *N. gonorrhoeae*. At the morphological, phenotypical, and genotypical levels, the gonococcus is closely related to the pathogen *N. meningitidis*, a major cause of bacterial meningitis in infants and adults. However, meningococcal mucosal colonization leads to bacteremia and central nervous system infection, whereas gonococcal infection is primarily localized to the genitourinary tract. Meningococci only rarely colonize the genital mucosa. The success in the development of a meningococcal vaccine (see the chapter by Rappuoli et al.) emphasizes differences in the biology and immunology of these pathogens. However, some important lessons can be learned from the development of a meningococcal vaccine, as discussed below.

Gonococcal infection occurs almost exclusively by horizontal sexual spread, transmitted most efficiently from men to women (90% per episode of intercourse), although both men and women are generally exposed to a large inoculum ( $10^6$  bacteria) during intercourse [8,23]. Because of the differences in the anatomy and physiology of the male urinary and female reproductive tracts, the manifestations of the disease in men and women are significantly different. Within males, gonococcal urethral infection may be asymptomatic [24] or present as painful but ultimately self-limited urethral inflammation. Acute gonococcal urethritis produces an exuberant granulocytic inflammatory discharge. Gonococcal orchitis and epididymitis are infrequent complications of urethral infection. Anal intercourse may lead to

gonococcal proctitis, and increasingly antibiotic resistant organisms have been recovered from infected gay men. Gonococcal infection in women can be asymptomatic or can cause endocervical inflammation and upper genital tract disease. Gonococci can cause bacteremia with skin lesions and attendant septic arthritis, with gonococcal arthritis being the most common cause of septic arthritis in young people.

In large part, surface-accessible antigens mediate the efficiency of infection and disease caused by *N. gonorrhoeae*. If vaccination is possible for the prevention of this disease, it is reasonable to suggest that the immunogenic component will be derived from a prominent "Surface-Accessible Gonococcal Antigen."

### B. Surface-Accessible Gonococcal Antigens

The gonococcal cell envelope, such as those of other gram-negative bacterial species [25], consists of a cytoplasmic membrane separated from the outer membrane by the periplasmic space. The external leaflet of the outer membrane is strategically arrayed at the interface between the host and the microbe such that molecules associated with this surface (a) implement the host pathology, or (b) represent targets for a host immune response. This external leaflet is comprised of a complex mixture of phospholipids, lipooligosaccharides (LOS), and proteins as diagrammed for the gonococcus in Figure 1. However, the gonococcal outer membrane differs from that of *Escherichia coli* in at least two important ways. First, gonococci appear to lack a functional analogue of Braun lipoprotein, which serves to anchor

the *E. coli* outer membrane to the relatively rigid middle layer of peptidoglycan [25]. This may explain the spontaneous release of outer membrane fragments or "blebs" from viable gonococci [26]. Because blebs can display surface-associated antigens in their native orientation, they may be capable of binding antibodies to gonococcal outer membrane antigens, thereby serving as antigenic decoys for the organism. In the same regard, blebs may be exploited as vaccines to present novel antigens in their native form, and this has formed the basis for a new class of meningococcal vaccines [27].

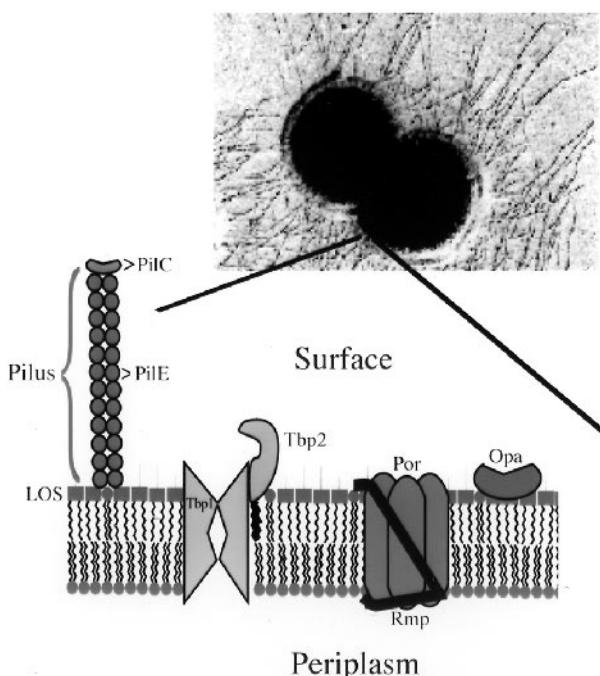

Studies of purified gonococcal outer membranes reveal several prominent surface-accessible antigens. The relative molecular masses of these proteins and their quantitative expression depend upon the strain analyzed [28], the extent of in vitro passage [29–32], the growth conditions used for propagation [33–36], and the procedure used to isolate and analyze the outer membrane [33,37]. These surface-accessible gonococcal antigens can be categorized as constitutively expressed, phase variably expressed, or environmentally regulated.

#### 1. Constitutively Expressed Outer Membrane Antigens

**Lipooligosaccharide.** The most prominent of all surface-accessible gonococcal antigens is LOS. This antigen is the principal component of the gonococcal outer membrane, oriented on the outer leaflet. In this context, it is the "mortar" in which gonococcal protein antigens are presented to the immune system.

**Biochemistry of Gonococcal Lipooligosaccharide.** Like the rough lipopolysaccharide (LPS) mutants of Enterobacteriaceae [25], gonococcal LOS contains a lipid A molecule attached to two 2-keto-3-deoxy-manno-octulose acid (KDO) residues and two heptoses but lacking the O-repeating polysaccharide. This basic structure is further modified by the attachment to oligosaccharide chains consisting of two regions: (a) a basal oligosaccharide linked to KDO, and (b) a middle linear segment containing varying numbers of residues that determine the length of the LOS. The nonreducing terminal sugar is similar in monosaccharide content [38] and anomic linkage [39] to human cell surface glycosphingolipids. Most gonococcal strains produce from one to six LOS species that are antigenically and structurally distinct; this structural heterogeneity can be experimentally appreciated by differences in migration when analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) [40–42]. Like the LOS of *Haemophilus influenzae*, the structural heterogeneity of the LOS oligosaccharide is modulated by the expression of different glycosyltransferases as a result of high-frequency genetic events such as slipped-strand DNA synthesis [43,44]. A demonstration of the genetic basis for LOS variation has been a major contribution to understanding gonococcal pathogenesis.

Variations in gonococcal surface oligosaccharide composition can lead to further modification by host factors. For example, Smith et al. [45] noted that gonococci acquired resistance to killing activity associated with normal human serum after a brief exposure to human blood or

**Figure 1** Diagram depicting the most prominent and well-characterized gonococcal surface antigens.

secretions, and ascribed this to the sialylation of a 4.2-kDa LOS species that can be identified by binding to a specific monoclonal antibody. The sialylation of gonococci requires a bacterially derived sialyltransferase and the host-derived substrate CMP-NANA, found in saturating concentrations in all human tissues. The sialylation of LOS is enhanced by growth in lactate compared to glucose [45], and lactate is generated by granulocytes that form the gonococcal exudate [46]. Gonococci harvested directly from urethral exudates are sialylated [47].

**Contribution of Lipooligosaccharide to Gonococcal Pathogenesis.** Antibodies specific for gonococcal LOS can be detected in sera and vaginal fluids of infected patients [48]. In addition, LOS contains a principle antigenic determinant recognized by the “natural” bactericidal antibody of the IgM class that, in combination with serum complement, mediates the killing of serum-sensitive strains. Lipooligosaccharide promotes injury to the mucosa and may be responsible for the loss of ciliary activity and the sloughing of ciliated epithelial cells [49] by inducing the proinflammatory cytokine, TNF- $\alpha$  [50]. This effect is proposed to be an important contributor to gonococcal salpingitis and may mediate postsalpingitis infertility and ectopic pregnancy [50].

Gonococci expressing full-length LOS (containing the lacto-*N*-neotetraose moiety) are serum-sensitive, whereas the sialylation of LOS renders them serum-resistant [51]. The decreased uptake and decreased killing of sialylated gonococci by polymorphonuclear (PMN) cells have been reported [52]. The modulation of LOS may have a significant role in the invasion of cells [53]. Sialylated gonococci are less invasive for a variety of host cells when compared to non-sialylated gonococci [54]. However, other factors also influence this property. For example, the invasiveness of some gonococcal strains depends upon the expression of a terminal glucose [55] or other terminal sugars (e.g., lactosamine) [56].

The structural and antigenic similarity noted above between the terminal oligosaccharides of LOS and human cell surface glycosphingolipids has been examined [39,57]. One terminal LOS trisaccharide was found to resemble a precursor of human blood group antigens, and another was found to be related to the globoseries glycolipids, known to constitute the *E. coli* P-pilus receptor on human uroepithelial surfaces. The “molecular mimicry” of gonococcal LOS with host cells has been proposed to confer three advantages for infection: (a) LOS may resemble “self”-antigens of the host, reducing their immunogenicity; (b) human cell surface lectinlike proteins, which normally recognize specific glycosphingolipids, could bind LOS and thus mediate epithelial cell adherence and invasion by gonococci; and (c) host-derived glycosyltransferases, which normally modify the oligosaccharide moieties of glycosphingolipids, might also modify gonococcal LOS and create neoantigens on the gonococcal surface.

**Por and Rmp.** Embellishing the analogy of LOS as the mortar of the gonococcal cell surface, two protein antigens, Por and Rmp, act as “bricks” that are prominently displayed on the gonococcal surface. Por and Rmp are unique among other gonococcal surface antigens in that they always asso-

ciate with the outer membrane in abundant amounts, regardless of how the organism is propagated or how the outer membranes are prepared. Por and Rmp have historically been referred to as Protein I and Protein III, respectively, with Por denoting a well-characterized *porin* function, and Rmp denoting a characteristic reduction modifiable protein property [28].

**Biochemistry of PorB and Rmp.** The genomes of the pathogenic *Neisseria* contain two porin genes, *porA* and *porB*. Unlike meningococci, which express both PorA and PorB proteins, gonococci contain mutations in the promoter region and frameshift mutations in the coding region of *porA* that have effectively silenced this locus [56a]. Hence, *N. gonorrhoeae* express a single porin designated as PorB. The deletion of PorB is lethal for *N. gonorrhoeae* propagated in vitro, underscoring its critical presence for gonococcal survival even in the absence of host defenses. By one estimate, PorB comprises ca. 60% by weight of the total repertoire of gonococcal outer membrane proteins [37]. The apparent molecular mass of the gonococcal PorB is between 32 and 39 kDa, depending upon the gonococcal isolate. PorB is organized within the outer membrane as a trimer. In this state, PorB forms an anion-selective channel essential for the diffusion of solutes with molecular masses of less than 1 kDa [58]. PorB forms a trimeric complex in the outer membrane with the monomeric Rmp [59,60].

*N. gonorrhoeae* isolates from global locations reveal that PorB can be separated into two immunologically distinct classes, referred to as PIA and PIB [61–63]. The differences in antigenicity between PIA and PIB are associated with a substantial variation of surface-exposed loops. More subtle variations within surface loop sequences account for over 40 distinguishable serovars, defined by reactivity with PorB-specific monoclonal antibodies [64]. PorB expression is stable upon passage in vitro; unlike other gonococcal surface antigens, it is not subject to high-frequency phase or antigenic variation within a strain. Nevertheless, gonococcal PorB protein undergoes antigenic variation in vivo over time as evidenced by the diversity of serovars characteristic of the species.

In contrast to PorB, Rmp is a highly conserved, surface-exposed outer membrane protein expressed by all pathogenic *Neisseria*. Its descriptive name derives from its migration properties in SDS-PAGE; Rmp has an apparent molecular mass of approximately 31 kDa under nonreducing conditions, but migrates more slowly in the presence of reducing agents [28]. Gonococcal mutants that do not produce Rmp are viable when cultured in vitro [65], unlike PorB mutants. While surface-exposed, Rmp does not exhibit phase or antigen variation [28]. The precise biochemical function for Rmp is not well understood.

**Contribution of Por and Rmp to Gonococcal Pathogenesis.** PorB has been implicated in specific responses by host epithelial and phagocytic cells that are relevant to gonococcal pathogenesis [66]. Purified and detergent-solubilized PorB can be incorporated into natural or synthetic lipid bilayers, conferring the property of voltage gating to these bilayers [67]. PorB can translocate from the outer membranes of viable gonococci to the plasma and mitochondrial

membranes of eukaryotic cells and to artificial lipid bilayers, where voltage-dependent changes can be detected [68]. The gating properties of certain porins are modulated by nucleotide triphosphates [69]. Purified PorB interferes with degranulation by neutrophils [70], suggesting that PorB may play a role in “managing” the host inflammatory response to gonococcal infection. The addition of purified PorB to human monocytes triggers a  $\text{Ca}^{2+}$  influx [71]. The significance of this property is that hyperpolarization of plasma membranes activates macrophages and granulocytes [67]. Thus, the disruption of this polarization may limit the ability of host cells to respond to and control gonococcal infection.

The ability of the gonococcus to transcytose through the epithelial cell barrier is recognized as an important property that contributes to infection (Figure 2). The contribution of the gonococcal PorB to transcytosis is suggested by experiments using isogenic gonococcal strains carrying different *por* alleles [72]. This study demonstrated that constructs expressing PorB associated with disseminated gonococcal infection conferred an increased ability to invade epithelial cells. Furthermore, this invasive phenotype was influenced by nucleotide triphosphates or polyphosphates [72]. The current view is that PorB functions to promote invasion in combination with other surface-associated adhesions [18].

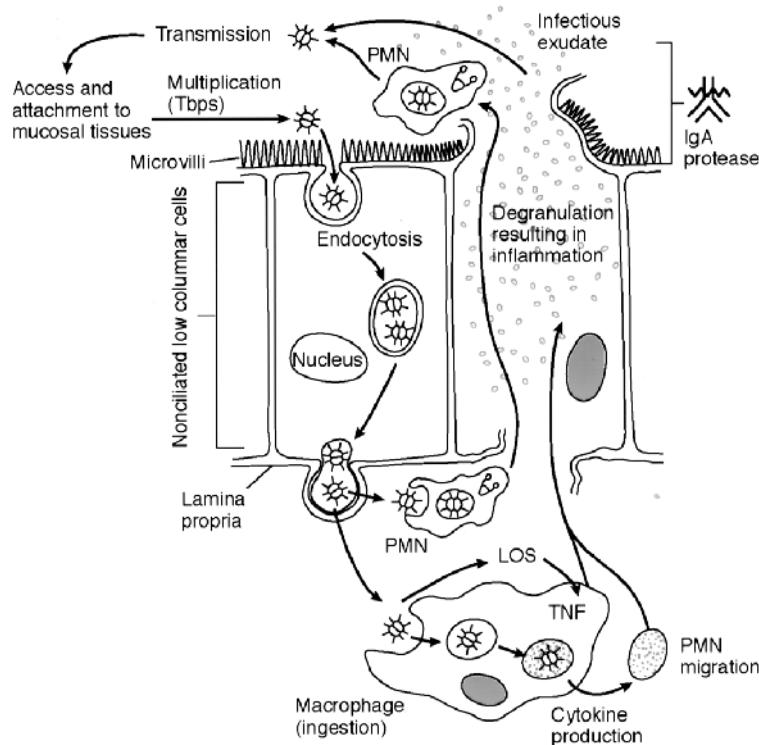

The PorB phenotype contributes to complement-mediated killing of gonococci by normal human serum. Nearly all gonococcal strains expressing a PIA PorB are serum-resistant, apparently because serum proteins that downregulate

complement-binding proteins (C4bp and factor H) are bound to loop 5 sequences found in PIA porins, but not in PIBs [73–75]. PIB serum-resistant variants also bind C4bp via a conformational epitope between loops 5 and 7 [74]. Strains sensitive to serum killing fail to bind these factors, but may acquire serum resistance if sialylated LOS binds factor H [75].

Examination of the Rmp sequence reveals an area that is partially homologous with the carboxy-terminal portion of the OmpA proteins of *Shigella dysenteriae*, *E. coli*, and *Enterobacter aerogenes* [76]. It has been proposed that “natural” antibodies to homologous regions of the enterobacterial OmpA proteins cross-react with Rmp and function as “blocking” antibodies [77]. Antibodies to Rmp can be found in the sera and vaginal fluids of patients convalescing from gonorrhea, although in general, Rmp is not as immunogenic as other surface-exposed gonococcal antigens [48]. Binding by these antibodies has a profound blocking effect on the bactericidal activity of sera [78,79]. It is proposed that blocking antibodies to Rmp in these sera may have arisen in response to a previous gonococcal infection, or represent an immune response to enterobacterial OmpA proteins that cross-react with Rmp.

## 2. Phase-Variable Surface Antigens

**Fimbrial Adhesins—*PilE* and *PilC*.** Fimbriae, also called pili, are long axial appendages (1–4  $\mu\text{m}$  in length, 60

**Figure 2** Diagram summarizing the steps in the pathogenesis of gonococcal infection, which include attachment, invasion and transcytosis, multiplication, stimulation of a vigorous immune response, and transmission, as described in the text.

Å in diameter) that extend from the surface of bacteria [80]. Pili participate in a number of different functions including DNA transfer, bacterial attachment to host cells, intrabacterial adhesion, and bacterial movement [81]. As with many bacterial pathogens, gonococcal pili are important for the pathogenesis of infection. First, gonococci undergo natural transformation [82,83], and this property is significantly enhanced by the expression of pili [84]. Second, the attachment properties of gonococcal pili confer tissue tropism as well as the ability to overcome the bacterial–host cell charge repulsion [85]. Finally, gonococcal pili, like other type 4 pili, mediate twitching motility, a mode of migration along liquid–solid or air–liquid interfaces [81]. Twitching motility has been implicated in a wide number of biological processes [18].

Evidence for the involvement of pili in gonococcal pathogenesis came first from the seminal observations by Kellogg et al. [86] in 1963, who reported that clinical materials freshly propagated on solid media gave rise to gonococcal colonies of two morphotypes, termed T<sub>1</sub> and T<sub>2</sub> (now designated as pilated or P<sup>+</sup>). Upon nonspecific passage in vitro, two additional colonial forms appeared, termed T<sub>3</sub> and T<sub>4</sub> (now designated as nonpiliated or P<sup>-</sup>). P<sup>+</sup> colonial morphotypes were subsequently found to be substantially more infective for male volunteers following intraurethral challenge than types P<sup>-</sup> [86]. Later, Jephcott et al. [87] and Swanson et al. [31] described piluslike appendages extending from the surface of organisms comprising P<sup>+</sup> colonies but not P<sup>-</sup> colonies. Since this discovery, studies have provided detailed information about the biological properties, molecular structure, immunochemistry, and regulation of expression of gonococcal pili.

**Biochemistry of Pili.** Among bacteria, several structural classes of pili (e.g., type 1, Gal–Gal, etc.) that have either unique structural or receptor-binding characteristics exist. Gonococci express a type 4 pilus defined by the ordered assembly of a principal repeating polypeptide subunit termed pilin, an 18- to 22-kDa polypeptide encoded by the *pilE* locus [88]. The pilin protein of type 4 fimbriae is synthesized as a precursor protein with a unique secretory signal sequence shared among many type II secretion systems [89]. During processing, the pilin precursor is modified by the PilD prepilin peptidase/transmethylase [90]. The result is a mature pilin subunit with a methylated phenylalanine residue at its N-terminus (*N*-met-Phe). This maturation is coupled with transport and assembly. Recently, a protein identified as PilQ has been described as one of many protein products associated with pilus biogenesis and function [91–93]. This protein was formerly described as a high-molecular-weight common outer membrane antigen and designated as OMP-MC [94]. PilQ is surface-exposed and common to diverse gonococcal isolates. It is thought to function by forming a multimeric channel in the outer membrane through which the assembled pilus fiber is presented. This process results in the aggregation of thousands of pilin molecules in an extended linear structure, which can be readily viewed in negatively stained transmission electron micrographs of gonococci propagated on agar media (Figure 1).

Parge et al. [88] reported the atomic structure of gonococcal pilin. This structural information largely explains much of the serological and biological data described below by demonstrating how packing of the pilus structure is preserved in the context of antigenically variable regions [95]. The pilin monomer contains a C-terminal globular head region and an N-terminal hydrophobic tail that folds into an unusually long α-helix. The helical region packs as a “stalk” presenting an antigenically variable C-terminal “flower.” A surprising finding from these studies is the observation that the C-terminal pilin domain can be phosphorylated and glycosylated, further increasing the antigenic diversity of this structure.
